Having thus given a general account of the Bell Rock, and the erection of the Light-house, we shall now describe the building, noticing its principal dimensions, and making such farther remarks as may appear interesting to the reader. The Bell Rock Light-house is a circular building, the foundation-stone of which is nearly on a level with the surface of the sea at low-water of ordinary spring-tides; and consequently at high-water of these tides, the building is immersed to the height of about 15 feet. The two first or lower courses of the masonry are imbedded or sunk into the rock, and the stones of all the courses are curiously dovetailed and joined with each other, forming one connected mass from the centre to the circumference. The successive courses of the work are also attached to each other by joggles of stone; and, to prevent the stones from being lifted up by the force of the sea, while the work was in progress, each stone of the solid part of the building had two holes bored through it, entering six inches into the course immediately below, into which oaken tree-nails, two inches in diameter, were driven, after Mr Smeaton's plan at the Eddystone Light-house. The cement used at the Bell Rock, like that of the Eddystone, was a mixture of pozzolano, earth, lime, and sand, in equal parts, by measure. The building is of a circular form, composed of stones of the weight of from two tons to half a ton each. The ground course measures 42 feet in diameter, and the building diminishes, as may be observed from the plate of the light-house, as it rises to the top, where the parapet-wall of the light-room measures only 13 feet in diameter. The height of the masonry is 100 feet, but including the light-room, the total height is 115 feet. The building is solid from the ground course to the height of 30 feet, where the entry-door is situate, to which the ascent is by a kind of rope-ladder with wooden steps, hung out at ebb-tide, and taken into the building again when the water covers the Rock; but strangers to this sort of climbing are taken up in a kind of chair, by a small moveable crane projected from the door, from which a narrow passage leads to a stone stair-case 13 feet in height. Here the walls are seven feet in thickness, but they gradually diminish from the top of the stair-case, to the parapet-wall of the light room, where they measure one foot in thickness. The upper half of the building may be described as divided into six apartments for the use of the light-keepers, and for containing light-house stores. The lower or first of these floors, formed by an inside scarsement of the walls at the top of the stair-case, is chiefly occupied with water tanks, fuel, and the other bulky articles; the second floor is for the oil cisterns, glass and other light-room stores; the third is occupied as a kitchen; the fourth is the bed-room,

Bell Rock. the fifth the *library* or strangers' room, and the upper apartment forms the light-room. The floors of the several apartments are of stone, and the communication from the one to the other, is made by means of wooden ladders, excepting in the light-room, where every article being fire proof, the steps are made of iron. There are two windows in each of the three lower apartments, but the upper rooms have each four windows. The casements of the windows are all double, and are glazed with plate-glass, having besides an outer storm-shutter, or *dead-light* of timber, to defend the glass from the waves and sprays of the sea. The parapet-wall of the light-room is six feet in height, and has a door which leads out to the balcony or walk formed by the cornice round the upper part of the building; which is surrounded by a cast-iron rail, curiously wrought like net-work. This rail rests upon batts of brass, and has a massive coping or top rail of the same metal.

Furniture of the House. In the kitchen, there is a kind of grate or open fire-place of cast-iron, with a smoke tube of the same metal which passes through the several apartments to the light-room, and heats them in its passage upwards. This grate and chimney merely touch the building, without being included or built into the walls, which, by this means, are neither weakened, nor liable to be injured by it. The timber of the doors, and the pannelled partitioning of the rooms from the stairs, and also of the bed frames and furniture in general, is of wainscot.

Light-room. The light-room and its apparatus was entirely framed and prepared at Edinburgh. It is of an octagonal figure, measuring 12 feet across, and 15 feet in height, formed with cast-iron sashes, or window frames glazed with large plates of polished glass, measuring about 2 feet 6 inches by 2 feet 3 inches, each plate being of the thickness of a quarter of an inch. The light-room is covered with a dome roof of copper, terminating in a large gilded ball, with a vent-hole in the top.

Description of the Light. The light of the Bell Rock is very powerful, and is readily seen at the distance of six or seven leagues, when the atmosphere is clear. The light is from oil, with Argand burners placed in the focus of silver-plated reflectors, measuring 24 inches over the lips; the silvered surface or face being hollowed or wrought to the parabolic curve. That the Bell Rock light may be easily distinguished from all other lights upon the coast, the reflectors are ranged upon a frame with four faces or sides, which, by a train of machinery, is made to revolve upon a perpendicular axis once in six minutes. Between the observer and the reflectors, on two opposite sides of the revolving frame, shades of red glass are interposed, in such a manner, that, during each entire revolution of the reflectors, two appearances, distinctly differing from each other, are produced; one is the common *bright light* familiar to every one, but, on the other, or shaded sides, the rays are tinged of a *red colour*. These red and bright lights, in the course of each revolution, alternate with intervals of darkness, which, in a very beautiful and simple manner, characterize this light.

Bells for Foggy Weather. As a farther warning to the mariner, in foggy weather, two large bells, weighing about 12 cwt. are tolled day and night by the same train of machinery which moves the lights. As these bells, in moderate weather, may be heard considerably beyond the limits of the Rock, vessels, by this means, get warning to put about, and are thereby prevented from running upon the Rock in thick and hazy weather; a disaster to which ships might otherwise be liable, notwithstanding the erection of the light-house.

Light-Keepers. Prior to, or about the time of the erection of the Bell Rock light-house, it was by no means uncommon to meet with various doubts, regarding the practicability of the works, expressed in such terms as the following: "That, even if it were practicable to erect a light-house, upon such a sunken rock, no one would be found hardy enough to live in an abode so dread and dreary, and that it would fall to the lot of the projectors themselves to possess it for the first winter." But the reverse of all this took place; for the confidence of the public had been confirmed by the stability as well of the wooden-beacon-house, as of the building itself, which, in its progressive rise, withstood the storms of two successive winters, in an unfinished state; so that, by the time the house was ready for its inhabitants, the applications for the place of light-keepers were much more numerous than the situations; and applicants on both sides of the Tweed were disappointed in their wishes.

The establishment of light-keepers at the Bell Rock, consists of a principal light-keeper, who has at the rate of 60 guineas *per annum*, paid quarterly; a principal assistant, who has 55 guineas; and two other assistants at 50 guineas each; besides a suit of uniform clothes, in common with the other light-keepers of the Northern Light-houses, every three years. While at the rock, these men get a stated allowance of bread, beef, butter, oat-meal, pot-barley, and vegetables, besides small beer, and an allowance of fourpence *per* day each for the purchase of tea and other necessaries. At Arbroath, the most contiguous town on the opposite coast, a suite of buildings has been erected, where each light-keeper has three apartments for his family. Here the master and mate of the light-house tender have also accommodation for their families; a plot or piece of an inclosed garden ground is attached to each house, and likewise a seat in one of the pews in the parish church of Arbroath. Connected with these buildings, there is a signal tower erected, which is about 50 feet in height. At the top of it, there is a room with an excellent five feet achromatic telescope, placed upon a stand. From this tower, a set of corresponding signals is arranged, and kept up with the light-keepers at the rock. Three of the light-keepers are always at the light-house, while one is ashore on liberty, whose duty it is for the time to attend the signal room; and when the weather will admit of the regular removal of the light-keepers they are six weeks at the rock, and a fortnight ashore with their families.

Attending Vessel. The attending vessel for the Bell Rock, and the light-houses of the Isle of May and Inchkeith, in the Firth of Forth, is a very handsome little cutter of about 50 tons register, carrying upon her *prow* a

model of the Bell Rock light-house, and is appropriately named the *Pharos*. She is stationed at Arbroath, and is in readiness to proceed for the Rock at new and full moon, or at spring-tides, carrying necessaries, and the light-keeper on leave, to the Rock, and returning with another. This vessel is navigated by four men, including the master, and is calculated for carrying a boat of 16 feet keel, or of sufficient dimensions for landing at the Rock in moderate weather. The master and mate are kept in constant pay, and have apartments in the establishment ashore; the former, acting as a superintendent, has the charge of the buildings and stores kept at Arbroath.

Expence of this Light-house.

The expence of the Bell Rock light-house, and its establishment, in a general way, may be stated to have amounted to about L.60,000. The undertaking does much honour to the exertions of the Commissioners of the Northern Light-houses, and is even creditable to the age which has produced it; especially when it is remembered, that it was commenced and completed amidst the difficulties and demands of a war, unparalleled in the history of our country. (HH.)

Our readers will perceive, that the account we have given of this Edifice is, necessarily, of a very general nature; but the public, we believe, will soon be gratified with an ample *Historical Account of the Northern Light-houses*, including a full detail of the whole operations connected with the Bell Rock light-house, and the Carr Rock Stone-Beacon, illustrated with numerous plates, showing the progressive stages of these works, by Mr Stevenson; and we are happy to learn, that the Commissioners of the Northern Light-houses, from a conviction of the utility of the design, have, as a Board, liberally expressed their desire to promote the intended publication of Mr Stevenson, whose name, as an Engineer, is so creditably connected with these two important national undertakings.

Geographical Situation and Boundaries.

BELOOCHISTAN, a country of Asia, situate on the north-west coast of the Indian peninsula. It is bounded on the north by Affghanistan and Seistan; on the west, by the Persian provinces of Kirman and Laristan; on the south, by the Indian Ocean; and, on the east, by a part of Sinde and Shikarpoor. In general, it may be said to comprehend all that space within the 25th and 30th degrees of north latitude, and the 58th and 68th degrees of east longitude; and its whole superficial extent may be computed at 550 geographical miles in length, and 300 in breadth.

History.

Of the early history of this portion of the Asiatic Continent, little or nothing is known. The poverty and natural strength of the country, combined with the ferocious habits of the natives, seem to have equally repelled the friendly visits of inquisitive strangers, and the hostile incursions of invading armies. The Greeks, from whom we derive the earliest information relative to the western frontiers of India, are almost entirely silent with respect to this mountainous and inhospitable tract; and scarcely any notice of it occurs for many centuries posterior to the Macedonian invasion. Hence it is impossible to trace the first settlement of this country; and the descent of its inhabitants can only be imperfectly ascertained by analogy and conjecture. As the natives have no written language, their historical annals are merely traditional, and therefore entitled to little credit. The Belooches ascribe their own origin to the earliest Mohummudan invaders of Persia, and are very desirous of being supposed to be of Arabian extraction; but the latter part of this supposition derives no confirmation from their features, their manners, or their language, which do not bear the slightest similitude to those of the Arabs. There can be little doubt, however, that they originally came from the westward; of which there is strong evidence in the affinity between the Beloochekee and Persian languages; and their institutions, habits, and religion, seem to indicate that they are of Toorkuman lineage. It seems highly probable, indeed, that, during the frequent sanguinary revolutions to which the monarchy of the Seljukide Tartars was subject, some of these barbarians had been forced to wander over the country in quest of new settlements; and that a portion of them had found refuge in the mountainous districts of Beloochistan. But, besides the Belooches, there are other distinct tribes of inhabitants in Beloochistan, whose peculiar habits and shades of character, we shall afterwards take an opportunity of describing. These are the Brahooes, apparently a race of Tartar mountaineers, who settled at an early period in the southern parts of Asia, but whose history is extremely obscure and uninteresting; the Dehwars, clearly a Persian colony, whose original settlement cannot be traced; and the Hindoos, who appear to have been the first settlers in the upper part of the Brahooick mountains, on their being expelled from Linde, Lus, and Mukran, by the armies of the Caliphs of Bagdad. This last tribe appears to have constituted the governing party, at the earliest period of which any thing approaching to authentic information has been obtained. The Brahooes and Belooches, however, gradually spread over the country; and the Hindoo power was at length subverted by a revolution, which placed the ancestors of the present Khan of Kelat upon the throne.

The precise period at which this revolution took place, cannot be accurately ascertained; but it is probable that two centuries have not elapsed since that event. The last rajah of the Hindoo dynasty found himself compelled to call for the assistance of the mountain-shepherds, with their leader, Kumbur, in order to check the encroachments of a horde of depredators, headed by an Affghan chief, who infested the country, and even threatened to attack the seat of government. Kumbur successfully performed the service for which he had been engaged; but having, in a few years, quelled the robbers against whom he had been called in, and finding himself at the head of the only military tribe in the country, he formally deposed the rajah, and assumed the reins of government.

The history of this country, subsequently to the accession of Kumbur, is involved in the same obscurity as during the Hindoo dynasty. It would ap-

Published by A. Constable & Co. 1816.

Beloochistan. pear, however, that the sceptre was quietly transmitted to the descendants of that chief, who seems to have persevered in a peaceable system of government, until the time of Abdoolla Khan, the fourth in descent from Kumbur; who, being an intrepid and ambitious soldier, turned his thoughts towards the conquest of Kutch Gundava, then held by different petty chiefs, under the authority of the Nuwwabs of Sinde.

After various success, the Kumburanees, at length, possessed themselves of the sovereignty of a considerable portion of that fruitful plain, including the chief town, Gundava. It was during this contest, that the famous conqueror, Nadir Shah, commonly called Thamas Koolee Khan, advanced from Persia to the invasion of Hindoostan; and while at Kandahar, he dispatched several detachments into Beloochistan, and established his authority in that province. Abdoola Khan, however, was continued in the government of the country by Nadir's orders; but he was soon after killed in a battle with the forces of the Nuwwabs of Sinde. He was succeeded by his eldest son, Hajee Mohummud Khan, who abandoned himself to the most tyrannical and licentious way of life, and completely alienated his subjects by his arbitrary and oppressive system of taxation. In these circumstances, Nusseer Khan, the second son of Abdoolla Khan, who had accompanied the victorious Nadir to Delhi, and acquired the favour and confidence of that monarch, returned to Kelat, and was hailed by the whole population as their deliverer. Finding that expostulation had no effect upon his brother, he one day entered his apartment, when the prince was alone, and stabbed him to the heart. As soon as the tyrant was dead, Nusseer Khan mounted the *musnud*, amidst the universal joy of his subjects, and immediately transmitted a report of the events that had taken place to Nadir Shah, who was then encamped near Kandahar. The shah received the intelligence with satisfaction, and dispatched a furman, by return of the messenger, appointing Nusseer Khan, Beglenbeg of all Beloochistan. This event took place in the year 1739.

Nusseer Khan proved an active, politic, and warlike prince. He took great pains to re-establish the internal government of all the provinces in his dominions, and improved and fortified the city of Kelat. On the death of Nadir Shah, in 1747, he acknowledged the title of the king of Caboul, Ahmed Shah Abdalli. In 1758, he declared himself entirely independent; upon which Ahmed Shah dispatched a force against him, under one of his ministers. The khan, however, levied his troops, and totally routed the Affghan army. On receiving intelligence of this discomfiture, the king himself marched with strong reinforcements, and a pitched battle was fought, in which Nusseer Khan was worsted. He retired in good order to Kelat, whither he was followed by the victor, who invested the place with his whole army. The khan made a vigorous defence; and, after the royal troops had been foiled in their attempts to take the city by storm or surprise, a negociation was proposed by the king, which terminated in a treaty of peace. By this treaty, it was stipulated that the king was to receive the cousin of Nusseer Khan in marriage; that the khan was to pay no tribute, but only, when called upon, to furnish troops to assist the royal armies, for which he was to receive an allowance in cash, equal to half their pay.

Beloochistan.

Subsequently to this period the khan frequently distinguished himself by his gallantry and judgment, in the wars carried on by the monarch of Caboul, and, as a reward for his eminent services, the king bestowed upon him several districts, to hold in perpetual and entire sovereignty. Having succeeded in quelling a dangerous rebellion, headed by his cousin Beheram Khan, this able prince at length died, at an extreme old age, after a happy and prosperous reign, in the month of June 1795, leaving three sons and five daughters. He was succeeded by his eldest son, Muhmood Khan, the present chief of Kelat, then a boy about fourteen years old. During the reign of this prince, who is described as a very humane and indolent man, the country has been distracted by sanguinary intestine broils; the governors of several provinces and districts have withdrawn their allegiance; and the dominions of the khans of Kelat have so gradually diminished, that they now comprehend only a small portion of the provinces which were formerly subject to Nusseer Khan.

Principal divisions of Beloochistan.

The territories of the last-mentioned prince are comprised under the following divisions:—1. The provinces of Jhalawan and Sarawan, and the district of Kelat. 2. The provinces of Mukran and Lus. 3. The province of Kutch Gundava and district of Hurrund Dajel. 4. Kohistan, or the Belooche country, west of the desert. 5. The desert. 6. The province of Sinde.

Mountains.

The features of this extensive tract of country vary considerably; but, in general, it may be described as extremely mountainous. A stupendous range, to which the appellation of the Brahooick mountains has been assigned, and which seems to be the primitive root of all the others, springs abruptly to a conspicuous height out of the sea, at Cape Mowaree (or Monze), in north latitude 25°, east longitude 66° 58′, whence it takes a north-easterly direction for 90 miles. There it projects a ridge, east by north, the base of which is washed by the river Indus, at the fort of Sehwan. From the separation of this arm, in latitude 25° 45′ to that of 30°, the primitive body runs due north, marking the western limits of Sinde, Kutch-Gundava, and a part of Seeweestan; and from thence it once more regains its original inclination to the north-east, and decreases in magnitude and elevation so rapidly, that, in the course of 40 miles, it sinks to a level with the hills inhabited by the Kaukers and other Affghan tribes, with which it becomes incorporated. To the westward, the Brahooick mountains send forth many collateral chains, some of which extend the whole length of Beloochistan, and join the mountains of Persia; others elongate southerly till they touch the sea, or come within a few miles of it, and then either take the inclination of the coast, or subside in the low and barren plains in its vicinity; while the main body, or rather its western face, stretches

Beloochistan.

away north-west by north, to the 28th degree of north latitude, where it meets the south-eastern corner of the sandy desert, about the 64th degree of east longitude; and from thence it inclines with a northern aspect, between the north-east and north points of the compass, to Nooshky, in latitude 30° north; from which place it runs more easterly, till at length it gradually sinks, like the eastern front, to a size of equality with the Affghan hills. Besides the Brahooick chain, there are several other ranges of mountains, extending in various directions and ramifications throughout Beloochistan, but all of them inferior to the former in magnitude and height. This stupendous chain is believed to have attained its greatest altitude at Kelat; from which city, according to the natives, whatever route he may pursue, a traveller must descend; but the descent is so very trifling, for a long way on either side of that capital, that it is not perceptible by the eye.

Rivers.

Throughout the whole of this country, there are no rivers of such size or importance as to merit particular notice. In general, they have a broad and deep channel from the coast, until they reach the mountains or stony hills, where they become contracted into narrow and intricate water-courses, that are quite dry during the greater part of the fair season; and, in the wet one, swell to terrific torrents, which run off in the course of a few hours after the rain that has filled them ceases.

City of Kelat.

The principal city of this country is Kelat, the capital of the whole of Beloochistan. This city stands on an elevated site, on the western side of a well-cultivated plain or valley, about eight miles long and two or three broad; a great part of which is laid out in gardens and other inclosures. The town is built in the form of an oblong square, three sides of which are encompassed by a mud wall, 18 or 20 feet high, flanked, at intervals of 250 paces, by bastions, which, as well as the wall itself, are pierced with numberless loop-holes for matchlock-men. The defence of the fourth side of the city is formed by the western face of the hill, on which it is partly built, being cut away perpendicularly. On the summit of this eminence stands the palace of Muhmood Khan, chief of Kelat, and nominal Beglerbeg of Beloochistan, commanding a distinct view of the town and adjacent country. That quarter of the hill on which the khan's residence is erected has been inclosed by a mud wall, with bastions; the entrance to it is on the south-western side; and here, as well as at the city gates, which are three in number, there is constantly a guard of matchlock-men. Within the walls, there are upwards of 2500 houses, and the number of those in the suburbs probably exceeds one-half of that amount. These houses are built of half-burnt brick, or wooden frames, and plastered over with mud or mortar. In general, the streets are broader than those of native towns, and most of them have a raised pathway on either side, for foot-passengers, and an uncovered kennel in the centre; the latter of which is a great nuisance, from the quantity of filth thrown into it, and the stagnant rain-water that lodges there. The upper stories of the houses frequently project across the streets, and thereby render the part beneath them gloomy and wet. This seems a very rude attempt to imitate the bazars of Persia and Caboul. The bazar of Kelat is extensive, and well furnished with every kind of goods; all the necessaries of life may be procured daily at a moderate price. The town is supplied with delicious water from a spring in the face of a hill on the opposite side of the plain, whence it meanders nearly through the centre of it, having the town and suburbs on one side, and on the other the gardens. It is a remarkable property of this spring, that the waters, at their immediate issue from the smaller channels, possess a considerable degree of tepidity, until after sun-rise, when they suddenly become exceedingly cold, and remain so during the day.

Inhabitants.

We have no data from which we can form an accurate computation of the total amount of the population of Beloochistan. The inhabitants are divided into two great classes, distinguished by the appellations of Belooche and Brahooé; and these two are again subdivided into an infinite number of tribes, which it were tedious and unnecessary to enumerate. The most remarkable distinctions between these two classes consist in their language and appearance. The Belooche, or Beloocheekee language partakes considerably of the idiom of the modern Persian, although greatly disguised under a singularly corrupt pronunciation. The Brahooekee, on the other hand, has nothing analogous to the Persian idiom. It appears to contain a great number of ancient Hinduwee words, and, as it strikes the ear, bears a strong resemblance to the dialect spoken in that part of India called the Punjaub. With regard to external appearance, the contour of these two classes seems to differ, in most instances, as much as their language. The Belooches, in general, have tall figures, long visages, and raised features; the Brahooés, on the contrary, have short thick bones, with round faces and flat lineaments.

Belooches.

The Belooches are a handsome active race of men, not possessing great physical strength, but inured to changes of climate and season, and capable of enduring every species of fatigue. In their habits they are a pastoral people, and much addicted to predatory warfare, in the course of which they do not hesitate to commit every kind of outrage and cruelty. The lawless excursions in which they frequently engage are called *Chupaos*, and are almost always conducted under the immediate orders of their chiefs. The depredators are usually mounted on camels, and furnished with food and water, according to the distance they have to go. When every thing is prepared, they set off, and march incessantly till within a few miles of the point where the *chupao* is to commence, and then halt in a jungul, or some unfrequented spot, to rest their camels. On the approach of night they mount again; and as soon as the inhabitants have retired to repose, they begin their attack by burning, destroying, and carrying off whatever comes in their way. They never rest for one moment during the *chupao*, but ride on, at the rate of eighty or ninety miles a day, until they have loaded their camels with as much pillage as they can possibly remove. If practicable, they make a circuit, which enables

Beloochistan. them to return by a different route from the one they came. This plan affords them a double prospect of plunder, and also tends to mislead those who go in pursuit of the robbers.

Notwithstanding their predatory habits, the Belooches are proverbial for their hospitality. Among them pilfering is considered a most despicable act; and when they once promise to afford protection to any person who may solicit or require it, they will die before they fail in their trust. Habitations. Their usual habitations are *Ghedans* or tents, made of black felt or coarse blanket, stretched over a frame of wicker-work, formed from the branches of the tamarisk. An assemblage of these *ghedans* constitutes a Toomun or village, and the inhabitants of it a *Kheil* or society, of which there may be an unlimited number in one tribe. These kheils are commonly discriminated by some appropriate title, such as the *Umeerée* kheil, the Noble Society, *Daodeé* kheil, David's Society, &c. These titles, however, they frequently change with their places of residence. Some of the Belooches, particularly the *Nharooé* clans, prefer mud houses to tents, and even live in forts; nor is it uncommon, in the western parts of Beloochistan, to find one half of the keil residing in ghedans and the other in huts. Reception of Visitors. When a visitor arrives at a toomun, a carpet is spread in front of the door of the *Mihman Khanu*, or house for guests, of which every village has one; the *Sirdar* or head of the kheil immediately appears, and he and the stranger having embraced, and mutually kissed hands, the followers of the latter successively approach, and the sirdar gives them his hand, which they press to their foreheads and lips. The parties then sit down, on which the chief addresses the stranger, and asks him, four several times, how he does, to which the other answers in the usual complimentary terms; he then inquires, in the same manner, for his family and friends, and even for the health of his followers who are present, to whom the visitor turns, as if to appeal for information: they all nod assent to being in good health; and the ceremony concludes by the new-comer making an equal number of inquiries for the welfare of the family, kheil or society, followers and friends of the sirdar.

Food. The food of the Belooches consists of wheaten and barley cakes, rice, dates, cheese, and milk, which last they prefer in a sour state; soup made from *dholl* or peas, and seasoned with red pepper and other heating herbs, and flesh-meat whenever they can procure it. The vegetables most esteemed by them are onions, garlic, and the leaves and stalk of the assafœtida plant, which they roast or stew in butter. They usually limit themselves to one or two wives, and their chiefs to four; but this depends altogether Women. upon choice. They treat their women with attention and respect, and are not so scrupulous about their being seen by strangers as most other Moosulmans. They keep a great number of slaves of both sexes, captured during their *chupaos*, who are treated Dress. with liberality and kindness. The common dress of the Belooches is a coarse white or blue calico shirt, buttoning round the neck, and reaching below the knee; their trowsers are made of the same cloth, or a kind of striped stuff called Soosee, and puckered round the ancles. On their heads they wear a small silk or cotton quilted cap, fitted to the shape of the skull, over which, when in full dress, they place a turband, either checked or blue, and a *kummurbund* or sash, of the same colour, round their waists. In winter, the chiefs and their relatives appear in a tunic of chintz, lined and stuffed with cotton; and the poorer classes, when out of doors, wrap themselves up in a surtout made of cloth, manufactured from a mixture of goats' hair and sheep's wool. The women's dress is very similar to that of the men; their trowsers are preposterously wide, and made of silk, or a mixture of silk and cotton. Warlike Weapons. A Belooche soldier carries a matchlock, sword, spear, dagger, and shield, besides a multiplicity of powder-flasks, priming-horns and pouches. They are all capital marksmen, and in battle avoid, as much as possible, coming to close combat. Their best warlike weapons are of foreign manufacture. At Kelat, there is an armoury for the manufacture of matchlocks, swords, and spears; but the workmanship is very indifferent.

Amusements. The principal amusements of the Belooches are shooting, hunting, and coursing; for which latter purpose they bestow a vast deal of attention in the training of their greyhounds. Firing at marks, cudgelling, wrestling, and throwing the spear, are likewise favourite diversions among them, and neighbouring kheils frequently cope with each other at these exercises. Their funeral and marriage ceremonies, being in a great measure such as are prescribed and regulated by the Koran, are similar to those of all other Moosulmans, and therefore merit no particular notice. Religion. With regard to religion, the Belooches are, with a very few exceptions to the westward, Soonee Moosulmans.

Brahooés. The Brahooés, or second great class of the natives of Beloochistan, are a still more unsettled and wandering nation than the Belooches. They reside in one part of the country during the summer, and emigrate to another for the winter season; and even change their immediate places of abode many times in the year, for the sake of pasturage for their flocks. The Brahooés are distinguished for activity, strength, and hardiness; inured alike to the cold of the mountainous regions of Beloochistan, and the heat of the low plain of Kutch Gundava. They are very laborious in husbandry, and other domestic occupations; and those who reside in the vicinity of the plains to the southward of Kelat, cultivate large tracts of land, and dispose of the produce for exportation to the Hindoos of Kelat, Bela, and Khozdar. This, and the sale of the cheese and *ghee* made from the flocks, with a few coarse blankets, carpets, and felts, constitute their only traffic. They are famous for having voracious appetites, and devour a great quantity of flesh in a half dressed state, without bread, salt, or vegetables. The Brahooés are as faithful in adherence to their promises, and as hospitable as the Belooches: They are more quiet and industrious; and although they are esteemed superior to the other inhabitants of Beloochistan in personal bravery, and the endurance of privations and hardships, yet their habits are decidedly averse

Beloochistan.

from that system of rapine and violence pursued by their neighbours. A Brahooé always dresses in the same style; whether it be summer or winter, his whole clothing consists of a loose white shirt, a pair of trowsers of the same texture, and a felt cap. The shepherds sometimes wear a covering of white felt, made so as to wrap round the body, and come to a peak above the crown of the head; this habit is used as a defence against rain or snow. The domestic life of the Brahooés is extremely simple: The men employ themselves in field labour, in which, if necessary, they are assisted by the women; but in general the latter are engaged in attending to the household affairs. The dress of the women consists of a long shift and pair of trowsers, both of cotton cloth; and after they arrive at the age of puberty; they wear over the former a kind of stays, made to lace behind, and decorated in front with ridiculous devices of birds or animals, worked in coloured worsted. In religion, the Brahooés are all Soonnitte Moossulmans. All their tribes intermarry with each other, except the Kumburanees, regarding whom there is a peculiarity which does not attach to any of the other tribes; that of being divided into three distinct gradations of rank, the Ahmedzgees, Khanees, and Kumburanees. The first consists of the family of the prince; the Khanees are of the secondary rank, of whom there are between twenty and thirty; and the Kumburanees include the remainder of the tribe; although, in general, the term is applied to the whole body.

Hindoos.

Besides the Belooches and Brahooés, there is a considerable number of Hindoos resident at Kelat, who are principally engaged in mercantile speculations, and are much respected both by the government and people. Their religion is tolerated; and they have a pagoda at Kelat.

Dehwars.

The Dehwars, or Dehkans, constitute the only remaining class of the population, which seems worthy of particular notice. They are to be recognised in different districts of the country under various names; quiet and harmless in their disposition, and addicted to agricultural pursuits. Their colloquial language is common, pure Persian; from which fact their origin may be deduced, although no traces of their first settlement have been discovered.

Government and Laws.

The fluctuation of power renders it difficult to define precisely the nature of the government at Kelat. During the reign of Nusseer Khan, the whole kingdom might be said to have been governed by a complete despotism; yet that ruler so tempered the supreme authority by the privileges granted to the feudal chiefs, within their own tribes, that, to a casual observer, it bore the appearance of a military confederation. The tribes all exercise the right of selecting their own *Sirdar*, or head; the Khan, indeed, has the power of confirming or disapproving of their nomination; but this power is never exercised, and appears to be merely nominal. The Khan of Kelat has the power of declaring war, and making treaties, connected with the whole of Beloochistan, and can order the Sirdar of each tribe to attend in person with his *quota* of troops. Agreeably to a code of regulations framed by one of the earliest princes of the Kumburanee dynasty, the entire administration of justice was vested in the person at the head of the government. The Sirdar, however, has the power of adjusting petty quarrels, thefts, and, in short, disputed points of every description, among the inhabitants of a kheil, or society; but in all cases of importance, an appeal lies, in the last instance, to the Khan at Kelat.

Army.

A register of the Belooche army, drawn up during the reign of Nusseer Khan, exhibits an aggregate of 250,000 men, but the number was probably exaggerated. At present the same documents comprise a list of 120,000 troops, after excluding all the revolted provinces and districts; but it is believed, that Muhmood Khan could not, on the greatest emergency, muster more than half that number of fighting men.

Revenues.

His total revenues, in their present reduced state, may be estimated at 350,000 rupees annually, a large portion of which is paid in produce. In Nusseer Khan's time, the revenue exceeded 30 lacks of rupees. The duties levied at Kelat are extremely moderate. Horses or cattle pay nothing whatever throughout the Belooche territories; but there is a species of land-tax, payable from all cultivated grounds.

Exports and Imports.

The exports from Kelat are, at present, very trifling; its imports are iron, tin, lead, steel, copper, indigo, beetel-nut, cochineal, sugar, spices, silks, keemkhab, gold-cloth, chintz, and coarse woollens from India.

Climate and Soil.

The climate of Beloochistan is extremely various in the different provinces. The soil, in general, is exceedingly stony. Of the province of Kutch Gundava, however, the soil is rich and loamy, and so very productive, that, it is said, were it all properly cultivated, the crops would be more than sufficient for the consumption of the whole of Beloochistan.

Metals and Minerals.

Gold, silver, lead, iron, tin, antimony, brimstone, alum, sal-ammoniac, and many kinds of mineral salts and saltpetre, are found in various parts of the country. The precious metals have only been discovered in working for iron and lead, at mines near the town of Nal, about 150 miles south south-west of Kelat. The different other minerals, above enumerated, are very plentiful.

Fruits.

The gardens of Kelat produce many sorts of fruit, which are sold at a very moderate rate, such as apricots, peaches, grapes, almonds, pistachio nuts, apples, pears, plums, currants, cherries, quinces, figs, pomegranates, mulberries, plantains, melons, guaivas, &c.

Grain, and other Productions.

All kinds of grain known in India are cultivated in the different provinces of Beloochistan, and they have abundance of vegetables. Madder, cotton, and indigo, are also produced; and the latter is considered superior to that of Bengal. The culture of the date fruit is conducted with great attention in the province of Mukran.

Domestic and Wild Animals.

The domestic animals of Beloochistan are horses, mules, asses, camels, dromedaries, buffaloes, black-cattle, sheep, goats, dogs, and cats, besides fowls and pigeons. They have neither geese, turkeys, nor ducks. The wild animals are lions, tigers, leopards, hyenas, wolves, jackalls, tiger-cats, wild dogs, foxes, hares, mongooses, mountain-goats, antelopes, elks, red and moose-deer, wild asses, &c. Of birds they have almost every species to be met with either in Europe or India.

For the information contained in this article we

Benefit Societies.

are entirely indebted to the *Travels* of Lieutenant Pottinger, recently published; whose journey, undertaken by authority of the East India Company, must be regarded as furnishing a valuable addition to our geographical and statistical knowledge of the Asiatic Continent. (H.)

BENEFIT SOCIETIES.

Definition and Objects.

The general conception of these institutions may be shortly expressed. A number of individuals associate together, and, by payments made at stated times, create a fund, out of which they receive certain specific sums on certain specific occasions.

The people, whose course of life is most apt to present to them occasions where sums of money, derived from other than their ordinary resources, are of great importance to them, are those of whom the ordinary resources are the most scanty; in other words, the whole mass of the people employed in the ordinary and worst paid species of labour.

The occasions on which sums of money, derived from other than their ordinary resources, are of most importance to these classes of the people, are those on which the ordinary sources are diminished or dried up,—those of sickness, disablement, and old age.

Benefit Clubs are, accordingly, associations of persons of the rank thus described, who agree to make certain payments, in general so much a-month; in consequence of which, they receive certain sums, proportioned to the money which they pay, in times of sickness, of disablement, and in old age.

History.

Sir F. M. Eden, in his work on the Poor, refers to Hickes's *Thesaurus* for a proof that Benefit Clubs are of very ancient date, as the *Gilds* of our ancestors were nothing but associations of the same description. A Saxon MS. in the Cottonian Library contains the constitution of a *Gild*, or *Sodalitas*, as it is rendered by Hickes, a Friendly or Benefit Club, established at Cambridge.

"It was first of all," says the MS. "agreed, that all members shall, with their hands upon the sacred relics, swear that they will be faithful to one another, as well in those things which relate to God as those which relate to the world; and that the whole society will always help him who has the better cause. If any member dies, the whole Society shall attend his funeral to whatever burying-place he himself may have chosen; they shall defray one half of the expence which is incurred by the funeral entertainment; and each member shall further pay twopence, under the name of alms. If any member kill another, he shall pay not more than eight pounds, in the way of satisfaction. But if he who has committed the murder refuses to satisfy, the whole club shall revenge their brother, and all shall contribute to the expence. If any member, who is poor, shall kill a man, and have satisfaction to make; and if the person killed was worth one thousand two hundred shillings, every member shall contribute half a mark, and so in proportion. If any member shall address another with coarse and uncivil language, let him pay a sextarius of honey," &c.

From the same source we have the formula of another *Club* or *Gild*, formed at Exeter. After the religious services which the members were to perform for themselves, and for one another, it is ordained, "that when any member shall go abroad, each of the other members shall contribute fivepence; when the house of any one is burnt, each shall contribute one penny. If any one neglects the appointed times of meeting, he shall be fined; for the first offence, the price of three masses; for the second, the price of five; if, after admonition, he is absent a third time, without substantial ground, of sickness, or other cause, he shall not be excuseable. If any member shall use towards another gross and uncivil language, he shall make compensation by thirty pence." *

Gilds, we are told, did not confine themselves to cities, though it is only in cities that the vestiges of them remain. Little *Gilds*, it appears, were established in every parish. And of all those unions, the object was to entitle each of the members individually, on certain occasions, on which it was most apt to be required, to receive pecuniary or other specified aid from each of the rest.

Sir F. M. Eden speaks of Clubs which had existed in the north of England, for the purposes above described, above one hundred years; and there is a treatise on the poor laws by Mr Alcock, printed in 1752, which represents a number of them as existing at that time in the west of England. From that time to the present, they have been gradually multiplying; and have grown so numerous, within the last fifty years, as to have become an object of great importance in our national economy, and one of the most striking manifestations of virtue that ever was made by any people.

Striking Feature in these Institutions.

For persons merged in poverty, and totally deprived of education, as the English population heretofore have so generally been, it is not easy or common to have much of foresight, or much of that self-command which is necessary to draw upon the gratifications of the present for those of a distant day. When a people thus situated have a provision made for them, to which they can with certainty have recourse, as often as they themselves are deprived of the means of earning their own subsistence; and yet, notwithstanding this security, choose to form themselves almost universally into Benefit Societies, in order that, by taking something from the means of their present scanty enjoyments, they may in sickness, disablement, and old age, be saved from the necessity of having recourse to public charity, and

* See Hickes's *Thesaurus*, T. II. *Dissertatio Epistolaris*, p. 20, 22.

Benefit Societies.

may continue to live to the end of their days upon the fruit of their own labour, no burthen to the public, or dependent upon its bounty,—they exhibit a combination of admirable qualities, the existence of which could hardly be credited, if it were not seen; above all, in a country in which the higher ranks too often display an eager desire to benefit themselves at the public expence.

There is much similarity in the constitution of these societies. The rules and regulations of from twenty to thirty of those established in the metropolis, as well as those of several in other places, have been perused for the purpose of this article. The payments are, in general, monthly, and about two shillings the most common amount; though sometimes associations are formed of persons whose incomes are fixed pretty high, and then the payments are somewhat larger. The mode of regulating the benefit is commonly by three different rates of allowance; one during a temporary sickness; another, commonly one half of the former, during a chronical illness; and a third, still less than the preceding, a permanent annuity for old age. When a member falls sick, so as to be unable to labour, he receives the allowance for sickness; if the disease continues beyond a specified number of weeks, he is reduced to the chronical allowance; if the chronical illness continues beyond a certain number of months, the member is put upon the superannuation list, and receives the allowance for old age. Besides these rates, there is almost always a sum of several pounds which is paid for the funeral expences of a member or his wife. It is one of the ill-grounded desires of the least instructed part of the population of this country, to have what they call a decent, meaning by decent an *expensive*, funeral. As this is so much absolute waste, a consumption for which nobody is the better, and ravaged from a suffering family at a moment when most commonly their resources are diminished, or rather destroyed, the sooner they can be weaned from this superstition so much the better. It might soon be done by the example of their superiors. If those among them who are above vulgar error would enjoin their successors to put them in the earth at the smallest expence which the physical operation would admit, the childish passion for a costly funeral would soon disappear. It is necessary that sepulture should be performed in places, and by persons pointed out by the proper authority, for the security due to the health of the living. But if the business of the cemetery is not performed altogether at the public expence, and in the same manner for all, which would be the best regulation, there assuredly ought to be no fees, nor any charge beyond the rigid payment of the labour. When the religion of the relatives requires a devotional service to be performed at the grave, it ought assuredly to be performed without any fees or presents to the actors in the scene. Fees to the clergyman, and others, in a church of England funeral, are a serious grievance to the poor.

Constitution and Rules of these Societies.

The mode of doing the business is exceedingly simple. When the society is not numerous, there is, in general, a monthly meeting of all the members. When they are numerous, a committee is formed, of which the meetings are monthly; and general meetings, at more distant periods, are held of the whole. Two or more stewards, as the business may require, are chosen at certain short intervals, whose business it is to visit the members applying for relief, and to pay their allowance. Members are admitted only within a specified age, most commonly between twenty and forty-five; and the persons belonging to occupations regarded as unwholesome or dangerous, are excluded by name from most of the clubs not expressly established for themselves. There are some curious exclusions in most of the London societies. From a great proportion of them, Irishmen are excluded; and in almost all of them, it is particularly declared, that no *attorney*, or *attorney's clerk*, shall be admitted a member.

Some of their rules are in a very remarkable manner favourable to virtue. In almost all the London clubs, it is a rule that sickness or disablement, produced by drinking, by the venereal disease, or by fighting, except in self-defence, shall receive no benefit. If any member, while in the receipt of an allowance, is found gaming or intoxicated, or out of his own house after a certain hour in the evening, he is subject to heavy penalties, very often expulsion. If any member appears at a meeting of the society in a state of intoxication, or uses rude or provoking language to any person present, or is guilty of profane cursing and swearing, or offers wagers, he is fined; in some cases he is fined if he comes to the meeting without being clean in his dress and person; and, in other cases, attention to this object is recommended without being enforced.

Of some of the rules, which are also very generally adopted, the reason is not so easily seen. One of them is, that none of the members shall belong to any other association of the kind. If a member complies with all the rules of one society, it can be of no detriment to that society, if he belongs to another. A man whose earnings place it in his power, may thus secure to himself a double benefit in sickness, disablement, or old age. It would lead to the same end if a man was allowed to take more than one of what may be called the shares of one society, double, for instance, the monthly and other payments, on condition of receiving all the allowances double; but his security, as long as clubs are on a precarious footing, would be somewhat increased by dividing the risk.

By another of these rules, the utility of which seems rather more than doubtful, a member, while receiving aid, is not allowed to work. The intention of this is sufficiently evident. It is to prevent that sort of imposition to which the societies in question are most exposed, receipt of bounty at seasons when it is not required. The question is,—whether if a man was allowed to earn, were it ever so little, as soon as he was capable, and even, when entitled to relief, to divide the produce with the club; deducting, for example, from his allowance, a portion equal to one half of his earnings,—both parties would not find their account in it? and whether means might not to be discovered of guarding against imposition as effectually in that case as by the expedient which is now in use? In the case of the superan-

Benefit Societies.

nuation annuity, the member is, in general, at liberty to do any thing which he can for himself, provided his earnings go not beyond a particular amount.

Such, then, in a general point of view, is the end aimed at by these societies, and the means through which they endeavour to accomplish it.

We shall next consider the effects which they have a tendency to produce.

Effects produced by these Societies.

The effects which they have a tendency to produce, regard either the individuals themselves, who are the members of the societies, or the community at large.

1. The effects which they most immediately produce with regard to the individuals themselves, are two; *first*, They deduct somewhat from the ordinary enjoyments; *secondly*, They diminish greatly certain occasional pains; and there can be no doubt that what is lost by the diminution of the ordinary enjoyments, is much more than compensated by what is gained in the diminution of the extraordinary pains. The pains are either those of want, in times of sickness and disablement, where no provision is made for the poor, or those of disgrace and aversion, where relief may indeed be received, but in a way inconsistent with all sense of independence, and in general various little habits from which the idea of happiness can no longer be disjoined.

Under this head, something may perhaps be allowed on the score of temperance. Of the money paid by the members to the club, part, if not so paid, might have been spent upon intoxicating liquors, by which the health and strength would have been impaired.

2. The effects which Benefit Clubs produce in regard to the public, are either pecuniary or moral. Whatever portion of money would otherwise have been spent by the public in maintaining, during sickness, disablement, and old age, the persons who, in these circumstances, are maintained by the clubs, this exactly is the pecuniary advantage which accrues to the public.

The moral effects are not so easy to define. But circumstances present themselves in sufficient abundance to prove that they are not inconsiderable. In whatever degree they contribute to diminish the use of intoxicating liquors, they weaken one of the grand causes of the uselessness and mischievousness of human beings. In whatever degree they contribute to keep alive the sensibility to disgrace, they preserve one of the greatest of all incentives to useful conduct, and one of the greatest securities against a course of life, either mischievous or useless. That they contribute greatly to keep alive the sensibility to disgrace is not to be disputed. It follows that they contribute greatly to all that virtue and good conduct of which the labouring classes of this country are day after day displaying a greater and a greater share.

Compared with Savings Banks;

Since Frugality Banks became the fashion, it has been customary to allege, that all the benefits capable of being derived from Benefit Clubs, and still higher benefits, may be derived from the banks, and with the avoidance of several evils. It will not require many words to enable us to effect a comparison. We shall follow that division of the effects, into those regarding the individuals, and those regarding the public, which was presented above.

First, In regard to the Individuals;

1. In regard to the individuals, it is supposed that the banks will make them save more eagerly. If this enables them to make a greater provision for the seasons of distress, it is good; if not, all that they would have spent in innocent enjoyments is so much good lost.

But it may well be questioned whether banks are calculated to make them save more rigidly. The idea of a stock which they may leave behind them is something. But the idea of a better provision for the occasions of their own distress is something also; and with the greatest number, it is probable, the greatest something of the two.

With regard to the convenience of taking the money in small sums, the monthly payments of two shillings, are nearly as small as can be desired. If this is too small for the rate of any man's abilities, there might in each society be different rates, or one man might belong to several societies.

A circumstance which has been urged more strongly is, the inconvenience of paying, as required in Benefit Clubs, on a particular day; to banks the payment is made whenever it is convenient. This has its advantages, and its disadvantages. The disadvantages appear to exceed the advantages. With this opinion Mr Duncan was so deeply impressed, that he thinks stated payments, with penalties, a proper law for Frugality Banks. "Though it may bear hard," he says, "on a contributor to be bound to pay annually a stated sum, as in Friendly Societies, under the pain of forfeiting the whole, it is, notwithstanding, useful in such institutions, that some strong motive should exist for regular payments. The reason on which this opinion is founded, must be obvious to all who know any thing of human nature. What we have no pressing motive to do at a particular time, we are apt to delay till it is beyond our power to do at all. So sensible are the common people themselves of this tendency, that we frequently observe them having recourse to contrivances for *forcing* themselves to save money for a particular object. It is partly on this principle that Friendly Societies find so many supporters; and that there are such frequent associations among the lower classes, with the view of raising funds, for the purchase of family Bibles, or some of the more expensive articles of furniture." (*Essay on Parish Banks*, p. 24.)

This important fact, of the voluntary associations of the people to raise funds, not merely for support in seasons of distress, but for the purchase of articles of fancy and luxury, is a strong argument in favour of Clubs. It shows two things; it shows the pleasure the people take in them; and it gives the experience of the efficacy which attends them.

The difficulty of making good the stated payments to the club, at moments of great pressure, as when employment is wanting, or a man's wife and children are sick, is objected to Benefit Societies. This is an inconvenience, no doubt; but we have seen that it is not unattended with compensation. In fact, a man must be in a state of distress very uncommon, if he is prevented by real necessity from paying his

club-money. Besides, this is one of the occasions on which very extraordinary exertions are made by his acquaintance and friends; especially if he is not a man thoroughly worthless, whose vices, not his misfortunes, are the cause of his distress, to supply him with the means. And this is an exercise of virtue in these acquaintances and friends, which is highly useful; and tends forcibly to the increase of the benevolent feelings in the minds both of those who make it, and of those in favour of whom it is made.

It is urged as a hardship of great magnitude, that a man, after he has been a long time a contributor to a club, should lose the benefit of the whole, for a delay in payment at a season of peculiar distress. But a certain degree of indulgence is allowed; a defaulter does not forfeit till the first meeting, which is a month after the quarter-day. Besides, it is very common to misrepresent the amount of the loss in this case. What a man really and truly loses is that which will be necessary to place him in the same situation. But that is only as much as will be necessary to entitle him to the allowances of another club. This may be nine or twelve months' contributions. Suppose the rate of contribution is 2s. a-month, and 5s. of entry-money. What a man loses by expulsion, however much he may have paid, is only 29s. If, indeed, he is an old man, past the age of admission into another club, what he loses is much more serious; it is the value of all the benefit which he would have been entitled to derive. And, in this case, some modification of the rule of forfeiture would be desirable. It is, however, no fundamental objection, because such a modification may be easily made. Lastly, the number of those who suffer forfeiture from real necessity, and not from their vices, is small, bearing a very insignificant proportion to the whole. For a hardship to the very small number, a great benefit to the very great number is not to be foregone. This is the very principle on which bad government is distinguished from good.

It is brought as a strong argument against Benefit Clubs, that the meetings are held at public-houses. From this, it is inferred, that the members are at these meetings very commonly seduced to drink; and acquire, increase, or confirm habits of intemperance. This appears to be an inference altogether unwarranted, and contrary to the fact. The members are, in general, under the necessity of holding their meetings at a public-house, because it is only at a public-house where they can, in general, hire an apartment for the purpose. The use of the apartment is sometimes paid for by the money spent, which is always a limited, and always a very small sum, threepence most commonly, or a pint of porter for each; and sometimes the room is paid for, not in this way, but by the contribution of a penny or other small sum from each; and intoxication, at the time of meeting, is punished with a fine. It is affirmed by those who have most attended to the practical proceedings of these societies, that instead of being a source of intoxication, they have been one of the grand causes of its decrease.

One decided advantage which the Benefit Clubs possess above the Savings Banks is, that the money paid to the club cannot be taken out, first, to gratify any unnecessary desire; secondly, to buy furniture for the sake of an early, and hence, in all probability, a fruitful, that is, a deplorable marriage; thirdly, to satisfy the parish for a bastard, which often would not have been gotten, but for the reflection, that if the worst came to the worst, means were had to get rid of it.

In a moral point of view, the formation of the people into little combinations and fraternities is of the greatest importance. It concentrates the eyes of all upon each individual; and renders good conduct a thing of infinitely more value to him, as it renders bad conduct for men detrimental. It is this circumstance which the sage mind of Dr Adam Smith loads with such emphatic praise in the supposed case of the division of a country into so great a number of religious sects, that each congregation might be regarded as differing from the rest. In this manner, without difficulty, and without care, is exercised one of the most vigilant and effectual of all censorships; the most salutary of all inspections. When an ignorant, or almost any man can say to himself, my conduct is regarded by nobody,—it is astonishing how easy it is for temptation to subdue him; when he must say to himself, I cannot perform a disgraceful act without reading aversion and contempt in the eyes of all my acquaintance,—it is astonishing how much he is strengthened for resistance.

There is yet another thing of cardinal importance. If it were possible for the superior to do everything for the inferior people, and to leave them nothing to do or care about for themselves, nothing would be more calamitous than the accomplishment of such an event. The mass of the human species would thence become what the people of Paraguay became in the hand of the Jesuits; most perfectly helpless, and ready, on the least derangement in the machinery which conducts them, to fall into the deepest wretchedness and barbarity. As that machinery would be liable to be deranged by the slightest accidents, it could not be preserved in order long, and would then serve as an introduction, a necessary and certain introduction, to one of the most deplorable conditions of human affairs. The case is altogether different where the power of suffering for themselves is generally spread throughout the community; where the people have resources; where every man is accustomed to combine for himself the means of warding off evil, and attaining good. There the machine of society cannot be easily disordered, and human happiness is placed on a much more secure foundation. Then, if any of the larger arteries of the body politic is obstructed, the nourishment of the system is carried on by the admirable service which may be rendered by the smaller. To a system which has thus a *vis medicatrix* in all its parts, no shock can be given that is not immediately repaired. Were the greatest disorder introduced, things of their own accord would hasten to their proper place.

It is, therefore, a prodigious recommendation of Benefit Societies, that in them the people act for themselves. We do not mention this, however, as one of the circumstances in which they differ from

Savings Banks. It is, indeed, true, that in most of the Savings Banks which have yet been started, the upper people have taken upon them to manage for the under. But this is not necessary. The contributors to Savings Banks may themselves, if they choose, manage a bank just as well as a club-box; in fact, the business of the bank is far more simple than that of the box. There is one important example of a bank conducted by the people themselves, in that established in Clerkenwell, at the suggestion of Charles Taylor, Esq.

So much with regard to the effect of Benefit Societies, as compared with Savings Banks, in promoting economy and other good qualities among the contributors. Let us next compare them with regard to the benefit received. This part of the subject has already been so well handled by the Reverend Richard Vivian, rector of Bushey Herts, in *A Letter on Friendly Societies and Savings Banks,* published in 1816, that it would be improper to do anything more than transcribe what he has written.

"For a view of the powers of the institutions, to secure independence, let Mr Rose's table be compared with the Benefit Society long established in this parish. By the table the amount of *one shilling per week* after one year is L.2, 12s. If the contributor should be ill at the beginning of this year, there is nothing for him: if quite at the end of the year, he should be ill four weeks, and should draw equal to the allowance of the Bushey Benefit Society, his capital is gone; and he must begin again. A member of the society pays *two shillings per kalendar month,* and, if he has paid one pound to be free, supposing him under twenty-five years of age (and other ages in proportion), he will receive 12s. a-week during illness in any part of the whole of the year; and will find his right to the same payment for future years undiminished. There is no occasion to go through the intermediate years. Let us take the twentieth. After twenty years, the contributor to the bank (if he has had no illness, which would quickly have exhausted his stock, especially in the earlier years) will have paid L. 52, and will be worth L. 77, 8s. 6d. We will suppose that he is come to old age, or some lasting infirmity. He can afford 6s. a-week for five years, and then comes to the parish, with the aggravation of disappointed hopes of independence. In the society the payments in twenty years will amount to L. 24; the receipt 6s. a-week in old age, if his life should be protracted to the (I hope incalculable) date of a national bankruptcy.

"You will perceive, that the great defect of Savings Banks is the want of benefit of survivorship. But (say their advocates) there are the advantages of bequeathing their stock, and of taking their money, whenever they want it; the advantage of bequeathing I will leave to be estimated by the most sanguine admirers of Savings Banks, only desiring them to take into their account, the high probability that his little stock will be hardly worth bequeathing, even if not exhausted by the illness of the testator, in the case of his dying in youth; and the certainty of his being his own heir, if he should die in his old age. The power of taking out the money at any time is the very circumstance which fills me with alarm. There is danger lest the subscriber should leave his club, and become a contributor to a bank, from the fallacious hope of enjoying this advantage *in addition* to all the others. No doubt this may be an advantage to prudent persons in certain situations. But is there no danger of cases, which I might have mentioned before, in which the stock will be sunk in unfounded projects, in wanton expences, in a childish impatience of possessing money? All this imprudence would be of comparatively little consequence, if the parties were by any means protected from absolute want; that is to say, if they were, at the same time, members of Benefit Societies.

"The truth is, Savings Banks are not calculated for the lowest and most numerous rank of the community. This is evident from Mr Rose's table, beginning with 1s. *per* week. Many members of Benefit Clubs cannot make good their payments of less than half that sum without the best charity that can be bestowed by the rich—assistance towards the payment of their subscriptions to members of Benefit Clubs, with large and helpless families. Men in elevated stations imagine that they see the *lowest* order, when they see but the lower. The "*Corinthian capital" looks down, and mistakes the cornice of the pediment for its base.* While the great are providing for their immediate dependants, they seem to be providing for the poor. I do not wish to retort upon some of the defenders of Savings Banks, and by exaggerating their possible ill effects to exalt the merit of Benefit Societies. Savings Banks have done, and I hope will continue to do, much service to many. They often lift a little higher them who are not already very low. But a man should be secured from sinking into absolute wretchedness, before he is encouraged to mount into a higher sphere. By a Savings Bank, a butler may lay up money enough to keep a public-house. But there must be a Benefit Society to keep a ploughman and his family from the workhouse. Now, I hope I may be allowed to say, that it is better that one ploughman should be preserved from a receptacle of misery, than that ten butlers should be exalted into publicans."

Even Mr Duncan says, "There is one point of view in which the Friendly Society scheme can claim a decided advantage. An individual belonging to the labouring part of the community cannot expect, by making the most assiduous use of the provisions of the Parish Bank, to arrive at sudden independence;—on the contrary, it is only by many years of industry and economy that the flattering prospects held out by that system can be realized. But health is precarious, and an accident or disease may in a moment put an end to all the efforts of the most active and expert. It is under such circumstances that a very striking difference appears in favour of the scheme we are considering. He who should trust to the progressive accumulation of his funds in a Parish Bank, might now find himself fatally disappointed. If he had not been fortunate enough to realize a considerable capital before the sources of his subsistence were dried up, the illness of a few weeks or months might re-

duce him to a state of want and dependence, and cause him to experience the unhappiness of mourning over impotent efforts and abortive hopes. On the other hand, the man who has used the precaution to become a member of a Friendly Society, has made a comfortable and permanent provision against the sudden attack of disease and accident. The moment that he comes to acquire the privileges of a *free member*, which, by the rules of most of these institutions, is at the end of the third year after he began to contribute, he is safe from absolute want, and the regular manner in which his weekly allowance is paid him enhances its value. Nor is this provision liable to any of those objections, which have been so strongly and so justly urged against the well-intended but mistaken system of poor rates. Instead of degrading and vitiating the mind, its tendency is directly the reverse. The poor man feels that he is reaping the fruit of *his own* industry and forethought. He has purchased by his own prudent care an honourable resource against the most common misfortunes of life, and even when deprived of the power to labour for a livelihood, the honest pride of independence remains to elevate and ennoble his character."

It is objected, that Benefit Societies have been established on improper calculations, and thus have come to ruin. But this is an evil which has a tendency to correct itself. Experience, if there were nothing else, discovers what rate of benefit the payments can afford, and the thing is now so well understood, that mistakes, it is probable, are very seldom incurred. At any rate, this is a chance of evil which may always be precluded by communicating information.

The funds, it is said, of Benefit Societies, are often confided to improper hands, and by consequence lost. This, too, is an evil, which, so far from being necessary, has a sure tendency to correct itself. People learn by a little experience where their money may be safely lodged. It is, indeed, a lesson which probably they have already learnt. We perceive it is a rule in most of the London Societies, that whenever the fund exceeds what is necessary for the current expenditure, it is invested in Government securities. Another thing should be observed, that it is a great advantage of Benefit Clubs not to require much in the way of fund. If the calculations are correct, the outgoings within an average period will balance the incomings; and all that is requisite in the way of fund, is a small sum to meet accidental inequalities. When this fund is lost, it is not much that is lost. If a small additional sum is subscribed by each member; or, instead of this, if the allowances are for a short time suspended, or only reduced, the society is placed in its former situation. The case is wofully different with a bank. There, if the funds are lost, the whole is lost.

Secondly, In regard to the Community.

2. Thus stands the comparison between Savings Banks and Benefit Societies, in regard to the members or contributors. How stands it in regard to the community as a whole?

In the first place, it is evident, that the classes, of whom such members and contributors are composed, being the whole population, with the deduction of a number comparatively small, it is not easy for any thing which is good for them, one by one, not to be good for the whole conjointly.

Further, if Benefit Societies afford, as appears to be ascertained, a better security for the maintenance of the people, free from public aid, than Savings Banks, the public is benefited to the amount of all the support which otherwise it would have been obliged to afford.

If the moral and intellectual qualities of the people are more favoured by the societies than the banks, the public is benefited in respect to a cause of good, the effects of which are incalculable.

Thus far on the side of good. On the side of evil, a great fear has been expressed, that out of any joint proceedings of the people would arise mischief to the government. The operation of fears of this description has been one grand cause of the evils which human beings have brought upon one another. It is a circumstance full of suspicion, when governments count upon the hatred of their people. It seldom happens, and seldom can happen, unless when they know well that the people have reason to hate them. It is not natural for the people to hate their government, unless oppressed by it. The people, instead of being disposed to hate a good government, are far too much disposed to be pleased with a bad one; as the history of the whole earth so abundantly and wofully testifies. If a government takes care of the interests of the people, and gives them instruction sufficient to know their own interests, that is to say, takes no measures to prevent their instruction (for that, in such a state of society as ours, includes all that is necessary), it will have nothing to fear from the little societies which the people may form, to insure one another against some of the calamities to which they are most commonly exposed. Besides, if ever the people are stimulated to combine against the government, they will find better mediums of combination than the Benefit Societies, which appear to have an unnecessary and improper jealousy of one another.

A fear has been also expressed, that Benefit Societies may be rendered subservient to conspiracies for the raising of wages. Upon this it may be sufficient to observe, that many instances of what the workmen call *striking for wages* have taken place, since Benefit Clubs were frequent; in these instances, other means of combination have always been found; and Benefit Clubs are by their nature ill adapted to the purpose.

Such is the present state of the business of Benefit Clubs in this country at this moment, and such are the effects they have a tendency to produce. The grand cause why more of the good effects which they are calculated to produce have not been realized, is the unhappy state of the law in England.

This deserves a few words of illustration.

Inconveniences experienced from peculiarities of English Law.

For a long time, the unhappy state of the English law rendered the Benefit Societies a mere object of prey. Any person whatsoever, who found it agreeable to cheat them, might do so with perfect impunity. They had no means of redress. This was owing to one of the fopperies or quaint conceits of the English law, bred in times of ignorance and im-

posture, and hugged with ecstasy by the lawyers, in spite of the wisdom of an enlightened age. In consequence of the conceit to which we allude, no assemblage of men could be regarded as one body, or entitled to sue for property possessed in common, unless they had certain ceremonies performed in regard to them,—ceremonies exquisitely useless; after the performance of which, the lawyers would give them a nickname (that of a corporation), and would then permit them to sue as one party, for any cause of action common to them all. The ceremonies, the performance of which gave an assemblage of persons this potent name, depending upon the will of great men, were not easy to be got; nor was the getting of them without an expence fatal to such institutions as Benefit Clubs. They remained, therefore, deprived of the benefit of law till the year 1793, when an act was passed which had two objects in view. One was to take securities against certain dangers at that time intensely associated with the idea of any thing called an assemblage of the people. Another was, to give to Benefit Societies, though without the name corporation, which performs legerdemain, if not magic, in the kingdom of the lawyers, something of the protection of law. The treasurers and trustees, as vested with the property of the society, were enabled to bring or defend any action, suit, or prosecution, relative to the property of the society. But to obtain this advantage, it was rendered incumbent upon the society to make known all its rules to the justices of the peace, and obtain their approbation.

As the expence of law-proceedings was so great, that the expence of a suit, or at least of a few suits, would be completely ruinous to a Benefit Society, something was also done towards the diminution of that expence. It was ordered that no fee should be taken by any officer or minister in the courts, and that the proceedings should not be chargeable with any stamp duty.

This was most undoubtedly travelling in the right path; but it was not doing enough. It did not render the access to justice sufficiently easy. The proceedings of English law are full of delay, and full of intricacy. The business of the great mass of the people, of which Benefit Clubs is a part, requires dispatch and simplicity. A suit at law in behalf of a Benefit Society is still attended with so much trouble, and so much expence, that, virtually, the doors of the Courts are well nigh shut upon them down to the present hour. And this want of the protection of law they are obliged to supply, as well as they can, by rules of their own,—rules of some inconvenience, and of which they would never think, if the protection of law were as it should be.

Thus, with the delay, trouble, and expence of the regular courts, it would never do to sue for arrears, as often as a few shillings became due. The societies are therefore obliged to make a law of their own, that a member who does not at a certain time pay up his arrears, forfeits his place as a member. If a single attendance of a few minutes at a summary court, which would be all that would be required, would suffice to procure a sentence and execution upon the goods of a defaulter, the law of expulsion would not be required.

It is evident that, to give to Benefit Societies all the salutary operation of which they are capable, some court is wanting, where, free from the superstitious perplexities of barbarous law, the matter of all applications may be immediately tried, in the way of natural and rational inquiry; the parties themselves and their witnesses instructing the judge upon their oaths, and receiving his award without delay and without expence. If every man who fancied himself aggrieved by his club, and every club who had a complaint against an offender, could receive justice on these terms, the business of societies would be very simple, and their benefits sure. Their rules might then be limited to the fixing of the periodical payments, apportioning the benefits to be returned, and settling the order of conducting the business. They would attain a sort of ideal perfection, could they only obtain in a degree at all approaching to perfection, the benefit of law. With no other than the functionaries at present in Great Britain administering the law, the easiest mode of composing a judicatory for Friendly Societies would be to make the reference to a single Justice of the Peace, who should hold a regular tribunal for this purpose, and go through immediately, even to execution, with all disputes, reserving one appeal to any of the neighbouring Justices, upon whom the parties should mutually agree. Upon no part of the proceedings should there be the shadow of a tax or a fee; and, as lawyers would be altogether unnecessary, and the witnesses would in general be few and at hand, justice would in general be done without an hour's delay; with the loss, even in the most tedious cases, of but a few hours of time, either to the parties or the witnesses; without any expence in most cases, with a very small expence in any. The consequence would infallibly be, that, in such cases, no man would have any interest in an injustice, for which he would be immediately called before the judge, which he would be immediately obliged to repair, and from which he could therefore derive no advantage, not so much as a little momentary ease. (FF.)

BENTINCK (William Henry Cavendish), third Duke of Portland, was born on the 14th of April 1738. Having finished his education at Christ Church, Oxford, he went on his travels. Soon after his return, he was elected for the borough of Weobly, in the first Parliament of the King's reign. For this borough, however, he did not sit long; for, on the death of his father, on the 1st of May 1762, he was called up to the House of Peers. He immediately joined the opposition; and, in 1763, his name is found among the minority against the cyder bill, and along with that of the Duke of Grafton, in a protest against it. The next session, he also signed a protest on the motion to vote away the privilege

Bentinck. claimed by members of Parliament in matters of libel. In 1765, when his friend the Marquis of Rockingham came into power, he was appointed Lord Chamberlain, and he retired when the Marquis went out of office. In 1768, there was a violent contest for the county of Cumberland; and as the Duke warmly supported the two opposition candidates, the ministry, in order to weaken his influence, and at the same time to increase that of Sir James Lowther, who was one of the ministerial candidates, granted to the latter Inglewood forest, an extensive and valuable estate, which had been granted by King William III. to the first Duke of Portland, and had remained in possession of that family ever since. The new grant was made in consequence of a report from the surveyor-general of crown lands, that the premises were not comprised in the original grant from King William to the Duke of Portland, but were still vested in the crown. A letter was written from the Treasury, directing the Duke to prepare his title, and assuring him that nothing should be decided concerning the grant till such title had been stated and maturely considered; but while his Grace's agents were busily employed in their researches and inquiries, he received a second letter, informing him that the grants were passed, and the leases signed. A caveat had been entered at the Exchequer to stop the progress of the grant, but, when Lord North was prayed to withhold affixing the Exchequer seal, he replied that, as Chancellor of the Exchequer, he was bound to obey the orders of the Treasury. On the 19th of November 1771, this great cause was tried before the Barons of the Exchequer, in Westminster-Hall. The Court recited all the records, and prerogatives of the crown, from Edward I. to the lease made to Sir James Lowther; when, after a full and impartial examination of the said lease, it was found invalid; agreeably to the statute of the 1st of Anne, which expressly requires that, upon every grant from the crown, there shall be a reserved rent, not under the third part of the clear yearly value of the manors, lands, &c. as shall be contained in the grant. Sir James Lowther's grant from the crown being only a quit rent of 13s. 4d. for the whole of Inglewood forest, was immediately determined by the Court an inadequate third proportion, and he was nonsuited accordingly. The *nullum tempus* bill, or the act for quieting the possessions of the subject against all pretences of concealment whatsoever, which was brought into Parliament in 1768, and passed in the following year, owed its rise to this grant of the Portland property to Sir James Lowther.

In 1766, the Duke of Portland had been bound more closely than ever to the Rockingham party, in consequence of his marriage with Lady Dorothy Cavendish, sister to the Duke of Devonshire. On the resignation of Lord North, he was appointed Lord-Lieutenant of Ireland; and, during his government, the Parliament of that country was declared independent of the British Parliament. After an administration of somewhat more than three months, he was recalled, when Lord Shelburne came into power. On the death of the Marquis of Rockingham, he was recommended by the Privy Council to the King as his successor at the Treasury; but Lord Shelburne was preferred. When the Coalition came into power, however, he obtained the situation of Prime Minister, and went out of office with them. During Mr Pitt's difficulties, when he first came into administration, in consequence of the House of Commons being against him, an attempt was made to form a coalition between him and the Duke of Portland; but his Grace objected to the conditions on which Mr Pitt came into power, and refused his support, unless he would resign his place, and come in again on equal terms with himself and his friends.

Bentinck || Berbice.

In 1792, he was elected Chancellor of the University of Oxford; and, soon afterwards, he, as well as several other friends of Mr Fox, who differed with him respecting the French revolution, left the opposition, and joined the ministry. Upon this, he was appointed Lord-Lieutenant of the county of Nottingham; and, in 1794, Secretary of State for the Home Department. The scarcity and high price of provisions, and the state-trials, which occurred soon after he became Secretary of State, rendered his office arduous and unpleasant. He discharged his duty, however, under these circumstances, with moderation, and with acknowledged good intentions, though not always perhaps with vigour and judgment. He continued Secretary of State, till Mr Addington became Prime Minister in 1801, when he exchanged this situation for the more easy duty of President of the Council. On the death of Mr Pitt, and the appointment of Lord Grenville and Mr Fox to the ministry, in the spring of 1806, he was removed from the Presidentship of the Council; but he was again called into public life, and placed at the head of the Treasury, in March 1807, when Lord Grenville's administration closed. His Grace, however, though nominally the Prime Minister, was too infirm to take an active part in the high and arduous duties of this situation, which were discharged almost entirely by Mr Perceval, the Chancellor of the Exchequer. He continued nominally the First Lord of the Treasury till a very short time before his death, which happened on the 30th of October 1809.

The abilities of his Grace were certainly but moderate, and very far inferior to those which he must have possessed, had he been, as latterly there has been an attempt to prove, the author of *Junius's Letters*; but his understanding was good, and he was by no means unwilling or unable to give regular attention to official business. His political integrity was never questioned, even by the party whom he left. (c.)

BERBICE is a colony belonging to the British, situate on the banks of the river of that name, in the province of Guiana, in South America. The latitude of the mouth of the river Berbice is 6 degrees, 20 minutes north; and its longitude 57 degrees, 11 minutes west from London. The plantations are situate on each side of the river, and extend nearly 300 miles from its entrance. Previously to the year 1799, this colony was bounded on the east by the Devil's Creek, and on the west by Abarry Creek, which separated it from Demerary, its breadth being then 30 miles. But when Surinam surrendered to the British in that year, a negocia-

Situation, Boundaries and Extent.

Berbice.

tion was entered into between the Governors of these two colonies, by which Surinam conceded to Berbice the tract of country between the Devil's Creek, and the river Courantine; thus increasing its breadth to about 45 miles. The sea coast, extending nearly 50 miles, and the west bank of the Courantine, were immediately surveyed, and laid out into regular allotments. The extent of this colony was farther enlarged by the British, who cleared and embanked from the sea the whole line of coast between the Demerary and the Courantine, forming upon it a carriage-road 60 feet broad, with six-foot parapets on each side for the convenience of travelling.

Face of the Country.

Previously to this improvement, the face of this country resembled that of the rest of Guiana. On the shores there was a border of low ground, between high and low-water marks, covered with mangrove. When the tide flowed, this border had several feet of water over it; and when it ebbed, it presented an inaccessible mud-bank. This is now rendered dry and productive. Behind this border of mangroves, at the distance of 400 or 500 paces, commence low, level, swampy savannahs, formed by the rains, which are prolonged in the direction of the coast, with a depth more or less considerable, according to the distance of the mountains. This part of the colony was almost entirely neglected by the Dutch, who fixed their principal plantations in the more elevated and interior part of the country.

Climate.

The year, here, is divided into two dry and two wet seasons; light showers begin to refresh the land about the middle of April; the rain increases till the middle of June, when it falls in torrents; at the beginning of July, these heavy rains begin to decrease; and in August, the long dry season begins, and continues till November. December and January constitute the short and rainy season; and February and March the short dry season. The land winds prevail during the two wet seasons, and are unhealthy; in the dry season, the air is refreshed, by regular, diurnal sea-breezes. The temperature of this colony is not so great as might be expected from its latitude; the thermometer very seldom rises to 91 degrees; in general, during May, June, and July, it varies between 83 and 84; the lowest degree is about 75. The weather always changes very gradually.

Rivers.

There are two rivers in this colony; the Berbice, and the Canje. The former runs from south to north, and discharges itself into the Atlantic Ocean. The coast on each side of it forms a bay at its entrance, which is nearly a mile in width, having a small island in the middle, called Crab Island, from the number of land-crabs on it; the entrance is protected by three forts, but they are of little use, as Berbice must, from its situation, always follow the fate of Demerary. Without the entrance of the river is a bar of sand, over which, at high tide, there is seldom more than 16 feet of water; but within, the water is of sufficient depth, and the river is navigable, for ships of burden two hundred miles from its mouth. On account of the bar, however, few vessels rendezvous here, but anchor off the port of Demerary.

The river Canje is narrow, but deep, running at first nearly from south to north, but afterwards diverging to the east, till it falls into the Berbice about a mile from the sea. It is navigable for colony schooners 30 miles up. At its head are immense falls, and about 40 miles below, there is a creek which connects it with the Courantine. In this route, and by means of this creek, or island, dispatches are brought from Surinam to Berbice by the Indians. The water on all the coast of Berbice is brackish. The rain-water, which lodges in the low parts of the forests, called bush-water, is collected by the Indians for the purposes of drinking and cooking. The forests are extensive, and contain many very large trees. Dr Pinckard describes an enormous tree of the Tonquin Bean, the body of which rose perpendicularly to the height of between 70 and 80 feet, before it threw out a single branch.

Towns.

The only towns in this colony are Old Amsterdam, and Fort Nassau, or New Amsterdam; the former is said, by Bolingbroke, to be 50 miles up the river Berbice, but Dr Bancroft places it at 100 miles from the mouth. The inconveniences attendant on this situation of Old Amsterdam were so numerous and obvious, arising chiefly from the uncertain and intricate navigation of the river, that, in the year 1766, when Dr Bancroft visited Guiana, it was resolved to remove the seat of government to a point of land on the eastern shore of the Berbice (about a mile from its entrance), formed between that river and the Canje. So slow, however, were the Dutch in their operations, that New Amsterdam, for so this town was called, was scarce begun, in the year 1796, when Berbice capitulated to the English. Under the greater activity of the conquerors, New Amsterdam soon assumed the size and appearance of the capital of the colony. It lies on the south side of the Canje; and the houses extend up the banks of the Berbice about a mile and a half, facing the water. The Dutch, in laying out the town, paid particular attention to health and convenience. Round each allotment there are trenches, which fill and empty themselves every tide, so that all the filth is carried off before it stagnates and becomes unwholesome. Each lot contains a quarter of an acre of land; a free circulation of air, as well as ground for a kitchen-garden, is thus secured to the inhabitants. The houses are very long and narrow, and not more than a story and a half high, with galleries on each side, to protect them from the sun. Those inhabited by the Dutch are thatched with troolie * and plantain leaves, which they prefer to shingles on account of coolness; but

* The troolies are perhaps the largest leaves that have been hitherto discovered in any part of the world. Each leaf is supported by a single stem, which arises immediately from the root, and becomes the middle rib to the leaf. These stems are hard and strong, and about three inches in circumference near the root. Each leaf is from 20 to 30 feet in length, and from 2 to 3 feet in breadth. They will effectually exclude the most violent rains, and last for many years.

Berbice.

the English shingle their houses, from their dislike of the insects and vermin which the troolie and plantain leaves harbour. The government-house and colonial offices are built of brick, in the European style, and with considerable pretensions to architectural taste and magnificence.

Estates.

Before Berbice surrendered to the British, in 1796, almost all the plantations were at a distance from the coast, considerably up the banks of the Berbice and the Canje; but within a very short time after the colony came into our possession, the plantations were greatly extended. The west coast was first cultivated; and in the year 1799, that to the eastward of the river Berbice, as far as the Devil's Creek, was cleared and cultivated. This part was surveyed and cut into two parallel lines of estates, with a navigable canal between them, for the convenience of water-carriage. Behind the second row of estates, the river Canje runs, both the banks of which are cultivated with sugar, coffee, and plantains. The estates are distinguished as follows: those on the line facing the sea are the coast estates; the second line consists of the canal estates; and the remainder are called the Canje estates. Besides these, there are valuable and extensive plantations on each side of the Berbice, stretching, as has been already mentioned, nearly 300 miles from its mouth.

Produce.

The principal and most valuable produce of the colony are sugar, coffee, cocoa, tobacco, cotton, and the arnotta, or roucou shrub. This last was, for a considerable time after the settlement of the colony, cultivated almost exclusively by the Indians; they macerated its seed in the juice of lemons, in which the gum of the manna tree had been dissolved, aud thus obtained the celebrated Indian pigment, or crimson paint, with which they adorn their bodies. The roucou is now cultivated by the Dutch and English planters, as a dyeing stuff. Cotton thrives best, and is principally cultivated on the coast estates. The sugar plantations are deemed the most valuable.

Negroes, and Indians.

Agriculture, and all other labour in Berbice, is almost wholly performed by negroes. On an estate, which, on an average, produces annually 140,000 cwt. of coffee, and 10,000 cwt. of cocoa, there are generally 200 slaves employed, calculated at the value of from L. 50 to L. 100 each. The Indians who inhabit this part of the South American coast, consist of four tribes; from these, particularly, the tribe of the Arrowaucs, the inhabitants derive some assistance, as a few of them reside on almost every plantation, and are employed in various services, particularly in hunting and fishing. They have no animals domesticated, nor any grain or roots, except the cassada, brought into cultivation; a small species of deer, which something resembles the hare, and the armadillo, are their favourite food. They scald off the fur of the deer, cut the body in pieces, and stew it in cassada juice, seasoning it very highly with capsicum. The weapons they employ are the common bow and arrow, and the poisoned arrow, which they blow from a tube. Their accuracy and skill in using both these is surprising. With the common arrow, which is formed of a reed nearly six feet long, they can hit a chicken with tolerable certainty at nearly 100 yards distance. The poisoned arrow they can shoot from a tube of about seven feet in length, to the distance of eight or ten yards, with great accuracy; and, at 12 or 14 feet distance, they seldom fail in striking the edge of a penknife stuck on the back of a chair. The plants from which this poison is extracted are not known.

Population.

Mr Bolingbroke states, that the negro population of Berbice was doubled within ten years after it came into possession of the English; and that, in 1805, it amounted to about 40,000, besides 1000 free people of colour, and 2500 whites. From the papers, relative to the British West Indies, ordered by the House of Commons to be printed in 1815, it appears that, in October 1811, the population of Berbice must have decreased very considerably, if Mr Bolingbroke's estimate be correct; since, at that time, it consisted of

Whites - - - - -	550
Coloured - - - -	240
Blacks - - - -	25,169
Total	25,959

Taxes.

A capitation-tax on the white and black inhabitants, an excise on every fifty pounds of sugar made, a weighage-toll of about 2 *per cent.* on all imports and exports, and a tonnage-duty of three florins *per* last on the burden of ships, are the principal sources of the revenue of the colony. In October 1811, there was only one private dwelling hired as a church for the use of the Dutch. The salary of the curate was 7000 stivers, that of the clerk and sexton 500 each, and that of the churchwarden 375. These sums were raised by a tax of one stiver *per* acre, with the exception of the Coromantine coast of the colony, which, in the return to Parliament, is represented as consisting of 80 estates, at 500 acres each.

Exports and Imports.

The imports and exports were,—

	Imports.	Exports.
1809,	L. 193,663	L. 49,662
1810,	191,566	51,785

In the years ending the 5th of January, there were imported into Great Britain from Berbice, of rum,—

	1810.	1811.	1812.	1813.
Gallons,	20,355	6193½	1866	23,139

And, in the year ending 5th January 1813, there was imported of sugar 9084 cwts. In 1809, the exportation of cocoa from the colony amounted to 17,665 cwts. and, in 1810, to 22,582 cwts. In the former year, the exportation of cotton was 1,874,195 lbs.; and, in the latter year, 1,656,057 lbs.

History.

The colony of Berbice was founded in the year 1626, by a merchant of Flushing, to whose family, in 1678, it was granted as an hereditary fief. Three-fourths of it, however, were, not long afterwards, given to Van Hoorn and Company, in consequence of their discharging a heavy contribution levied on the colony by some French privateers. The new proprietors being allowed by the Dutch East India Company to import a certain number of negroes annually from Africa, and obtaining other privileges,

Berbice ‖ Berkshire.

greatly extended the cultivation of sugar, cocoa, and indigo; but they were restricted from exporting the produce of their plantations to any port not within the province of Holland. In 1763, an insurrection happened among the slaves of Berbice, which was quelled chiefly by the assistance of the Indians, and the English from Barbadoes. In 1796, the colony capitulated to the British; but it was restored to the Dutch by the peace of Amiens. In 1803 it was again reduced, and its possession was confirmed to Britain by the peace of Paris. In consequence of the Lords of the Treasury learning that the loss of slaves on the Crown estates from the year 1803 to 1810, had been at the rate of 26 *per cent.* they appointed, in 1811, commissioners for the management of these estates, who were especially directed and empowered to maintain and protect the negroes, and to reward and encourage industry among them.

By an act of the British Parliament, passed in the 56th of George III. (1816), cap. 91, Berbice is placed on the same footing in relation to the regulations of trade, as the British West India Islands. The subjects of the King of the Netherlands, who are proprietors in Berbice, may import into it from the Netherlands the usual articles of supply for their estates, but not for trade;—wine imported for the use of their estates, to pay a duty of 10s. *per* ton. The Dutch proprietors may export their produce, but not to Britain; both exports and imports to be in ships belonging to the Netherlands,—the duties to be the same as those payable by British proprietors.

See Pinckard's *Notes on the West Indies*, 2d edition, Vols. I. and II.—Bancroft's *Essay on the Natural History of Guiana*.—Bolingbroke's *Voyage to Demerary*.—Tuckey's *Maritime Geography*, Vol. IV. —Baron Sack's *Account of Surinam*. (c.)

BERKSHIRE. As the article on this county, in the original work, is inaccurate and imperfect, nearly in the same respects as we have remarked the account of BEDFORDSHIRE to be, we shall follow the same plan here, as we did in the supplementary article on that county.

Extent and Boundaries.

This county extends from 51.19 to 51.48 north latitude, and from 0.34.30 to 1.43 west longitude. In shape it is very irregular, the whole northern side being figured by the windings of the Thames, which, taking a southern course from Oxford, almost cuts this county asunder at Reading, and renders its whole western part much broader than its eastern. A part of Wiltshire, detached at a considerable distance from the rest of that county, lies in the neighbourhood of Woking and Reading, surrounded by Berkshire; and two Berkshire parishes lie on the north side of the Thames, surrounded by Oxfordshire. It is bounded on the north by Buckinghamshire and Oxfordshire, from which it is separated by the Thames; on the east by Surrey; on the south by Hampshire; and on the west by Wiltshire. At the north-west corner, it just touches upon Gloucestershire. Its greatest length, from Old Windsor to the county cross, near Hungerford, is 42 miles. Its greatest breadth from Witham, near Oxford, to the borders of Hampshire, south of Newbury, 28½ miles; and its narrowest, from the Thames by Reading, to the borders of Hampshire, in a direct south line, only 7 miles. It is 207 miles in circumference. The area assigned to it in the original work is much too large. According to the agricultural report, the number of acres in it is only 438,977. According to the returns respecting the poor-rates, 476,170; and, according to Dr Beeke, 469,500.

Strata.

The chalk stratum crosses quite through the whole of this county, but it is only in the western part of it that it is so elevated as to possess the name and character of Downs, and to be chiefly used as a sheep-walk. The Thames, entering the chalk-hills at Streatley, crosses them obliquely from thence onwards, leaving their more elevated part on the north of the river in Oxfordshire and Buckinghamshire, so that the eastern part of that stratum in Berkshire, is sufficiently covered with soil to be used in tillage-husbandry. To the south of the elevated part of the chalk ridge is a vale, which, beginning about the middle of Wiltshire, continues almost in a straight line from thence to the Eastern Sea, having in it the Channel of the Kennet, from Hungerford almost to Reading, and that of the Thames from Bray in Berkshire to the sea. Besides the great chalk stratum of the kingdom, which crosses Berkshire, there is a line of moderately elevated hills, which extend from Oxford to Farringdon. The substratum of this line is, for the most part, calcareous stone, of various degrees of hardness; being part of the same stratum, which, with a few interruptions, crosses the kingdom in a north-eastern direction, from the west of Dorsetshire, nearly parallel to the great line of chalk, and a few miles distant from it. Gently descending from this elevated line of country, is the vale of Berkshire, which crosses the country from the parish of Shirenham on the west, to Cholsey on the eastern boundary. Next to this vale on the south are the chalk-hills already mentioned.

Natural Divisions.

The natural divisions of the county, which are as follows, are strongly marked, as might appear from our account of its surface: 1. The vale, as it is emphatically termed, or the vale of Berkshire, or the White-horse Vale, which, crossing the country from Shirenham to Cholsey, is bounded on one side by the Thames, and on the other by the White-horse hills, a continuation of the Chiltren range. 2. The Chalky-hills, which run nearly through the centre of the lower part of the county. 3. The vale of Kennet; and, 4. The forest, which nearly occupies the whole of the eastern part, commencing on the east of the Loddon, and extending the breadth of the county to Windsor.

Soils.

The prevalent soils in this county are light and calcareous: the soil of the vale of Berkshire is a gray calcareous loam, probably of more tenacity than any other soil in the county; it is evidently formed by vegetable earth and chalk; of course easily cultivated at all seasons, and very productive. On the sides of the vale of Kennet is, for the most part, a reddish earth, more or less mingled with chalk and flints; in the vale itself, the prevailing soil is gravel, but with some very fertile corn-land, or deep loam, easily cultivated. The whole course of the river Kennet is through a bed of peat, from Hungerford to Reading. The mode and cause of the formation of this peat are very evident. In the town

Berkshire. of Reading, the Kennet passes between two hills; and it would appear, that formerly the channel between them could not have been sufficiently low to carry the waters off, and prevent them from forming a morass in its whole extent, for about 25 miles above this obstruction. To the south of this river, near Hungerford, a tract of poor gravel and clay commences; at first, for several miles it is very narrow; but in the eastern part of the county it becomes very wide. It is everywhere ferruginous, and in most places very barren. The southern boundary of the county everywhere passes through this line of coarse land. In the forest division there is gravel, clay, and loam; the last in the centre, and the two former in the southern parts; the substratum of nearly the whole of Berkshire is calcareous.

Climate. The climate of this county is mild and dry, except on the elevated line of chalk, where it is rather cold and piercing. We are not aware of any meteorological observations that have been made in the county.

Rivers. The principal rivers are the Thames, the Kennet, the Loddon, the Ock, the Lambourn, and the Auborn. The Thames enters this county about a mile south from Lecklade, and forms its boundary during a course of more than 100 miles; in its progress watering the towns of Abingdon, Wallingford, Reading, Maidenhead, and Windsor, besides several villages; it is navigable as high as St John's Bridge, near Lecklade. In its course through Berkshire, it produces pike, trout, and various other common fish, besides carp and tench, which are supposed to be brought thither by floods. The Kennet, having divided this county from Wiltshire for about two miles, enters it at Hungerford. At Newbury, where it is joined by the Lambourn, it becomes navigable, and flowing thence through rich meadows to Reading, it there unites with the Thames. Its course through Berkshire is nearly thirty miles. The trout of this river have long been celebrated for their size and flavour; it produces also pike, perch, eels, cray-fish, chub, roach, and dace. The river Loddon, which rises near Aldershot in Hampshire, becomes a boundary between that county and Berkshire at Blackwater. After continuing so for eight miles, it enters Berkshire at Swallowfield, and falls into the Thames near Wargrave; its course in the county being about twelve miles. The Ock, which rises near Uffington, falls into the Thames at Abingdon; its pike are remarkably fine. The Auborn rises in Berkshire, but afterwards becomes a boundary between it and Hampshire; beyond Hede-end, it again enters the county, and falls into the Kennet a little below Wasing; its whole course is about seventeen miles. The Lambourn rises among the hills in the vicinity of the town of the same name, and, as has been already mentioned, falls into the Kennet near Newbury.

Canals. The Wiltshire and Berkshire canal commences on the banks of the Isis near Abingdon, and, passing through Wantage, Chippenham, and Mielksham, joins the canal from the Kennet to the Avon, at Trowbridge. From this canal, collateral cuts are made to Wantage, Calne, and Chippenham. The Kennet and Avon canal begins a little above Newbury, and runs parallel with the Kennet to Kintbury, where it crosses the river twice. It afterwards crosses it in three other places during its course to the head of the river. From Crofton to Barbage it goes through a tunnel 2$\frac{2}{5}$ miles long. After crossing the Avon thrice, it proceeds by the side of it till the junction with it is completed. The entire length, from Newbury to Bath, is 60 miles; with 176 feet rise, and 369 feet fall.

Botany. This county does not produce many rare plants; among those which occur the least frequently are *Myrica gale*, sweet willow, Dutch myrtle; *Monotropa hypopithys*, bird's-nest; *Asarum Europæum*, asarabacca, found by Dr Abbot in the beech-wood between Henley and Maidenhead; *Antirrhinum monspessulanum*, growing abundantly on the chalky banks of Henley hill; and *Lycopodium selago*, and *L. inundatum*, fir club-moss, and marsh club-moss, in a bog on Upton Common. The probable origin of the peat found in the Vale of Kennet has already been noticed in our account of that river. It is found on both sides of the Kennet for several miles above and below the town of Newbury. The stratum lies at various depths below the surface of the ground, and varies in thickness from 1 to 8 or 10 feet; gravel is usually found underneath it. Horns, heads, and bones of various animals, have been found in it. According to the analysis of Sir H. Davy, it consists of

Newbury Peat.

Oxyde of iron - - - -	48
Gypsum - - -	32
Muriat of sulphur and potash -	20
	100

The mineralogy of Berkshire presents very little that is interesting. Oyster-shells are found in the sand strata near Reading; and in one place in the vicinity of that town, a stratum of fuller's earth.

Landed Property. Landed property is very much divided in this county; the largest estate not exceeding L.10,000 *per annum*; and very few amounting to L.5000. Property is least divided in the lower part of Berkshire. By far the greatest portion of the land is freehold. Leases on lives, and leases renewable every seven years, are not unfrequent. A few estates are held by leases of 1000 years. The farms are very various in respect to size; but in general they are small. According to Dr Beeke, on the supposition that there are 469,500 acres in the county, they are distributed in the following manner:—

Arable land, about - -	255,000
Meadows and dairy land -	72,000
Sheep walks - - - -	25,000
Other dry pastures, parks, &c.	30,000
Wastes, chiefly barren heaths	30,000
Woods, copses, &c. -	30,000
Space occupied by buildings, fences, wood, rivers, &c. -	27,500
	469,500

roduce of able land. From this statement it will be seen, that a large proportion of the land in Berkshire is under the plough. Wheat and barley are very extensively cultivated, and are produced of the very best quality. The flour which comes to the London market from Reading and its vicinity is deemed little if at all inferior to that which is produced from the wheats of Essex and Kent; between 20,000 and 30,000 sacks are sent annually to the metropolis. The malt of Berkshire, particularly that made at Reading, Newbury, and Wallingford, is equally celebrated for its goodness; it is principally sent to London and Bristol. At Wallingford alone, upwards of 120,000 bushels are made annually. On the grass lands in the vale of White-horse, are many good dairy farms, on some of which peculiarly rich cheeses are made.

heep. The Berkshire breed of sheep are very similar in size, form, and qualities, to the breed of Dorsetshire and Wiltshire. Besides this native breed, there are kept on the sheep farms the Wiltshire, Dorset, South Down, and a few of the Bagshot-heath breed. The whole produce of wool in this county is estimated at 4150 packs. ogs. The swine of Berkshire have long been noted for the smallness of their bone and their disposition to fatten quickly. They are now common in most parts of the kingdom, and are generally preferred at the distilleries, being good either for pork or bacon.

griculture. The agriculture of this county presents nothing else peculiar or deserving of notice, except the Newbury peat, which, when burnt, affords an excellent manure, and is very extensively used as such, not only in this but in the neighbouring counties.

oodland. The south and east sides of Berkshire have a large proportion of woodland; the most common kind of wood is hazel, occasionally mixed with oak, beech, ash, and alder. The chief quantity of timber is at the eastern extremity of the county, in and about Windsor forest, in the Vale of Kennet, and by the banks of the Thames. indsor orest. Windsor forest was formerly of much greater extent than it is at present. According to Norden's map of it, taken in the year 1607, its circuit was 77½ miles, exclusively of that part of it which extended into Buckinghamshire. The present circuit of it, according to Rocque's map, is about 56 miles; but it will probably be soon much lessened, in consequence of the act of Parliament lately passed, by which commissioners are appointed to dispose of parts of it to the proprietors of neighbouring lands. Windsor great and little parks are in the forest. The former is embellished with some rich forest scenery. In it his Majesty had two large farms, one of which was conducted on the Norfolk, and the other on the Flemish system of husbandry. On the south-east side of Windsor little park was formerly a venerable tree, immortalized by Shakespeare, and since known by the appellation of Herne's Oak.

anufactures. Berkshire was formerly one of the principal seats of the clothing-manufacture, which flourished particularly in the towns of Abingdon, Newbury, and Reading. In the middle of the seventeenth century, this manufacture was carried on to a considerable extent; but it declined soon afterwards, and for several years has been wholly discontinued. In the vicinity of Newbury there is a large paper-mill; and in the town itself, a small manufactory of serge. There is another paper-mill at Bagnor; a manufacture of sacking at Abingdon, and a few other trifling manufactures in other parts of the county. The only one, however, which deserves particular notice, is the copper manufacture at the Temple Mills, in the parish of Bisham. In the early part of the last century, when they were employed for making brass and copper pans and kettles, they were known by the name of Bisham Abbey Battery Works. The manufactures now carried on at these mills are confined to the rolling of copper sheets, for various purposes; the rolling of copper bolts, for the navy and merchant service, and the hammering out copper pans and bottoms for distilleries. During full employment, from 600 to 1000 tons of copper are manufactured here. These mills are said to be the most powerful and complete in the kingdom.

Markets. There are many very great markets in Berkshire; Abingdon, Reading, Newbury, Wallingford, and Windsor, have great corn-markets. Ilsley is celebrated for its sheep-market, which is supposed to be the largest county market in England; it commences on the Wednesday in the Easter week, and continues to be held every alternate Wednesday till Midsummer; 20,000 sheep have been sometimes sold in one day; the annual average is upwards of 250,000, comprising lambs. Oakingham market is remarkable for its abundant supply of poultry, which is principally bought for the supply of the metropolis. At Farringdon is the principal market for bacon and hams; 4000 swine are said to be slaughtered annually here, between November and April, for the supply of London and Oxford.

Architecture. Berkshire affords many specimens of Saxon architecture, the most remarkable of which are Avington Church, and the Nave of Windsor Church; the churches of Uffington, Englefield, and Farringdon, and the Chapel at Little Farringdon, exhibit some striking specimens of the early Gothic. One of the most complete and splendid specimens of the later style of Gothic architecture, is St George's Chapel at Windsor.

Poor-rates. In the year 1776, the poor-rates of this county amounted to the sum of L. 39,933, 9s. 3d.; in the year 1783, they had increased to L. 49,866, 10s. 8d.; and in the year 1803, to L. 96,860, 19s. 10½d.: in this year the rate was at 4s. 11d. in the pound. Of the sum thus collected, L. 82,604 was expended in the maintenance of the poor; there were relieved, in and out of workhouses, 22,588 poor people, at the rate of L. 3, 12s. 10d. annually, for each person relieved. The number relieved in the workhouses was 1169, at the rate of L. 12, 6s. 5¼d. *per* head; the number relieved at their own houses was 21,419, at the rate of L. 3, 2s. 10¼d. *per* head. The total money raised by rates was 17s. 9d. *per* head, on the population at that time. Twenty-one persons in a hundred were relieved. There were 47 *Friendly Societies*, containing 2843 members; and there were 305 children in the Schools of Industry. By the last return to Parliament, 192 parishes in Berkshire

(31 not having made any return) paid, in the year ending the 21st of March 1815, L. 125,710, 0s. 4½d. for poor's-rates, and other parochial rates.

Population.

The population of this county, at the time of the Norman survey, amounted to between 40,000 and 50,000. In the year 1700, it was estimated at 75,000. The number of inhabited houses, in 1800, was 20,573, of uninhabited houses 622, and of inhabitants 109,215. Of these 52,821 were males, and 56,394 females; 38,155 were chiefly employed in agriculture, and 16,921 in trades, manufactures, or handicraft. In 1811, the number of inhabited houses was 22,104; of families inhabiting them, 24,051; houses building, 129; uninhabited, 563; families employed in agriculture 13,409, on land, the annual rent of which was L. 407,186; families employed in manufactures and trade 7584, the amount of their annual profits being L. 272,582; families not included under these two heads 4058; males 57,360 and females 60,917. Total population 118,277. The number of people to a square mile was 744; the annual proportions of baptisms were one to 34 persons; of burials, one to 53; and of marriages, one to 144.

Historical Notices.

During the civil war in the seventeenth century, this county was frequently the scene of action between the contending parties. In September 1643, the first battle of Newbury was fought, in which the celebrated Lord Falkland lost his life. In October 1644, a second battle was fought near Newbury; in each of them, both parties claimed the victory.—See Mavor's *Agricultural Report of Berkshire; Beauties of England and Wales*, Vol. I.; Lyson's *Magna Britannia;* Smith's *Map of the Strata of England, and Memoir.* (C.)

BERTHOUD (Ferdinand), Chronometer-maker to the French Admiralty, member of the Institute of France, and of the Legion of Honour, was born in the county of Neufchatel in 1727. His father's profession was that of architect, and the son was intended to be bred to the church, but, having shown a taste for clock-work, an experienced workman in that art was got to instruct him in its principles, and young Berthoud was afterwards sent to Paris to improve in the knowledge and practice of the art he had thus commenced. He settled in Paris in 1745, and applied himself to the making of chronometers, an art which was then in its infancy. A chronometer is an accurately made watch, whose chief peculiarity consists in a piece of mechanism intended to render the number of vibrations of the balance equal in equal times, at all the degrees of temperature to which the instrument is exposed; and the chronometer being a portable instrument, which can be used on ship-board, is by this mechanism made to move at a constant rate;—say at the rate of mean solar time, so that it shows what hour it is at the meridian of Greenwich, if the chronometer, at the commencement of the voyage, was set to Greenwich time, whilst the observation of the height of the sun or of a star gives the hour, angle, and the hour at the place where the ship is: the difference between these two times is the longitude of the ship. Fleurieu and Borda, by order of the French Government, made a voyage from La Rochelle to the West Indies and Newfoundland, for the purpose of trying the chronometers of Ferdinand Berthoud, and found that they gave the longitude with only a quarter of a degree of longitude of error, after a cruize of six weeks. Satisfactory results were also obtained from his chronometers in the expedition of Verdun, Borda, and Pingré, which was appointed to try them, together with those of Le Roy. An account of this expedition is published.

Sully, an English watch-maker established in Paris, was the first who, in that city, attempted the construction of chronometers for finding the longitude; this he did in 1724. In 1736, the chronometers of the English artist, Harrison, were tried at sea. In France there were no chronometer-makers of note, from the first attempts of Sully, till Pierre le Roy and Ferdinand Berthoud, between whom there was some discussion about the priority of their discoveries and improvements. Ferdinand Berthoud's chronometers were long the most esteemed of any in France. Louis Berthoud, the nephew and successor of Ferdinand, has improved upon the machines of his uncle, and has made them generally of a smaller size, so as to become more portable. And many farther improvements have been made by the English chronometer-makers.

Ferdinand Berthoud was regular in his habits of life; he retained the use of his faculties to the last; and died, of hydrythorax, at his country-house, in the Valley of Montmorency, in 1807, having attained the age of 80. The principal published works of Ferdinand Berthoud are, *Essai sur l'Horlogerie*, 1786, 2 vols. in 4to; two *Tracts on Chronometers*, 1773; *De la Mesure du Temps*, 1787, in 4to; *Les Longitudes par la Mesure du Temps*, 1775, in 4to; a *Tract on Chronometers*, 1782, in 4to; *Histoire de la Mesure du Temps par les Horloges*, 1802, 2 vols. in 4to; *l'Art de conduire et de régler les Pendules, et les Montres*, 1760, in 12mo. In this tract directions are given for regulating clocks and watches suited to general readers; it has gone through several editions. (Y.)

BERWICKSHIRE, a county in the south-east of Scotland, bounded by East-Lothian on the north, the German Ocean on the east, Mid-Lothian on the north-west, Roxburghshire on the west and south-west, and by the Tweed, which separates it at first from Roxburghshire, and afterwards from England, and by the township of Berwick on the south and south-east; is situated in the 56th degree of north latitude, its central parts two degrees west from London; and contains 446 square miles or 285,440 acres, of which more than a third is cultivated, or fit for cultivation. Situation. Extent.

It has usually been described as consisting of three great divisions, Lammermoor, Lauderdale, and the Merse, of which the boundaries are by no means accurately defined (see article in the body of the work); but for every useful purpose, Lauderdale may be held as included in the other two divisions, and the greater part of it as belonging to Lammermoor. This mountainous district, on which Berwickshire meets with East-Lothian, commences at St Abb's Head on the north-east of the county, and passes into Mid-Lothian on the north-west. That Divisions. Lammermoor.

Berwickshire.

part of it which belongs to Berwickshire is in many places from 1000 to 1500 feet above the level of the sea; but as it sinks towards the low grounds of the Merse, for the most part by an easy declivity, and is intersected by several small valleys through which its streams flow, it contains a considerable extent of good pasturage, with many smaller tracts of arable land. This whole range, however, and particularly the higher parts, covered with heath and the coarsest grasses, is, generally speaking, very barren; and both the climate and the soil are unpropitious to vegetation in a greater degree than its elevation alone would lead one to expect. The gradual rise of the mountains and their continuity afford little natural shelter; and it is only in particular spots, themselves somewhat sheltered, that trees can be made to grow to any height. The winters, therefore, are more severe and protracted, cultivated crops more precarious, and the pastures much less rich and verdant, than at the same altitude on the hills around Cheviot, on the opposite side of the Tweed; which springing suddenly and separately from their bases in a conical form, protect one another in every direction. This extensive district is accordingly chiefly occupied with the hardy coarse woolled mountain sheep, and yields but a small revenue to its proprietors, and to its thinly scattered husbandmen.

The Merse.

The *Merse*, the other great division, comprises all the low lands of the county. From the Tweed the country rises gradually towards Lammermoor; and the sea coast on the east is also high, bold, and precipitous, being accessible only at Eyemouth, Coldingham and a few other places. The general appearance, therefore, of this district, when viewed from some commanding eminence, is that of an unbroken plane, slightly inclined towards the south, surrounded on all other sides by high grounds; but on which, when seen nearer, there is perceived a considerable diversity of surface;—hills rising from gently undulating swells, of which that on which Home Castle stands is among the most conspicuous, and winding vales, along which the Whitadder, Blackadder, Leader, and a number of smaller streams, urge their course to the Tweed. The whole of this tract, computed at about 170 square miles, well cultivated, and generally fertile, inclosed and subdivided by white-thorn hedges, sheltered by thriving plantations, and adorned by many seats and pleasure-grounds, and still more, everywhere, by excellent farm-houses, presents a scene of peaceful industry and of rural prosperity, which is not perhaps exceeded on so large a scale in any part of Britain;—forming a striking contrast to the habits of plunder, and the general wretchedness by which, till the union of the British crowns, the inhabitants of this, as of all the border districts, had never ceased to be distinguished.

Waters.

The rivulets already noticed, with the Eye and a few others, are all too inconsiderable to merit any particular description; and the Tweed, by which the county is for the most part bounded on the south, rising in another district, and discharging itself into the sea three miles beyond its limits, can hardly be said to belong to Berwickshire.

Fisheries.

The salmon-fishery on this river, a source of employment to a great number of people in its different stages, is shared with the inhabitants of the opposite bank as far as it forms the boundary; but nearer the mouth of the river the fishery is by far the most productive. The fish are sent to Berwick, where they are pickled, dried, or, more generally of late, packed in ice and shipped for the London market. The fishery on the coast employs about a hundred men with twenty boats, at eight small fishing stations. Herrings visit this coast occasionally.

Minerals.

No seams of coal worth working have been found in this county; and this necessary article is procured partly by sea, but chiefly by a most expensive land carriage from the south side of the Tweed, and from the Lothians. A few veins of limestone, which have been discovered in the inland parts, cannot be worked with advantage owing to the want of coal; and the immense quantity of lime required by its spirited system of agriculture, must also be brought from a distance, and from almost the same quarters. Clay-marl, found along the banks of the Whitadder and Blackadder, was once extensively employed as a manure, but has for many years been superseded by lime. Shell-marl, discovered in small quantities in many places, is worked to some extent in the western parish of Merton. Sandstone of different colours, some of it of a very fine grain, occurs in different parts, particularly at Dryburgh, on the Tweed; from whence, it is probable, stones had been procured for the beautiful structure of Melrose Abbey. The outer pier of the harbour of Eyemouth is built without cement, of a coarse pudding-stone, found in a rocky promontory contiguous; and has withstood, for almost 40 years, the fury of the German Ocean, without any apparent waste.—A mineral spring in the parish of Edrom, about a mile from the town of Dunse, and known by the name of the Dunse Spa, was at one time in much repute, but has been almost entirely neglected for many years.

Agriculture.

In a general view of Berwickshire, its agriculture is by far the most prominent object. At a distance from a crowded population—without coal and lime—having a rocky coast, which confines its exports and imports to one or two places, 10 or 12 miles from the centre of the county,—and enjoying no peculiar advantages in soil or climate,—there are certainly few districts, at all accessible to cultivation, less favourably situated. Yet almost the whole of the Merse is cultivated in the best style of modern husbandry, and there are few, if any, districts of the same extent in Britain, where the most approved management of arable land is so skilfully and successfully combined with that of live stock and pasturage. The leading feature in the husbandry of the south-east of Scotland is, the alternation of corn with pulse, herbage, or roots; or what is commonly called, white and green crops; but the farmers of Berwickshire, adopting this course invariably, have rendered it more productive, and better suited to their soil and climate, by reserving their cultivated herbage, red and white clovers, with ryegrass, from the plough, for two or more years, so that above half the cultivated land is always depastured by sheep and cattle. The sheep in the lower parts of the county are almost universally of the New Leicester

Berwickshire. variety; and the short-horned breed of cattle, introduced from the north of England, are now spreading fast over all its better pastures. Farms are of all sizes, from 40 to 1000 acres and upwards; but the more common size, in the Merse, is from 400 to 600 acres. All the farm-houses, out-buildings, and cottages recently erected, are most substantial, convenient, and well-situated, and contribute greatly to the beauty of the landscape.

Rental. The valued rent of Berwickshire is L.178,366, 8s. $6\frac{7}{24}$d. Scots; and the real rent, as assessed to the property-tax for the year ending April 1811, was, for the lands, L.231,973, 2s. 7d.; and for the houses, L.8,152, 17s. 6d. Sterling. About a third part of the valued rent is held under entail. In 1795, the rental was estimated at L.112,000; so that it had more than doubled in sixteen years. It is universally paid in money; and the farms are held on leases for a term of years; here, as in every other part of Scotland, nineteen years being the most common period.

Manufactures. The manufactures of this county are quite inconsiderable; that of paper, made at two extensive works, being almost the only one that affords an article for exportation. There are bleachfields, breweries, corn-mills, and other small establishments for the home supply; and some of the millers are in the practice of purchasing grain, which they send chiefly to Berwick, and Dalkeith in Mid-Lothian, after converting it into flour, meal, or shelled barley.

Commerce. The commerce of the district is, therefore, necessarily confined to the export of raw produce, and the import of coals, lime, timber, iron, groceries, &c. Yet the value of the corn exported, of which the greater part is carried to Berwick, and of the cattle and sheep driven to Edinburgh, and to Morpeth, and other markets in England, must amount to a very large sum; the stationary live stock alone having been estimated, several years ago, at near half a million of pounds Sterling.

Antiquities. Berwickshire having been the scene of incessant warfare between the Scots and English for many ages, still exhibits traces of military stations and ruins of fortifications, which time and the progress of cultivation is fast obliterating. But the most interesting remains of antiquity are the nunnery of Coldingham and Dryburgh Abbey, proofs, not more, perhaps, of the piety, than of the oppression of our ancestors.

Pease Bridge. The deep glen, called the Pease, in the north-east angle of the county, on the road from Edinburgh to Berwick, has been celebrated in history as one of the natural defences of Scotland. The bridge which has been thrown over it consists of four arches; and its romantic situation, and stupendous height of 123 feet from the small stream below, render it an object of some curiosity to travellers.

Berwickshire is divided into thirty-one parishes. There is no large town in it, and but a few villages of any extent. (See the ENCYCLOPÆDIA.) It is one of the few Scottish counties in which regular assessments are made for the poor.

Poor's Rate. In 1808, the average number in three parishes was one in fifty-five of the inhabitants. The rate, imposed equally upon landowners and tenants, amounted to $3\frac{1}{3}$d. on the pound of rent.

Population. The following tables exhibit a summary of the population returns for 1800 and 1811:

1800.

HOUSES.			PERSONS.		OCCUPATIONS.			
Inhabited.	By how many *Families* occupied.	Uninhabited.	Males.	Females.	*Persons* chiefly employed in Agriculture.	*Persons* chiefly employed in Trade, Manufactures, or Handicraft.	All other *Persons* not comprised in the two preceding classes.	Total of Persons.
5965	6835	273	14,094	16,327	6396	3343	19,767	30,621

1811.*

HOUSES.			PERSONS.		OCCUPATIONS.			
Inhabited.	By how many *Families* occupied.	Uninhabited.	Males.	Females.	*Families* chiefly employed in Agriculture.	*Families* chiefly employed in Trade, Manufactures, or Handicraft.	All other *Families* not comprised in the two preceding classes.	Total of Persons.
5730	6867	308	14,466	16,313	3124	2013	1730	30,779

* The population of the parish of Stitchell, which lies partly in the shire of Roxburgh, is not included in this abstract of the returns for 1811.

(A.)

Betel.

BETEL, a substance compounded of different ingredients, which is chewed in the east in the same way as tobacco is used in other parts of the world, but to much greater extent. All individuals, without exception of age or sex, begin at an early age to accustom themselves to betel, and it gradually becomes an article of such necessity, that those acquainted with the usages of the eastern nations affirm, they would more readily dispense with their ordinary quantity of food than with it. Europeans also, who have resided long in Ceylon or India, contract the same habit, and enjoy chewing of betel equally with the natives. Betel, or *pawn*, as it is denominated in Bengal, consists of part of the fruit of the *areca* palm, wrapped in the leaves of a kind of pepper plant called *betel*, smeared with a little shell lime; and its name betel-nut is thence derived. The areca palm is a tree growing 40 or 50 feet high, with a straight round stem six or eight inches in diameter, covered with a smooth ash-coloured bark, marked with parallel rings. All the leaves, which are only six or seven in number, spring from the top; they are six feet long, declining downwards from a stalk of considerable length. The fruit or nut is covered with a green shell or skin, thin, brittle, and of the consistence of paper; it is of an oval shape, the size of a small egg, and resembles a nutmeg despoiled of its husk. When ripe, it appears in clusters of a reddish colour, forming a beautiful contrast with the vivid green of its leaves, and then falls off to sow itself in the ground. The betel plant is a species of vine, bearing a leaf, somewhat resembling ivy; it is called *Piper betel* by botanists, and is of the same genus as the *Piper nigrum* of Linnæus. Its culture, which is carefully attended to, is managed in the same manner. Poles are planted in the earth, around which the betel twines itself, and as it runs up, the poles acquire greater height also. It is a creeping plant, seeking support from stronger vegetables, but it is said not to be destructive of them, like some other plants of a similar nature. Particular regard is paid to the cultivation of areca and betel throughout the countries of which they are natives, as we shall afterwards explain. Some years ago, it was found, on enumeration, that the number of trees, probably meaning the areca only, in Prince of Wales's Island, amounted to 342,110. The lime used with the nut is called *chunam*, and is obtained from the calcination of shells, as producing the finest kind. But the fresh nut must be avoided; it then contains a white viscous matter, insipid to the taste, and occasioning delirium, like ebriety from wine, but losing this property when dried; and it is employed either boiled or raw. The latter has undergone no change; the former is cut in slices, boiled with a small quantity of *terra japonica*, and then dried. Betel is compounded, therefore, of these three substances, with some additions or variations, according to the customs of the place where consumed; such as cardamoms, and coarse pounded tobacco, by persons of more depraved taste. The union of the three ingredients is supposed to correct the effects which each would produce singly; the nut improves the bitterness of the leaf, and the lime prevents any injury to the stomach. When combined, the first consequences are reddening the saliva, giving a bright hue to the lips; and, in progress of time, the teeth are rendered quite black. The saliva, however, will not be tinged, if the chunam be omitted; and its pernicious operation on the enamel of the teeth may be averted, by rubbing them with a preparation whereby they are coated with a black substance that does not readily yield to any dentrifice, and preserves them from corrosion. Its medicinal effects are the dispelling of nausea, exciting an appetite, and strengthening the stomach. It possesses nutritious and enlivening qualities, which render it particularly acceptable to its consumers. The *terra japonica*, above alluded to, is not a universal ingredient; it is used only in certain countries, and is generally supposed to be a preparation from the areca-nut itself. It consists of two varieties, the one very astringent; the other less so, and rather sweet, which is preferred by the betel-eaters. To obtain the former, the nuts are taken from the tree, and boiled some hours in an iron vessel; they are then removed, and the water remaining is inspissated by continual boiling. The nuts being dried, undergo a second boiling, and, having been taken out, the water is also inspissated, whereby the best *terra japonica* is obtained. The nuts are then dried, cut in equal halves, and sold. Or it is obtained by inspissated decoctions of the wood of the keira tree, or *Mimosa catechu*. A great quantity of this substance is made in the Mysore, and some of inferior quality in Bengal. Probably it is something of this same kind that is prepared in Sumatra, under the name of *catacamber*, and chewed along with betel to give it an additional flavour.

Its universal consumption in the East. From what produced. Betel. Its Medicinal Effects.

Betel is not only used as an article of luxury, but as a kind of ceremonial which regulates the intercourse of the more polished classes of the east. When any person of consideration waits on another, after the first salutations, betel is presented as a token of politeness: to omit it, on the one part, would be considered neglect, and its rejection would be judged an affront on the other. No one of inferior rank should address a dignified individual without the previous precaution of chewing betel; two people seldom meet without exchanging it; and it is always offered on the ceremonious interviews of public missionaries. In some countries, it is not uncommon for the guest, who receives the betel from his host, to pass it between his thumb and fore-finger, and apply his own chunam, which never gives offence; and is thought to have originated in guarding a stranger against the insidious conveyance of poison, formerly too frequently practised in destroying persons who were obnoxious. Philtres or amatory charms are still conveyed along with the chunam, which are conceived to consist of some powerful stimulant. Mahometans abstain from this indulgence during the fast of Ramadan, though possibly not in every country, as it would be too great a privation; and the use of it is so interwoven with the existence of the natives of the warmer climates, that females of the higher ranks are said to pass their lives in doing little else than chewing betel. When the Cingalese retire to rest at night, they fill their mouths with it, and retain it there until they awake. According to

Ceremonial use of it.

Betel.

Knox, who passed many years in captivity on the island of Ceylon, most people going abroad carry a small box of gold or silver, containing the ingredients for compounding betel; and the poor keep a constant supply about them in purses of coloured straw, securely lodged in a fold of their garments. The stand or box containing it is often the subject of elegant workmanship; it consists of silver, gold, or tortoiseshell, and forms a piece of ornamental furniture in the houses of the wealthy. It is sufficiently valuable to constitute a present between sovereigns.

Culture.

Extensive gardens for cultivating betel are formed in different parts of India. The soil most favourable for the palm is a black mould on a substratum of limestone, or intermixed with calcareous nodules. Here it is planted in rows, and carefully manured and watered, during several years. It begins to bear from the eighth or tenth to the fifteenth year, and remains in perfection for thirty years; soon after which, it either dies or is cut down. Some, however, continue producing fruit from the fiftieth to the seventieth, or even the hundredth year; but it gradually declines both in quantity and quality. It appears that a very fertile tree produces, at an average, 857 nuts, and an ordinary one 600; but not everywhere, as there are trees affording no more than 200. The betel-leaf is either cultivated in separate gardens, where a red stony soil on the side of a rising ground is preferred, and plantains or bamboos planted along with the vines, which are arranged in trenches, to support them as they grow; or when an areca plantation is formed, and the palms are fifteen years old, cuttings of the vine are planted near the roots, and trained up to the trees. In twelve or eighteen months, the leaves of the vine are fit for sale, and in three years they are full-sized; but in another year they die, when all must be removed, and young plants immediately substituted for them. We do not know whether their duration is never longer; but in the southern parts of Canara in India, the gardens require renewal every four years, and in eighteen or twenty the soil is considered to be exhausted. These gardens are always surrounded by a hedge; sometimes the cultivators are annoyed with the depredations of squirrels and elephants. The crop of the areca is produced during three months; and the nut being pulled, is cut into seven or eight pieces, and piled up in a heap; then the same quantity of it and *terra japonica*, together with 100 leaves of betel-leaf, are beat together with water, and the juice strained into a pot. This is mixed with a decoction of the bark of the *Mimosa Indica* and water, and the nuts from the whole heap successively boiled in it. They are then exposed to be dried in the sun.

Commerce.

Betel is a very considerable article of traffic in India and China; and, indeed, throughout Asia. In the British settlements of Bombay, Madras, and Bengal, the value of the imports amounted in a single year to L. 138,836; and, if the quantities consumed throughout the East are taken into view, it will appear surprising how they can be obtained. But, owing to the constant and extensive demand, the plants affording the necessary ingredients are carefully cultivated; and multitudes are employed and subsisted in the production of this Eastern luxury. (s.)

Bettinelli.

BETTINELLI (Xavier), one of the most celebrated Italian literati of the eighteenth century, was born at Mantua, the 18th of July 1718. After studying under the Jesuits in his native city and at Bologna, he entered in 1736 upon the noviciate of this society. He then undertook a new course of study; and afterwards taught the belles-lettres, from the year 1739 to 1744, at Brescia, where the Cardinal Quirini, Count Mazzuchelli, Count Duranti, and other scholars, formed an illustrious academy. He there began to distinguish himself by some pieces of poetry, composed as scholastic exercises. Being sent to Bologna to pursue his divinity, he continued, at the same time, to cultivate his poetical talent, and wrote also, for the theatre of the college, his tragedy of *Jonathan*. The number of learned and literary persons collected in this city exceeded by far what he had met with at Brescia. The *Institute*, recently founded by the Count Marsigli, the Clementine Academy of Design, the School of the astronomical poet Manfredi, the growing reputation of his ingenious and learned pupils, Zanotti, Algarotti, and others, at this time fixed the attention of the literary world on Bologna. It was in the midst of this society, to which he was admitted, that Bettinelli completed his education, and attained the age of thirty. He went in 1748 to Venice, where he became Professor of rhetoric. He left it for various missions, and returned to it again often. We may see by his epistles in free verse (or *sciolti*), that he was connected on friendly terms with all that this city and state could boast most illustrious. He was destined by the Superiors of his order for the oratorical department; but the weakness of his chest compelled him to relinquish it. The superintendence of the college of nobles at Parma was entrusted to him in 1751; he principally directed the studies of poetry and history, and the entertainments of the theatre. He remained here eight years, but not without visiting, at intervals, different cities of Italy, either on the affairs of his order, or for pleasure, or for health. In 1755, he undertook a longer journey, traversed a part of Germany, proceeded as far as Strasburg and Nancy, and returned by way of Germany into Italy; taking with him two young princes, sons or nephews of the Prince of Hohenloe, who had requested him to take charge of their education. He made the year following another journey into France, along with the eldest of these two young Princes, and lodged, while at Paris, at the College of Louis-le-Grand. It was during this excursion that he wrote the famous *Letters of Virgil*, which were published at Venice with his *sciolti* verses, and those of Frugoni and Algarotti. The opinions, and we may add without much hesitation, the literary heresies, maintained in these letters against the two great luminaries of Italian poetry, and particularly against Dante, created him many enemies, and, what was still more unpleasant to him, embroiled him with Algarotti. Willing to know something more of France than Paris, he made several excur-

Bettinelli. sions into Normandy and other provinces; he went also into Lorraine, to the court of King Stanislaus; from thence he proceeded to Lyons, and from thence to Geneva. Soon after his arrival he went to visit Voltaire. This celebrated writer sent to his inn an edition of his works, upon which he inscribed this stanza, in allusion to Bettinelli's *Letters of Virgil:*

> Compatriote de Virgile,
> Et son secretaire aujourd'hui,
> C'est a vous d'ecrire sous lui;
> Vous avez son ame et son style.*

From Geneva, where he consulted Tronchin the physician, Bettinelli proceeded to Marseilles, from thence to Nismes, and returned by Genoa to Italy and Parma, where he arrived in 1759. The same year, he took a journey to Venice, and afterwards to Verona, where he meant to settle. He resided here till 1767. Having resumed the occupations of preaching and teaching, he, according to the Chevalier Pindemonti, in his *Poesie campestri,* converted the youth to God in the church, and to good taste in his own house. He afterwards lived for some years at Modena, and he had just been appointed professor of rhetoric there, when, in 1773, the order of Jesuits was abolished in Italy.

He then returned into his own country, where he resumed his literary labours with new ardour. He there published several works, and regretting, as it appears, that he had written so much in his life without having been able, till then, to write anything to please the women (perhaps in consequence of the habit which he wore), he determined to make up for lost time, by publishing, one after the other, his *Correspondence between two Ladies*—his *Letters to Lesbia on Epigrams*—his *Letters on the Fine Arts*—and, lastly, his *Twenty-four Letters on Love.* These he published in 1796, when the war raged in all parts of Italy, and when the siege laid by the French to Mantua compelled him to leave it. He retired to Verona, and there formed the most intimate friendship with the Chevalier Hippollito Pindemonti, notwithstanding the disproportion of their age. In 1797, after Mantua had surrendered, he returned there. Though nearly eighty years old, he resumed his labours and his customary manner of life. He began, in 1799, a complete edition of his works, which was finished at Venice, in 24 volumes *duodecimo.* Arrived at the age of ninety years, he still retained the gaiety and vivacity of his mind, and died the 13th of September 1808, after fifteen days of illness, with the firmness of a philosopher, and the sentiments of a believer. Without giving a list of all his works, or specifying the separate editions, it will be sufficient to refer to them in the order in which they are placed in this last edition.

1. *Ragionamenti Filosofici, con Annotazioni.* These philosophical discourses, which occupy the two first volumes, form a system of religious morality, in which the author endeavours to exhibit man under all his relations, and in all states, following the order of the sacred writings, and treating, first, of man as created,—as reasonable,—as lord of the other creatures,—and in all the different states of solitude, society, innocence, error, repentance, &c. He only finished ten of these discourses. The notes are themselves little philosophical treatises,—On Beauty in general,—On Beauty of Expression,—On Physiognomy, &c. Bettinelli.

2. *Dell' Entusiasmo delle Belle Arti,* 2 volumes, in three parts, of which the last is an appendix to the two others, and treats of the history of enthusiasm in different nations, and the influence which climates, governments, and all the modifications of society, have had on enthusiasm. In the two first parts, the author, who was not very subject to enthusiasm, sometimes writes a little obscurely on it, becomes turgid when he endeavours to be sublime, and remains a stranger to the warmth which he affects.

3. *Dialoghi d'Amore,* 2 volumes. The object of the author is to point out the influence which the imagination, vanity, friendship, marriage, honour, the love of glory, the study of the sciences, and fashion, have on the passion of love; and afterwards to trace the influence which it exercises on the productions of the arts of genius, and of the dramatic art in particular. The last dialogue, which is entitled, *On Love and on Petrarch,* is followed by the *Eulogy of Petrarch,* one of the author's best pieces.

4. *Risorgimento negli Studj, nelle Arti e ne' Costumi dopo il Mille,* 3 volumes; a work regarded in Italy as superficial, but which, nevertheless, contains some enlightened sentiments, and in which facts are often presented under a philosophical point of view, which wants neither novelty nor justness.

5. *Delle Lettere e delle Arti Mantouane: Lettere el Arti Modenesi,* 1 volume,—almost entirely filled with anecdotes of literary history, tending to the glory of Mantua, the country of the author.

6. *Lettere dieci di Virgilio agli Arcadi,* 1 vol. These letters, which have been translated into French by M. de Pommereul, Paris, 1778, are, of all the works of Bettinelli, that which has made the most noise. They are followed in this volume by *Letters from an Englishman to a Venetian,* which treat somewhat vaguely on different topics of literature.

7. *Italian Letters from a Lady to her Friend on the Fine Arts,* and *Letters from a Friend, copied from the Originals,* 3 vols. of which the letters on the fine arts occupy only the first.

8. *Poetry,* 3 volumes, containing seven small poems, sixteen epistles in easy verse, sonnets, canzonets, &c. Without ever showing himself a great poet, the author is always elegant and ingenious. These three volumes are preceded by a well-written discourse on Italian poetry. Several of the epistles and smaller poems are seasoned with attic salt. Such is the poem in four cantos entitled, *Le Raccalte,* in which Bettinelli very happily turns into ri-

* "Fellow-countryman of Virgil, and at present his secretary, it is for you to write in his name: you possess his soul and his style."

Bettinelli || Beykaneer.

dicule those insipid collections of verses, which, in his time, appeared on every occasion in Italy.

9. *Tragedies*, 2 vols. These tragedies are *Xerxes*, *Jonathan*, *Demetrius Poliorcetes*, and *Rome Delivered*, a translation from Voltaire. Prefixed to them are some letters written in French, and a discourse in Italian, on the Italian tragedy. Some letters on tragedy, among others one on the tragedies of Alfieri, follow; and the second of these two volumes concludes with an eulogy on Father Granelli, a Jesuit, a preacher, and a poet, author of some tragedies, which are in much esteem, particularly for the elegance and beauty of the style.

10. *Lettre a Lesbia Cidonia sopra gli Epigrammi*, 2 vols. consisting of twenty-five letters, intermixed with epigrams, madrigals, and other light pieces, translated and original.

11. Lastly, an *Essay on Eloquence*, to which are added, some letters, discourses, and other miscellanies. It would be hazardous to pronounce a judgment on so great a diversity of productions, the author of which has so lately ceased to live and write. It should seem, in general, that he is distinguished more for wit and talent than for warmth and genius; that his writings contain literary opinions dictated by a taste not always correct, and which, having been publicly declared early in life, have often reduced the author to the unpleasant dilemma, either of retracting or of persisting, in spite of his better judgment, in what he must have perceived to be the errors of his youth; that his philosophy, of which the morality is pure, wants, when it aspires to metaphysical questions, both determinate principles and just conclusions, and is too often verbose and declamatory; but that, though his ideas are not always entitled to praise, his style is so almost always; that having been to blame, according to the Italian critics, in paying too little respect to the great writers of the fourteenth century, he has the merit of having remained constantly attached to those of the sixteenth, and to the authors who were his contemporaries, and who have taken him for their guide; and also of having defended to the last, both by his opinions and his example, the finest of the modern languages against the corruption which threatens, or rather which overwhelms it on all sides.—See *Biographie Universelle*, Tom. IV. (z.)

BEYKANEER or BICANERE, a principality of Asia, situate in the north-west of Hindostan, the precise dimensions and limits of which are scarcely ascertained by modern geographers. It extends from about 27° 40′ north latitude to 29° 45′, and from 72° 10′ to 75° 15′ east longitude; and its superficial area probably amounts to about 17,000 square miles. It is bounded on the north by a country occupied by the Batties or people of Batneer; on the east by the territories of Hurriana and Shekhawuttee, in the province of Delhi; on the south-east by Jeypour; on the south-west by Jesselmere; and on the west by Bahawulpoor. But these may be deemed obscure limits, for the countries named in them are scarcely better known than the subject of this article.

Description.

A vast proportion of the soil of Beykaneer is a barren sandy desert, or a hard flat clay, sounding like a board under horses' feet, and entirely destitute of inhabitants, water, and vegetation. Many miles are occupied in hills and valleys of loose heavy sand; the former from 20 feet to 100 in height, shifting their position and altering their shape according to the influence of the wind; and, during the heats of summer, clouds of moving sand threaten to overwhelm the traveller. Sometimes the phenomenon called *mirage* is exhibited in this desert, consisting of an optical illusion, whereby a spectator believes that he beholds a lake or a wide river well defined before him, reflecting surrounding objects, while there is nothing but a level uninterrupted surface in view.

Vegetation is exceedingly scanty throughout, except in a few patches, which are skilfully and industriously cultivated; and the whole country seems to depend on external supplies of grain. Nevertheless, in the midst of arid tracts, the water-melon, a juicy fruit, grows in profusion, attaining the remarkable size of three or four feet in circumference, from a stalk no larger than that of the common melon. The seeds are sown by the natives, and also grow wild, but it is difficult to account for such an enlargement of size with so little moisture. Water seems to be obtained only at an immense depth; the wells at Beykaneer are often from 300 to 345 feet deep, yet not above three feet in diameter; all are lined with masonry; and one of the most curious objects in the city of Beykaneer, is considered to be a well 300 feet deep, and 15 or 20 in diameter, worked by four pair of oxen drawing as many buckets of water. The water is always brackish, scanty, and insalubrious, and this, combined with the nature of the soil, principally occasions the prevalent sterility of this country.

Animals.

The wild ass, remarkable for its speed and its shyness, is found here, sometimes solitary, but oftener in herds. At a kind of shuffling trot, peculiar to itself, it will leave the best horses behind. Antelopes are seen in some parts, also foxes, smaller than those of Britain, and the desert rat is in great numbers, occasioning serious inconvenience to equestrians from the holes it makes where the ground is sufficiently solid. Of domesticated animals, horses, bullocks, and camels, are in abundance; the last kept in great herds for various purposes. The horses brought from the vicinity of the Lacky Jungle, an adjoining district, where they are reared on excellent pasture and with the strictest attention, are much prized. But the original breed was greatly improved by the introduction of fine Persian horses, brought hither during the successive invasions of Hindostan by Nadir Shah, and other eastern potentates. At present they bear very high prices, some of them bringing even L. 250 Sterling, a large sum in a poor country. But some decrease in the extent and quality of the breed has lately resulted from the impolitic conduct of the officers of the Rajah of Beykaneer, by whom the owners are compelled to sell them at an undervalue. When purchased thus, the horses are sent on speculation to different parts of the Indian peninsula.

Manners.

We are little acquainted with the manners and customs of the inhabitants of this country, otherwise

Beykaneer. than by their correspondence with those of the same tribes disseminated elsewhere in India. The natives are divided into two principal classes, Rajpoots and Jauts; the former the rulers, the latter the mass of the people. The Jauts are of small stature, black, ill-looking, and bear strong indications of poverty and wretchedness; the Rajpoots are stout and handsome, with Jewish features, of haughty manners, an indolent disposition, and greatly addicted to intoxication with opium. It is doubtful whether the Rajpoots of Beykaneer entertain those elevated and magnanimous sentiments so peculiar to their tribe, whether they are animated by that high sense of honour and impatience of indignity, which, united to the violence of their passions, lead to the most terrible catastrophes. When a man of rank finds himself beset by an enemy, from whom he has no chance of escape, he inquires whether, by surrender, he can preserve the honour of his family; should the answer be equivocal or unfavourable, he clothes himself in yellow, the symbol of despair, and repairing along with his nearest relatives to the apartments of the females, the whole are involved in promiscuous destruction; nor is it uncommon, on such occasions, for the women themselves to commit suicide. The Rajpoot then rushes furiously against his enemies, and though he should be successful and prevail over them, rather than survive his dire calamity, he plunges his sword in his own breast. The same sense of dishonour induces females of rank to deem themselves contaminated by the gaze of any man but their most intimate relatives; and it also leads them to ascend the funeral pile of their husbands, lest, by survivance, they should lose the consideration of the world. The people of the East, while more placid and resigned to fate, are, at the same time, agitated by more acute and ungovernable passions than the inhabitants of the Western World. A Mahometan officer of high rank, who was hard pressed by a victorious enemy, approaching the place where his wife and daughter had sought refuge on the banks of a river, gave the following account of his conduct: "I leapt from my horse, and seizing each by a hand, rushed with them into the water up to their waists, and covered the rest of their persons with a cloth: I drew my sword to defend them with my life from further insult, and, happily for my honour, their faces were not seen by the eyes of a stranger." Of late the Rajpoots of Beykaneer have been accused of being cruel and treacherous.

Towns. The population of this territory is altogether uncertain; but, from the scarcity of water, it is probably very much restricted. The inhabitants are dispersed in towns and villages, of which Beykaneer, near the southern frontier, in about 27° 55′ north latitude, the capital, and Churoo, on the eastern frontier, are the chief. Beykaneer, surrounded by lofty white walls, strengthened with numerous round towers crowned by battlements, presents the imposing picture of a great and magnificent city in the midst of a wilderness. But, on entering the gates, the illusion vanishes; it proves to consist, for the most part, of huts built of mud, and painted red. Nevertheless, there are some high houses, several temples, and at one corner a lofty and fine looking fortress, a quarter of a mile square, environed by a wall 30 feet high, and a good dry ditch. The interior is a confused assemblage of towers and battlements, overtopped by houses, and it contains the royal palace, a curious old edifice. Churoo, independent of the suburbs, is above a mile and a half in circuit, and, although situate among sand-hills, has a handsome appearance. All the houses have terraces, and are built of a pure white limestone like those of Beykaneer. Villages are occasionally seen in the most dismal situations, to which their miserable aspect corresponds. They consist of a few round huts of straw, with low walls and conical roofs like little stacks of corn, and surrounded by hedges of thorny branches stuck in the sand. A modern traveller speaks thus, in describing the town of Pooggul: "If I could present to my reader the foreground of high sand-hills,—the village of straw huts,—the clay walls of the little fort going to ruins, as the soil which supported them was blown away by the winds, and the sea of sand which formed the rest of the prospect, he would probably feel, as I did, a sort of wonder at the people who could reside in so dismal a wilderness; and of horror at the life to which they seemed to be condemned." The city of Beykaneer is said to stand 219 miles north-west of Delhi, but its real position is south-west, and we conceive the distance to be not less than 260 or 280 miles. Fortresses are not so common in this territory as in a large portion of Hindostan, owing to the equality of the surface.

Scarcely anything definite can be said regarding the occupation and pursuits of the people in their trade and manufactures. Cattle of an inferior breed, and horses, are the only exports; rice, sugar, opium, and indigo, are obtained from the Punjaub; salt from Samber; wheat from Jeypour; and spices, copper, and coarse cloth, are imported from Jesselmere.

Beykaneer is governed by a Rajah, who is a sovereign and independent prince, though he seems formerly to have been tributary to the monarch of Delhi; and even acknowledged the supremacy of Britain, when Delhi had fallen under a foreign power. He enjoys an absolute sway over the lives and property of his subjects, and maintains considerable state in his reception of strangers. His revenues do not exceed L.50,000 *per annum*, though occasionally augmented to nearly double that sum by vexatious imposts on merchandize *in transitu*. Therefore, those caravans which were accustomed to take the route of this province from Surat to Tatta, a town on the Indus, follow another course, in order to avoid such exactions. The resources of Beykaneer are thus very small, which is not surprising, considering they are derived from a country that becomes an absolute desert even within a few yards of the capital. The Rajah's forces amount to 10,000 men, of whom 2000 are cavalry, and he has 35 pieces of artillery; all which troops are paid by assignments of land. Soorut Sing, the reigning Rajah, having profusely dissipated the treasure accumulated by his predecessors, became cruel and tyrannical. Oppressive exactions to relieve pressing necessities alienated the regard of his subjects, and an army of mercenaries became necessary to preserve his authority. He was suspected of per-

Government.

soning an elder brother, and undoubtedly murdered the envoy of another prince passing through his dominions. Yet, being strict in his external devotions, and religiously abstaining from prohibited food, his people have admitted him to the character of sanctity. The sovereign of Beykaneer has to contend with many enemies, who, in their turn, are opposed by the most powerful obstacles. Water must be carried by an invading army; for the natives either poison the wells, fill them up, or cover them over in such a manner that they cannot possibly be found; and, besides, they mix arsenic with bread, which is insidiously disposed of in the hostile camp. Some years ago, George Thomas, a celebrated adventurer, who raised himself to the government of a neighbouring territory, invaded Beykaneer, and compelled the Rajah to purchase peace with L.25,000. He also aided the Batties in expelling him, on occasion of an incursion he had made into their country. More recently, a war having commenced between the Rajahs of Joudpour and Jeypour contending for the hand of an eastern Princess, the interference of Soorut Sing excited the wrath of some of the competitors against himself. Five different armies invaded Beykaneer in 1808, when the Rajah filled up all the wells within ten miles of the walls of his capital. The contest was protracted for a considerable time, but we are unacquainted with its issue.

BIBLIOGRAPHY.

The branch of knowledge to which the term Bibliography is now universally applied, would certainly be more correctly designated by the word *Bibliology.* It was originally employed to denote skill in the perusing and judging of ancient Manuscripts;* but is, at present, appropriated to the Knowledge of Books, in reference to their Constituent parts, their Editions and different degrees of Rareness, their Subjects and Classes.

It is in France, Germany, and Italy, that this species of knowledge has been most largely and successfully cultivated; for though it will appear in the sequel, that Britain has produced some valuable works in this department, it will also appear, that our Bibliographical labours have been greatly surpassed by the Continental Nations. It is to France, in particular, that we are indebted for the most popular and useful treatises in Bibliography; but whilst we make this acknowledgment, in which all who have had any experience of their utility will concur, we must add, that some of her Bibliographers have lately fallen into a very extravagant mode of describing the nature and rank of this branch of Learning. They go so far as to represent it as a Universal Science, in whose ample range all other sciences, and all other kinds of knowledge, are comprehended. *La Bibliographie etant la plus éntendue de toutes les sciences, semble devoir les renfermer toutes,* is the language of one;† *La Bibliographie est la plus vaste et la plus universelle de toutes les connoissances humaines,* is the language of another;‡ though, nothing surely can be more preposterously illogical than to view it in this light, merely because it is conversant about Books, and because Books are the vehicles of all sorts of knowledge. Yet this is the sole foundation that we can discover for these extravagant representations; which tend, as in all other cases of extravagant pretension, to bring ridicule upon a subject, that, were its nature and objects simply and correctly defined, could not fail to appear both useful and important. We have already stated, in a general way, what kind of knowledge of Books it is, to which the appellation of Bibliographical knowledge is applied; but, in order more fully to illustrate its nature and scope, as well as to point out its limits and its utility, we shall now endeavour to detail somewhat more particularly the chief objects of inquiry which it embraces.

It is the business of the Bibliographer, then, to trace the history of Books in regard to their forms and all other constituents, and, consequently, to trace the beginnings and progress of Typography. It belongs to him, in a particular manner, to mark the differences of editions, and to indicate that edition of every Book which is esteemed the most correct and valuable. In the case of Books published without the names of their authors, or under feigned names, it is his business to assign those names with which the discoveries of Literary History may have furnished him. All remarkable facts attaching to the history of Books,—such as the number of their editions, their rareness, their having been condemned to the flames, or suppressed, belong to the province of Bibliographical inquiry. Further, every one who engages in any particular line of study, must of course wish to know what Books have been published in re-

---

* Bibliographe. C'est le nom qu'on donne à ceux qui déchiffrent les anciens manuscrits, et qui sont versés dans la connoissances des livres; mais aujourd'hui on donne ce nom specialment à ceux qui connoissant les livres, et les editions, et qui en font des catalogues. *Dictionnaire de Trevoux,* Tom. I.

gard to it, or in regard to any particular point that interests his curiosity; now, it is the business of the Bibliographer to furnish this most useful species of information: in other words, the compilation of Catalogues of the Books which have appeared in the various Branches of Knowledge, constitutes another grand department of Bibliography. It is by means of such Catalogues that, to use the words of Dr Johnson, "the Student comes to know what has been written on every part of learning; that he avoids the hazards of encountering difficulties which have already been cleared; of discussing questions which have already been decided; and of digging in mines of literature which have already been exhausted." (Preface to the *Catalogus Bibliothecæ Harleianæ.*)

Such is the outline of the principal objects and pursuits of the Bibliographer; and while it must appear abundantly evident that his Science, as it is called, has no pretensions to those lofty epithets upon which we have animadverted; it must, we think, be allowed by every one, that it embraces many curious, as well as interesting subjects of inquiry; and that it is calculated to afford very useful aids to every other species of intellectual occupation. This view of it will be fully confirmed by the details which we are to offer in the course of this article; in which we propose to point out the progress and best sources of information, in regard to all those departments of Bibliographical knowledge, to which we have alluded. In doing so, we shall divide the subject into such a number of heads, as shall appear best suited to the purposes intended.

I. *Of the Constituent Parts of Books, and the Differences of Editions.*

The history of the Materials employed to make Books, of the arts of Writing and Printing upon these materials, and of the Forms and Sizes in which they have appeared, all belong to this head of inquiry. Almost the whole of these particulars have furnished topics for much elaborate research; and some of them for speculations and disputes not yet likely to come to any satisfactory conclusion; but as our main object at present is, to indicate the inquiries which belong to the different departments of Bibliography, together with the best guides to information in each, our notices of these subjects here, must be limited to what is necessary for that purpose. Most of them, indeed, necessarily form the subjects of separate articles in other parts of an Encyclopædia.

Much curious learning has been exercised in describing the various substances used for writing, previous to the important discovery of the art of making Paper from *linen rags.* The precise era of this discovery is not known, nor are authors agreed as to the country in which it was made; but it seems to be ascertained, that this kind of paper was in general use in Europe before the end of the fourteenth century. *Cotton paper* had been in general use more than a century before; and though of greatly inferior quality, its introduction was one of the most fortunate circumstances in the history of the arts; for parchment had become so scarce, that old writings were often erased, in order to apply the parchment to other purposes; and thus, by a metamorphosis of a singular and fatal kind, a Classic was sometimes transformed into a vapid homily or monkish legend. In this way, it is supposed, that some valuable works of antiquity have perished; and, indeed, there can be little doubt of this, when we consider the number of manuscripts that have been discovered, evidently written upon erased parchments. Upon some of them both writings remain legible, and, in this guise, some fragments of Cicero have lately been discovered. These twofold manuscripts are called *Codices Rescripti.* We shall quote from Mr Horne's *Introduction to Bibliography* (Vol. I. p. 115), an account of a *Codex Rescriptus*, discovered about twenty-five years since, at Dublin, by Dr Barret of Trinity College. "While he was examining different books in the Library of that College, he accidently met with a very ancient Greek *MS.*, on certain leaves of which he observed a twofold writing, one ancient, and the other comparatively recent, transcribed over the former. The original writing had been greatly defaced, but, on close examination, he found that it consisted of the three following fragments: the Prophet Isaiah, the Evangelist St Mathew, and certain orations of Gregory Nazianzen. The fragment containing St Mathew's gospel, Dr Barret carefully transcribed, and it has been accurately engraved in fac-simile, and published by the order, and at the expence, of the University. The original writing, or *Codex Vetus*, Dr Barret, with great probability, assigns to the sixth century; the *Codex Recens*, or later writing, he attributes to the thirteenth."

That part of the history of Books which regards the various substances upon which they have been written, is compendiously, but learnedly, treated in the first volume of that very valuable work, the *Nouveau Traité de Diplomatique*, compiled by two Benedictines of the celebrated Society of St Maur. This work was published at Paris in 1750, in six volumes quarto. M. Peignot gives a complete list of separate works on this subject, in the introduction to his *Essai sur l'histoire du Parchemin et du Vélin*, published at Paris in 1812.

The inquiry as to the *origin* of Writing, is a purely philosophical speculation; but the knowledge of the different kinds of writing peculiar to different ages, is a branch of the history of Books which belongs to the province of Bibliography, and upon which much information will be found in the learned work of the Benedictines of St Maur, just referred to. One of the best Books on this subject is Mr Astle's *Origin and Progress of Writing;* the first edition of which was published at London in 1784, and the second, with some additions, in 1803, both in one volume quarto. The chapters on the Transcribers and Illuminators, and the instruments, inks, and other matters which they made use of in their operations, will be found peculiarly interesting to the Bibliographer.

We are now so familiar with the wonders and glorious results of Printing, that it is only when we

look back into the history of the darker ages, that we are made fully sensible, of all the various advantages which it has conferred upon mankind. The mention of the *Transcribers*, that is, the class employed to copy Books, before the discovery of Printing, is well calculated to give rise to reflections of this kind. Their ignorance and carelessness were often the causes of much trouble and mortification to living authors, and of irreparable errors in the works of those who were dead. Petrarch, who flourished in the fourteenth century, has expressed himself in very moving terms, in regard to this double evil. "How shall we find out a remedy," says he, "for those mischiefs which the ignorance and inattention of the Copyists inflict upon us? It is wholly owing to these causes that many men of genius keep their most valuable Pieces unpublished, so that they never see the light. Were Cicero, Livy, or Pliny, to rise from the dead, they would scarcely be able to recognise their own Writings. In every page they would have occasion to exclaim against the ignorance and the corruptions of those barbarous Transcribers."* Upon the invention of Printing, the class of Copyists immediately took alarm, and exerted every means to extinguish an art which, whatever benefits it promised the rest of mankind, held out nothing but prospects of loss to them. They endeavoured, and their example is still steadily followed by other Crafts, to set up their own petty interests in opposition to the general good; and called upon their Governments to invest them with exclusive privileges, which all the great interests of society required to be done away. Thus, when Printing was introduced at Paris, the Copyists complained of the injury to the Parliament, and that body forthwith caused the Books belonging to the Printers to be seized and confiscated; but Louis XI. had the good sense to restore their property to these ingenious artists, and to authorize them to proceed in their laudable vocation. (Lambinet, *Origine de l'Imprimerie.*)

The question as to the *origin* of Printing, is of a complexion wholly different from that regarding the *origin* of Writing, as it turns entirely upon matters of fact; but it is not the less true, that this is a subject upon which opinions widely opposite are, to this day, entertained; for though this art, we mean the art of Printing with *moveable* types, was spread all over Europe within twenty years of the first discovery, it has unfortunately failed to record, in decisive terms, the name of the individual to whom the honour of the invention is due. The *place* where the discovery was made remains also a subject of doubt and contention. In Mallinkrot's work, *De ortu et progressu artis Typographicæ*, published in 1640, he enumerates a hundred and nine testimonies in favour of Mentz, as the birth-place of the art; and since that time the number has been greatly augmented; yet the latest author who has resumed the controversy, declares decidedly in favour of Haerlem, which, in Mallinkrot's day, ranked only thirteen advocates; and further, assigns the wreath which the supporters of Mentz have variously placed on the brow of Guttenberg, of Faust, and of Schoiffer, to Lawrence Coster, as its rightful owner.† All that we can do in this place, is to point out some of the most important works which have been published upon the origin and history of Printing, and which it may be necessary for the Bibliographer to examine, in order to enable him to judge of early editions; recommending those who wish to see a clear and compendious view of the various opinions which have been advanced upon this subject, to peruse M. Daunou's *Analysis* of these opinions, published in the fourth volume of the *Memoirs* of the Moral and Political Class of the French Institute.

The *Monumenta Typographica* of Wolfius, published in two thick octavo volumes, at Hamburg in 1740, contains a valuable and curious collection of treatises by various authors, and also of extracts, illustrative of the origin and early history of the art. Some of these pieces are in verse. Among several other elaborate tables, it contains one of all the authors, who, up to that time, had either directly or indirectly treated of the history, or of the mechanical part of Printing. Meerman's *Origines Typographicæ* is one of the most instructive works as to the progress of the art. It is illustrated with various specimens of early printing, and fac-similes of the Books called *Block-Books*, printed by means of wooden-blocks. Meerman, who was a Lawyer, and author of many elaborate treatises in the Civil and Canon law, was born at Leyden in 1722, and died in 1771, six years after the publication of his *Origines*; in which he supports the pretensions of Haerlem as the birth place of the art, and of Lawrence Coster as its inventor, with great ardour and learning. Another work of curious research on the origin and first progress of Printing, is that of Prosper Marchand, originally a Bookseller at Paris, but whom the repeal of the edict of Nantz drove to Holland, where he employed himself till his death in 1756, in composing various works in Literary History and Bibliography. He makes Guttenberg the inventor of the art, and Mentz the place where he completed the invention; the first idea of it, however, having been formed by him, whilst he resided in Strasburg. This work, entitled, *Histoire de l'Origine et des premiers progres de l'Imprimerie*, was published in 1740. A valuable Supplement, in which some errors of Marchand are corrected, and some new views are advanced, was published by M. Mercier, Abbé de Saint Leger, in 1773, and republished in 1775. The author of the original work was not at all pleased with this Supplement, and he accordingly criticised it with great severity in a long letter addressed to the Editors of the *Journal des Savans*, where it was published. The opinion that Guttenberg conceived the first idea of the invention at Strasburg, and afterwards completed it

* Quoted in Lambinet, *Origine de l'Imprimerie*, Tom. I. p. 38, 39.

† See Ottley's *Inquiry into the Origin and early History of Engraving*, cap. 3.

at Mentz, is also supported by Lambinet, in his *Recherches, historiques, litteraires, et critique sur l'Origine de l'Imprimerie*, first published at Brussels in 1799; and republished in two volumes octavo at Paris in 1810, with the addition of M. Daunou's *Analyse des Opinions*, already mentioned. Besides the main subject of inquiry, M. Lambinet's work embraces various other objects of curious research,—the history of the substances employed for Books, of Inks, of Engraving in relief, of Block-printing, and of Stereotype Printing. Upon the history of Printing, we shall only mention further, M. Serna Santander's *Essai Historique*, prefixed to his *Dictionnaire Bibliographique*, to be afterwards more fully described; and the *Initia Typographica* of Professor Lichtenberger, published at Strasburg in 1811; in both of which, the claims set up for Coster are treated as founded on fables; Guttenberg being represented as the inventor of the art, and Mentz the place where it was perfected; and in both of which, there are ample details as to its progressive establishment in the other cities and countries of Europe.

Besides the information afforded in these General Histories, as to the progress of Printing throughout Europe, there are various Histories of its establishment in particular countries and places, which it will often be necessary for the Bibliographer to consult. One of the most valuable, particularly to the English Bibliographer, is Ames's *Typographical Antiquities;* which contains memoirs of our early Printers, and a register of their publications, from 1471 to 1600. The first edition, published in 1749, consisted of one volume quarto. Another edition, enlarged by Mr Herbert to three volumes quarto, was completed in 1790; and a third edition, illustrated with superb embellishments, and containing some valuable additions, by Mr Dibdin, is now (1817) in course of publication. The French, Germans, and Italians, particularly the latter, are rich in Typographical Histories of this description; but for accounts of them, we must refer our readers to Peignot's *Repertoire Bibliographique Universel*, where they are enumerated and described.

A knowledge of the different classes and bodies of Letter used by Printers is necessary to the accurate description of Books, and discrimination of editions. The Bibliographer must also be acquainted with the corresponding appellations assigned to the different bodies of letter by foreign Printers. Thus the form called *pica* by English Printers, is called *Cicero* by those of France and Germany, because Cicero's *Epistles* were printed in that type. The form called *paragon*, is the only one which retains the same name among the Printers of all countries. Upon all these points, Stower's *Printer's Grammar*, and Fournier's *Manuel Typographique*, may be consulted with advantage. The latter is rich in specimens very neatly executed. It consists of two octavo volumes published in 1764, to which the author, who was a Parisian Letter-founder, and Engraver of great ingenuity and taste, intended to have added two more, but was prevented by his death, which happened in 1768.

The Books of the Ancients were generally in the form of cylinders, made by rolling the joined sheets upon a stick, to the ends of which, nobs or balls were affixed, often richly ornamented; there being just as much foppery among the Collectors of ancient times, as to the matter of ornamenting their Books, as among the *Bibliomaniacs* of the present day. In the infancy of Printing, the sizes were generally folio and quarto; and some have supposed that no Books were printed in the smaller forms till after 1480; but M. Peignot instances many editions in the smallest forms, of an earlier date; as may be seen in the article *Format* of the Supplement to his *Dictionnaire de Bibliologie*. An accurate knowledge of the different forms of Books is necessary to the Bibliographer, as, without this, no Book can be correctly described; and however easy of acquisition this knowledge may appear, it is yet certain, that errors in this respect are sometimes committed even by experienced Bibliographers; and that doubts have been entertained as to the existence of editions, owing to their forms having been inaccurately described. * These mistakes generally proceed from this, that there are different sizes of paper comprehended under the same name. But the water lines in the sheets afford a test; as they are uniformly perpendicular in all folio and octavo sizes, and horizontal in all quarto and duodecimo sizes.

When Books have gone through more than one edition, various minute inquiries must often be made, in order to determine the respective merits of those editions. It is a principal object of the Bibliographical Dictionaries, to be afterwards mentioned, to point out the editions of important works, which such inquiries have ascertained to be the best. There are many particulars in which one edition may differ from, or excel another. There may be differences and grounds of preference in Size, in Paper, and in Printing. The Text of one edition may be more correct than that, either of a preceding, or a subsequent one. An author sometimes corrects errors, makes alterations, or introduces new matter when his work comes to be reprinted, thereby giving the edition so altered a decided superiority over its predecessor. One edition may differ from another by having Notes, an Index, or Table of Contents, which that other wants; or these accompaniments may themselves furnish grounds of preference by being superior in their kind in particular editions. Plates make great differences in the value of editions, and even in the value of Copies of the same edition. In the beautiful engraved edition of Horace by Pine, there is, in the copies first thrown off, a small error, which serves as a test by which Bibliographers immediately judge whether any copy has the best impressions of those elegant vignettes which illustrate that edition. The medal of Augustus in page 108 of the second volume, has, in the copies

* See Boulard, *Traité Elementaire de Bibliographie*, p. 38, 39.

first thrown off, the incorrect reading *Post Est* for *Potest;* this was rectified in the after impressions; but as the Plates had previously sustained some injury, the copies which show the incorrect reading are, of course, esteemed the best. Mr Dibdin, in his Book called *The Bibliomania*, very absurdly points out this as an instance of preference founded on a *defect;* whereas the ground of preference is the superiority of the impressions, ascertained, without the necessity of any comparison, by the presence of this trifling defect. There are, sometimes, owing to particular circumstances, differences between Copies of the same edition of a work; and which, therefore, stand to each other in the same relation, as if there had been another edition with some variations. Walton's *Polyglott Bible* is a celebrated instance. The printing of that great work, for which Cromwell liberally allowed paper to be imported free of duty, was begun in 1653, and completed in 1657; and the preface to it, in some copies, contains a respectful acknowledgment of this piece of patronage on the part of the Protector; but in other copies, this compliment is expunged, and replaced by some invectives against the Republicans, Dr Walton having, at the Restoration, printed another preface to the copies which were undisposed of at that event.* The copies, with the original preface, are much rarer, and of course more prized, than those with the loyal one, which latter seems to have helped the author to the Bishopric he afterwards obtained.

II. *Of Early Printed Books.*

The productions of the Press, in the different countries of Europe, during the century in which Printing was invented, have engaged much of the attention of Bibliographers, and have been described in various works, compiled for that purpose. The first of those productions to which the name of *Books* has been applied, were printed, not with moveable types, but with solid wooden blocks; and consisted of a few leaves only, on which were impressed images of Saints, and other historical pictures, with appropriate texts or descriptions. These leaves were printed only on one side, and the blank sides were generally, though not always, pasted together, so as to look like single leaves. The ink used was of a brownish hue, and glutinous quality, to prevent it from spreading. These curious specimens of the infant art are called *Image Books* or *Block Books*. They have often been largely described, every particular concerning them being fondly cherished by Bibliographers. Their number is fixed by some at seven, and by others carried to ten; but there have been numerous editions of most of them; for they maintained their popularity long after the invention of the art of Printing, properly so called. One of the most celebrated is the *Biblia Pauperum*, consisting of forty leaves, printed on one side, so as to make twenty when pasted together; upon which, certain historical passages of the Old and New Testament are represented by means of figures, with relative inscriptions. It was originally intended, as its name imports, for the use of those poor persons who could not afford to purchase complete copies of the Bible. There is a copious account of all the *Block Books*, in Baron Heinecken's learned work, *Ideé générale d'une Collection complette d'Estampes*, published in 1771, in one volume octavo. Mr Dibdin's *Bibliotheca Spenceriana* contains fac-similes of the figures in several of them, as does also Mr Ottley's *History of Engraving*.

The first Book of any considerable magnitude printed with moveable metallic types, was the celebrated *editio princeps* of the Bible, printed at Mentz, between the years 1450 and 1455. It is printed in large, but handsome, Gothic characters, to resemble manuscript, having two columns in the page, and consisting in whole of 637 leaves, divided into two, three, or four volumes, according to the taste of the binder. (Santander, *Diction. Bibliog.* Tom. II.) The advance from the rude *Block Books*, of a few leaves, to this noble monument of early Typography, is great indeed; and it is impossible not to regret, that there should be still so much uncertainty as to the person whose ingenuity furnished the means of at once raising, almost to perfection, an art destined ever after to exercise so vast and so beneficial an influence on the affairs of the world. The *Psalter*, printed at Mentz by Faust and Schoiffer, in 1457, is the first Book which bears the Printer's name, with the date, and place of printing.

In general, in the very early printed Books, the name of the Printer, the date, and the place of printing, are either wholly omitted, or placed at the end of the Book, with some quaint ejaculation or doxology. The pages have no running title, or number, or catch-word, or signature-letters, to mark the order of the sheets. The character is uniformly Gothic, till 1467, when the Roman type was first introduced. There were no capitals to begin sentences; the only points used were the colon and full stop; and in almost every sentence there were abbreviations or contractions. In regard to these and other peculiarities of early printed Books, the reader may consult the following works: *The General History of Printing*, by Palmer (supposed, however, to have been chiefly written by the celebrated George Psalmanazer); Jungendres, *De notis characteristicis librorum a Typographiæ incunabilis ad an.* 1500 *impressorum;* and *Recherches sur l'origine des Signatures, et des Chiffres de page*, par Marolles.

Many of the early Printers had peculiar marks or vignettes, which they sometimes placed on the title-page, and sometimes at the end of the Books printed by them; and most of them, also, made use of monograms or cyphers, compounded of the initial or other letters of their names. These furnish a clue to the discovery of the Printer, where they occur on books without any Printer's name. An acquaintance with them, therefore, is necessary to the Bibliographer, because questions occur as to early

* See Vol. I. of Dr Clarke's *Bibliographical Dictionary*, for some curious details on this point.

editions which can only be decided by ascertaining the Printer's name. For explanations of these marks, the following works may be consulted :—Orlandi's *Origine e progressi della Stampa*, published at Bologna in one volume 4to, in 1722 ; and Scholtzius's *Thesaurus Symbolorum ac Emblematum*, in one volume folio, published at Nuremberg, in 1730. The monograms of the early English printers are explained in Ames's *Typographical Antiquities*.

The following works are appropriated to the description of early printed Books : 1. *Index Librorum ab inventa Typographia ad annum* 1500, *cum notis ;* 2 vols. 8vo, 1791. This work, by Laire, is one of the best of its kind. The descriptions are clear, the notes brief and instructive ; and there are four indexes, which furnish the means of ready reference to all the names, titles, places, and Bibliographical notices contained in the work : 2. *Dictionnaire Bibliographique choisi du quinzieme siècle.* Par Serna Santander, 3 vols. 8vo, 1805. This is a very learned and exact work ; and, like the preceding, embraces only the rarest and most interesting publications of the fifteenth century. 3. *Bibliotheca Spenceriana*, or a descriptive Catalogue of the books published in the fifteenth century, in the Library of Earl Spencer ; by the Rev. T. F. Dibdin ; 4 vols. 8vo, 1814. The abundance and beauty of the fac-similes and other embellishments, as well as the fineness of the paper and printing, render this by much the most splendid Bibliographical work ever published in any country. It contains some curious information, enveloped, however, in a much greater proportion of tasteless and irrelevant matter. 4. *Annales Typographici ab Artis inventæ origine*, by Michael Maittaire, published in 4to, as follows : In 1719, volume first, which embraces the period from the origin of printing to 1500 : volume second, published in 1722, extends the annals to 1536 ; and volume third, published in 1726, brings them down, according to the title-page, to 1557 ; but there is an Appendix, which affords a partial continuation to 1664. In 1733, the first volume was republished, with corrections and large additions, and is commonly called the fourth volume. The fifth and last volume, containing Indexes, was published in 1741. As four of the volumes consist each of two parts, the work is sometimes bound in five, sometimes in nine volumes. Several Supplements have been published to this elaborate work ; the most valuable of them, that by Denis, in two volumes 4to, was published at Vienna in 1789 ; and contains 6311 articles omitted by Maittaire. The latter has enriched his Annals with many learned Dissertations ; and the work is allowed to be the most important that has yet been compiled in England, in any department of Bibliography. But though written in this country, the last was the only volume published in it, the others having been published in Holland. 5. *Annales Typographici ab artis inventæ origine, ad annum* 1500, *post* MAITTAIRE, DENISII, *aliorumque emendati et Aucti ; opera S. W.* PAUZER ; 11 volumes 4to, published at Nuremberg, the first in 1793, the last in 1803. This work labours under great defects, in point of arrangement ; but it is unquestionably the most complete of its kind that has yet appeared. It comes down to the year 1536, though the title-page of the first volume limits it to the fifteenth century.

The works we have just described may fairly be set down as indispensable to every Bibliographical Collection. But they have a value, we think, independent of the assistance which they afford the Bibliographer, in his examination of the early productions of the Press ; they are also calculated to interest the Philosopher as curious registers of the extent and objects of intellectual industry, during a period when the human mind began to be acted upon by new impulses, and to receive the seeds of revolutions destined to change the whole aspect of the intellectual world.

III. *Of Rare Books.*

Rareness is a circumstance which must, generally speaking, confer some degree of value upon Books ; and it is, therefore, one of the objects of Bibliography to indicate those Books which, in a greater or less degree, come under this category. A passion for collecting Books, merely because they are rare, without inquiry as to any literary purpose they may be calculated to serve, is, no doubt, a very foolish habitude ; but it is just as foolish, on the other hand, to ridicule all solicitude about Books of this description ; for this implies that every valuable Book is common ; a notion which no one can entertain who has ever had occasion to follow out any particular line of literary research, to decide upon any fact involved in doubt or in controversy, or to speculate upon the progress of knowledge either in the Sciences or the Arts. With regard to the Bibliographical compilations appropriated to the description of Books of this class, it may be observed of most, if not all of them, that they have applied the epithet *rare* much too vaguely and lavishly. It must, indeed, in a multitude of cases, be exceedingly difficult to speak with precision on this point ; so difficult as to render it impossible, we apprehend, to compile a work of this kind, which shall not frequently mislead those who consult it.

David Clement, the author of a very learned work of this class, which we shall immediately notice, assigns the following, as the different degrees in which Books may be said to be rare. A Book, which it is difficult to find in the country where it is sought, ought to be called, simply, *rare*. A Book, which it is difficult to find in any country, may be called *very rare.* A Book, of which there are only fifty or sixty copies existing, or which appears as seldom as if there never had been more at any time than that number of copies, ranks as *extremely rare ;* and when the whole number of copies does not exceed ten, this constitutes *excessive* rarity, or rarity in the highest degree. This classification of the degrees of rareness is copied from Clement, by all subsequent Bibliographical writers in this department. It is abundantly obvious, that the justness of the application of these classifications to particular Books, must entirely depend on the extent and precision of the knowledge with which they are used.

We cannot in this department, any more than in the others embraced in this article, indicate any but the most prominent and useful Books belonging to it. The following, in this view, are particularly worthy of attention : 1. Beyeri, *Memoriæ*

Historico-criticæ Librorum rariorum, 1734, 8vo. 2. Vogt, *Catalogus historico-criticus Librorum rariorum*, 1732, 8vo. The last and best edition was published in 1793. In this work, the epithet *rare* is applied with more judgment and knowledge than in most others of the same class. 3. Gerdesii, *Florilegium historico-criticum Librorum rariorum*; first published in 1740, and again in 1763, in 8vo. It was partly intended as a Supplement to the preceding work by Vogt, and, therefore, notices only those books which are not included in his Catalogue. 4. *Bibliotheque curieuse, ou Catalogue raisonné des Livres rares*; par D. Clement. 1750-60. This work, to which we have before alluded, is compiled upon a more extensive plan than any of the preceding; for, though consisting of nine volumes quarto, it comes down no farther than to the letter H in the alphabetical arrangement of names; terminating here in consequence of the death of the Author. Clement is generally blamed, and with justice, for a very profuse and inaccurate application of his own nomenclature of rarity; his notes, too, are crammed with citations, and tediously minute; but, on the other hand, it must be allowed, that they contain many curious pieces of Literary History; and it has, upon the whole, been matter of regret to Bibliographers, that the work, voluminous as it must have proved, was not completed. 5. *Bibliotheca Librorum rariorum universalis*. Auctore Jo. Jac. Bawer; 7 vols. 8vo, 1770-91. This, we believe, is the latest publication of its class. It contains only the titles of Books without any further notices; and this being the case, it must be evident, that seven volumes could scarcely be occupied with titles of Books justly called rare.

IV. *Of the Classics.*

It is remarked by Mr Roscoe, "that the coincidence of the discovery of the art of Printing, with the spirit of the times in which it had birth, was highly fortunate. Had it been made known at a much earlier period, it would have been disregarded or forgotten, from the mere want of materials on which to exercise it; and, had it been farther postponed, it is probable, that many works would have been totally lost, which are now justly regarded as the noblest monuments of the human intellect." (*Lorenzo di Medici*, chap. i.) The rapid diffusion of the art, and the speedy appearance of the *Classics* in an imperishable form, afford sufficient proofs of the bent of the age, and the opportuneness of this great discovery. Gabriel Naudé observes, that almost all the good as well as bad Books then in Europe, had passed through the Press before the year 1474;* that is, within twenty years of the earliest date to which the use of moveable types can be carried. Within this period, editions had been printed of nearly all the Latin Classics. The whole works of some of them, of Cicero, for example, had not yet appeared in one uniform edition; but several of his treatises, the whole of Pliny the Elder, of Livy, Sallust, Cæsar, Tacitus, Suetonius, Justin, Lucan, Virgil, and of Horace, had been published before the end of 1470. Most of these early editions of the Classics were published in Italy. England remained greatly behind her Continental neighbours in the naturalization of these precious remains of ancient learning. Of all the Classics, only Terence, and Cicero's *Offices*, had, in 1540, been published in this country in their original tongue. Caxton and others made use only of French translations in the early versions and abridgments published in England. Gawin Douglas, Bishop of Dunkeld, so well known for his Scottish poetical version of Virgil, has, in his preface to that work, commemorated his indignation at the injustice done to "the divine Poet" by Caxton's second-hand translation, in the following curious and emphatic lines:

> Thoch Wylliame Caxtoun had no compatioun
> Of Virgill in that buk he preyt in prois,
> Clepand it Virgill in Eneados,
> Quhilk that he sayis of Frensche he did translait,
> It has nathing ado therwith, God wate,
> Nor na mare like than the Deuil and sanct Austin.
> Haue he na thank tharfore, bot lois his pyne;
> So schamefully the storie did peruerte,
> I reid his work with harmes at my hert,
> That sic ane buk, but sentence or ingyne,
> Suld be intitulit eftir the poete diuine.
> His ornate goldin versis mare than gylt;
> I spitte for disspite to se thame spylt
> With sic ane wicht, quhilk treuly be myne entent
> Knew nevir thre wordis at all quhat Virgill ment.

Almost all the Latin Classics had appeared in print, before the art was employed upon any one Greek author. But the desire to possess printed editions of the latter became general and urgent towards the end of the fifteenth century; and Aldus had the glory of ministering to that desire, by publishing in rapid succession, and with singular beauty and correctness, almost all the principal authors in that tongue. Beginning in 1494 with Musæus's *Hero and Leander*, he printed before 1515, the year of his death, upwards of sixty considerable works in Grecian literature, frequently joining the learning and the cares of the Editor to those of the Printer. "Yet his glory," to use the words of Mr Gibbon, "must not tempt us to forget, that the first Greek Book, the *Grammar* of Constantine Lascaris, was printed at Milan in 1476; and that the Florence Homer of 1488 displays all the luxury of the Typographical art." (*History*, Chap. 66.) Besides these works, there had been published before 1494, some Greek *Psalters*, the *Batrachomyomachia* of Homer, and the *Orations* of Isocrates; during that year, the *Anthologia Græca* was published at Florence; and the works of Callimachus, of Apollonius Rhodius, and of Lucian, were published at the same place within two years after the first essays of Aldus in Greek printing. Thus, though we have no sort of wish to detract from the just fame of this learned and beautiful Printer, we cannot admit the propriety of those eulogies of his late Biographer M. Renouard, in which he is represented as having given

* *Addition à l'Histoire de Louis XI.* Par G. Naudé.

an entirely new direction to the art of Printing, and, indeed, to the literary taste of Europe.* It is as incorrect in point of fact, as it is unphilosophical, to ascribe to Aldus the production of that taste for Grecian literature which he himself imbibed from the spirit of his age. He saw that there was a great and growing want of Greek Books; and his peculiar praise lies in this, that he applied himself to supply this want, with much more constancy and skill, and with much more learning, than any other Printer of that period. All that we have said on this point, is fully corroborated by the account which he himself has given, in his Preface to Aristotle's *Organon*, published in 1495, of the circumstances which induced him to undertake the publication of the Greek Classics. The passage is translated by Mr Roscoe in his *Life of Leo the Tenth* (Vol. I. p. 110), and is as follows:—"The necessity of Greek literature is now universally acknowledged; insomuch, that not only our youth endeavour to acquire it, but it is studied even by those advanced in years. We read but of one Cato among the Romans who studied Greek in his old age, but in our times we have many Catos; and the number of our youth, who apply themselves to the study of Greek, is almost as great as of those who study the Latin tongue; so that Greek Books, of which there are but few in existence, are now eagerly sought after. But by the assistance of Jesus Christ, I hope ere long to supply this deficiency, although it can only be accomplished by great labour, inconvenience, and loss of time. Those who cultivate letters must be supplied with Books necessary for their purpose, and till this supply be obtained, I shall not be at rest."

The *Editiones Principes* of the Classics have always formed capital objects in Bibliography, and are sometimes spoken of with a degree of rapture in Bibliographical works, which is apt to appear inappropriate and unreasonable to those who covet books solely as they are calculated to afford delight or information. The lover of first editions has, however, some plausible reasons to assign in justification of this expensive, and, as some think, factitious passion. These editions, it is said, are valuable, in the first place, as curious monuments of early Typography, and, in the next place, as being more faithful representatives of the best ancient Manuscripts, than any other editions. *Earum editionum authoritatem*, says Maittaire, *aliis omnibus esse preferendum, quippe quæ solà MSS. fida nitatur.* This ground of preference, however, has some learned oppugners. Schelhorn, in his *Amœnitates Literariæ*, speaks of those to whom we are indebted for the first editions of the Classics, as, in general, very ignorant men; quite incapable to collate Manuscripts themselves, and seldom taking assistance from those who were. The first Manuscript that could be procured, it has been said by others, and not that which, after a careful collation, appeared entitled to a preference, was hastily committed to the Press, in order to take advantage of the recent discovery. Thus Grævius, in the Preface to his edition of Cicero *De Officiis*, states, that the celebrated *editio princeps* of that work, by Faust, was printed from a very inaccurate manuscript.† On the other hand, there are many who view those editions in the same light with Maittaire. M. La Grange assures us, in the Preface to his French translation of Seneca's works, that he never, in any case of difficulty, consulted the *editio princeps* of 1475, without finding there a solution of his doubts; adding generally, *que ceux qui studient les auteurs anciens, soit pour en donner des Editions correctes, soit pour les traduire dans une autre langue, doivent avoir sans cesse sons les yeux les premiers Editions de ces auteurs.* To the same purpose, M. Serna Santander observes, that the *Editio Princeps* of Pliny the Elder, printed at Venice by Spira in 1469, is in many places more accurate than the celebrated edition of Father Hardouin. The truth seems to be, that though many first editions have a real literary value for such purposes as are specified by M. La Grange, there are others which have no value save what their extreme rareness gives them;—that, therefore, they who scoff at, and they who laud indiscriminately these literary rarities, are equally in the wrong;—in a word, that we must apply a different rule of estimation to the first editions of such a Printer as Aldus, and those of Sweynheim and Pannartz.‡

The Classics have often been published in Sets more or less complete, and more or less estimable for beauty, correctness, commentaries, and so forth. Lists of all these sets, with remarks on their relative extent and merits, will be found in the Bibliographical works to be immediately mentioned. As the origin of the *Delphin* Collection forms an interesting piece of Literary History, it may not be improper to notice it more particularly. This celebrated body of Latin Classics was originally destined for the use of the Dauphin, son of Louis XIV.; and was projected by his Governor the Duke of Montausier. This nobleman, who, though a Courtier and Soldier, was both a Philosopher and a Scholar, had been in the habit of carrying some of the Classics along with him in all his cam-

* *Annales de l'Imprimerie des* Alde, ou Histoire des trois Manuce, et de leurs Editions. Par A. G. Renouard. 2 tomes 8vo. Paris, 1803.

† See a curious chapter on *First Editions* in Marchand's *Histoire de l'Imprimerie*. He mentions, as a piece of extreme folly, that one hundred guineas had been paid for a copy of the first edition of Boccacio; but if that price deserved such a censure, what epithet shall we bestow on a late purchase of a copy, for which L.2260 was paid?

‡ When Mr Dibdin tells us, *Introduction to the Classics*, v. Aulus Gellius, "that all the first editions printed by Sweynheim and Pannartz are considered as particularly valuable by the curious in Bibliography," he should have added, chiefly on account of their being *curiosities* from their great rarity, and not on account of their superior accuracy.

paigns; and had often experienced impediments to their satisfactory perusal, from the recurrence of difficulties and allusions, which could not be removed or explained, without Books of reference, too bulky for transport on such occasions. It was in these circumstances that the idea first occurred to him of the great utility of a uniform edition of the principal Classics, in which the text of each should be accompanied with explanatory notes and illustrative comments; and when he became Governor to the Dauphin, he thought that a fit opportunity to set on foot an undertaking calculated to prove so useful to the studies of the young Prince. Huet, Bishop of Avranches, then one of the Dauphin's Preceptors, was accordingly commissioned to employ a sufficient number of learned men for this purpose, and to direct and animate the whole undertaking. Once every fortnight they came to him on a stated day, each with the portion of his work which he had finished in the interval, to undergo his inspection and judgment. The copious verbal indexes, which constitute so valuable a portion of these editions, were added at his suggestion; but not without considerable opposition on the part of his assistants, who were appalled by the prospect of so much irksome labour as would be necessary to do justice to this part of the plan. (*Memoirs* of Huet's Life, Book 5.) The collection, including Danet's *Dictionary of Antiquities*, extends to sixty-four volumes quarto. "It is remarkable," says Dr Aikin, in one of the notes to his excellent translation of Huet's *Memoirs*, "that Lucan is not among the number. He was too much the Poet of liberty to suit the age of Louis XIV."

The following are the most useful Bibliographical accounts of the Classics: 1. *A View of the Various Editions of the Greek and Roman Classics, with Remarks*, by Dr Harwood. This work, first published in 1775, has gone through several editions; the larger works of the same kind, to which it gave rise, not having superseded it as a convenient manual in this department of Bibliography. 2. *Degli Autori Classici sacri profani, Græci e Latini, Bibliotheca portatile*; 2 vols. 12mo, Venice, 1793. This work was compiled by the Abbé Boni, and Bartholomew Gamba; and contains a translation of the preceding, with corrections and large additions, besides criticisms on the works of Bibliographers, and a view of the origin and history of Printing. 3. *An Introduction to the Knowledge of Rare and Valuable Editions of the Classics*, by T. F. Dibdin. The first edition was published in 12mo, in 1803; but it has since been greatly enlarged in two octavo editions, the last of which appeared in 1808. The utility of this work is considerably enhanced by the full account which it contains of Polyglott Bibles, of the Greek and Latin editions of the Septuagint and New Testament, and of Lexicons and Grammars.

The improved editions, by Harles and Ernesti, of the *Bibliotheca Græca* and *Bibliotheca Latina*, of Fabricius, are well known to the learned, as immense magazines of information in regard to the Classics and classical literature; but as they extend over a much wider field of inquiry than is embraced by Bibliography, it does not belong to our present subject to give a more particular account of them.

V. *Of Anonymous and Pseudonymous Books.*

The great number of Books published anonymously, as well as under false or feigned names, early directed the attention of the learned to this branch of Bibliographical inquiry. In 1669, Frederic Geisler, a Professor of Public Law at Leipsic, published a Dissertation *De Nominum Mutatione*, which he reprinted in 1671, with a short catalogue of anonymous and pseudonymous authors. About the same period, a similar but more extensive work had been undertaken by Vincent Placcius, Professor of Morals and Eloquence at Hamburg, and which was published in 4to in 1674, with this title: *De Scriptis et Scriptoribus, anonymis atque pseudonymis, Syntagma.* Four years thereafter, John Decker, a learned German Lawyer, published *Conjecturæ de scriptis adespotis, pseudepigraphis, et supposititiis*; which was republished in 1686, with the addition of two Letters upon the same subjects; one by Paul Vindlingius, a Professor at Copenhagen, and the other by the celebrated Peter Bayle. In 1689, John Mayer, a Clergyman of Hamburg, published a letter to Placcius, under this title: *Dissertatio epistolica ad Placcium, qua anonymorum et pseudonymorum farrago exhibitur.* Placcius, meanwhile, had continued his inquiries; and after his death, the fruits both of his first researches and additional discoveries were embodied in one work, and published in a folio volume, at Hamburg, in 1708, by Mathew Dreyer, a Lawyer of that city. The work was now entitled, *Theatrum Anonymorum et Pseudonymorum*; and, besides an Introduction by Dreyer, and a Life of Placcius, by John Albert Fabricius, it contains, in an appendix, the before-noticed treatises of Geisler and Decker, with the relative Letters of Vindinlingius and Bayle, as well as Mayer's *Dissertatio Epistolica*, addressed to Placcius. This very elaborate work contains notices of six thousand books or authors; but it is ill arranged, often inaccurate, and three-fourths of it are made up of citations and extracts, equally useless and fatiguing. *

A part of this subject, that relating to Books published under false or fanciful names, had been undertaken in France by Adrian Baillet, nearly about the same period that Placcius commenced his inquiries. In 1690, this author published his *Auteurs Déguisés*; but this is little more than the Introduction to an intended Catalogue of such authors, which Baillet never completed; being deterred, as Niceron says, by the apprehension, that the exposing of concealed authors might some way or other involve him in trouble. In this piece, which was reprinted in the sixth volume of De la Monnoye's edition of Baillet's *Jugemens des Savans*, there are some curious

* See the copious article on Placcius, in Chaufpié's *Nouveau Dictionnaire Historique et Critique*, Tom. III.

literary anecdotes; particularly those illustrative of the rage which obtained after the revival of letters, for the assumption of classical names. In Italy, these names were so generally introduced into families, that the names of the Saints, hitherto the common appellatives, almost disappeared from that country.

The taste for this species of research, which the work of Placcius had diffused in Germany, produced several Supplements to it in that country. In one published at Jena, in 1711, under the name of Christopher Augustus Neuman, there is, besides the list of authors, a dissertation upon the question, Whether it is lawful for an author either to withhold or to disguise his name? which question he decides in the affirmative. This work is entitled, *De Libris anonymis et pseudonymis Schediasma, complectens observationes generales, et Spicilegium ad* PLACCII *Theatrum.* But the most considerable of these Supplements was that published by John Christopher Mylius, at Hamburg, in 1740. It contains a reprint of the *Schediasma* of Neuman, with remarks; and a list of three thousand two hundred authors, in addition to those noticed by Placcius. The notices of Mylius, however, are limited to books in the Latin, German, and French languages.

About the middle of last century, the Abbé Bonardi, Librarian to the Sorbonne, undertook a Dictionary of anonymous and pseudonymous works, but he died without publishing it. The manuscript is said to have been carried to Lyons; and, it is supposed, was destroyed there, during the disorders that followed the Revolution. In the third volume of Cailleau's *Dictionnaire Bibliographique*, published in 1790, there is a separate alphabet for anonymous Books, which occupies about half the volume. It embraces Books in all languages, but those only which the compiler thought rare or curious. The last, and by far the best work in this department, is the *Dictionnaire des ouvrages Anonymes et Pseudonymes*, by M. Barbier, Librarian to the late Emperor of France. It consists of four volumes octavo; two of which were published in 1806, and the remaining two in 1809. It comprises above twelve thousand articles; but the plan does not embrace any English, German, or Italian works, but those which have been translated into the French language. Works of this class are more particularly useful in regard to the literary productions of periods and countries which have been greatly restricted in the liberty of the Press. M. Barbier states, that in every Library composed of useful Books, it will be found, that a third part have not the names of the authors, translators, or editors; a proportion which, if true at all, can only hold true, we think, of Continental Libraries.

VI. *Of Condemned and Prohibited Books.*

Books supposed hurtful to the interests of government, religion, or morality, have sometimes been condemned to the flames, sometimes censured by particular tribunals, and sometimes suppressed. These measures have been followed by particular countries, both in respect to their own productions and those of their neighbours. In some countries, lists of the Books prohibited within them, have, from time to time, been published; and in these lists are often found the most highly prized productions of the Literature of other nations. This constitutes, indeed, a melancholy portion of the history of Books; for though the facts which it collects sometimes amuse by their folly, they oftener excite indignation and pity at the oppressions of Power, and the sufferings of Learning.

The practice of condemning obnoxious Books to the flames is of very ancient date. The works of Protagorus of Abdera, a disciple of Democritus, were prohibited at Athens, and all the copies that could be collected were ordered to be burnt by the public crier. Livy mentions, that the writings of Numa, which were found in his grave, were condemned to the flames, as being contrary to the religion which he had himself established. Augustus caused two thousand Books, of an astrological cast, to be burnt at one time; and he subjected to the same doom, some satirical pieces of Labienus. Tacitus mentions a work which the Senate, under Tiberius, condemned to the fire for having designated Cassius as the last of the Romans.* This practice was early introduced in the Christian world. "After the spreading of the Christian religion," says Professor Beckmann, "the Clergy exercised against Books that were either unfavourable or disagreeable to them, the same severity which they had censured in the heathens, as foolish and prejudicial to their own cause. Thus were the writings of Arius condemned to the flames at the Council of Nice; and Constantine threatened with the punishment of death those who should conceal them. The Clergy assembled at the Council of Ephesus, requested Theodosius II. to cause the works of Nestorius to be burnt, and this desire was complied with. The writings of Eutyches shared the like fate at the Council of Chalcedon; and it would not be difficult to collect examples of the same kind from each of the following centuries."

When the Popes caused the nations of Christendom to acknowledge their infallibility in all matters appertaining to religion, they also took upon themselves the care and the right of pointing out what Books should, or should not, be read; and hence originated those famous *Expurgatory Indexes*, which furnish such ample materials for the Bibliography of prohibited Books. There is a copious list of these *Indexes* in the work of Peignot, to be immediately noticed. The next step in the progress of usurpation was the *licensing* of Books. By the Council of Lateran, held at Rome in 1515, it was ordered, that in future all Books should, previous to publication, be submitted to the judgment of Clerical Censors. "To fill up the measure of encroachment," says Milton, "their last invention was to ordain, that no Book should be printed, as if St Peter had bequeathed them the keys of the Press also, as well as of Paradise, unless it were approved and licensed under the hands of two or three gluttonous Friars. Till

* See the chapter on *Book Censors* in Professor Beckmann's *History of Inventions*.

Bibliography.

then, Books were ever as freely admitted into the world as any other birth; the issue of the brain was no more stifled than the issue of the womb; no envious Juno sat cross-legged over the nativity of any man's intellectual offspring." (*Speech on the Liberty of unlicensed Printing.*)

The following works contain accounts of condemned and prohibited Books, and of the *Indices Expurgatorii.* 1. *Dissertatio historico-literaria de libris combustis*, in the seventh volume of Schelhorn's *Amœnitates Literariæ*. The same subject is resumed in the eighth and ninth volumes. 2. *Index generalis librorum prohibitorum à Pontificis; in usum Bibliothecæ Bodleianæ*; by Tho. James, 1627. We do not know that any other work of this kind was ever published in England. 3. Francus *De Papistarum Indicibus librorum prohibitorum*, published at Leipsic in 1684. 4. *Thesaurus Bibliographicus ex Indicibus librorum prohibitorum congestus*, published at Dresden in 1743. 5. *Dictionnaire Critique et Bibliographique des principaux Livres condamnes au feu, supprimes ou censures*, par G. Peignot, 2 vols. 8vo, Paris, 1806. This Book is amusing, and gives a copious list of *Indices Expurgatorii*, as well as of authors who have treated of the subject of condemned Books in general: but it cannot be allowed, that it contains anything approaching to a complete enumeration of the *principal* works which come under the scope of the title-page. There are very few English Books noticed, either those condemned in this country, or those prohibited in others; though in this latter class, the most valuable of our philosophical and literary works would be found to be named. One of the most preposterous sentences of prohibition, incurred by an English author, is that mentioned in a letter from Sir John Macpherson, while in Spain, to Mr Gibbon, viz. that Smith's *Wealth of Nations* was prohibited there "on account of the lowness of its style, and the looseness of its morals." (Gibbon's *Posthumous Works*, Vol. III.)

We should like to see an accurate account of works which have been condemned to the flames, or suppressed, in Britain. In former times, we should find some as abominable instances of oppression in this particular, as ever disgraced the worst governments of Continental Europe. The proceedings against William Prynne, on account of his *Histriomastix*, or *Player's Scourge*, furnish a noted example. We wish we could add, that these proceedings have always been mentioned in our Histories, in the terms which their singular atrocity is calculated to call forth from every heart that has one chord in unison with the rights of humanity. Prynne, who was by profession a Lawyer, is characterized by Mr Hume as being "a great hero among the Puritans." He was in truth a very fanatical person; but his learning was immense, his courage unconquerable, and his honesty certainly as great as that of any of his opponents or oppressors. His *Histriomastix*, a quarto of upwards of a thousand closely printed pages, with all its margins studded with authorities, came out in 1633; and was intended to decry all dramatic amusements, and all jovial recreations, and to censure the lax discipline, and the Popish ceremonies of Prelacy. In the Alphabetical Table at the end of the volume, there is a reference in these words, —*Women actors, notorious whores*; and as the Queen sometimes acted a part in Dramas played at Court, it was represented that Prynne pointed at her Majesty in this reference, and that the Book was in fact intended as a satire upon the Government. He was accordingly prosecuted in the Star-Chamber for a libel. The Book, which the Judges described as a huge misshapen monster, in the begetting of which the Devil must have assisted, was condemned to be burned; and after the example of foreign countries, this was ordered to be done, for the first time in England, by the hands of the hangman. It was ordered, that Mr Prynne should be expelled from Oxford, he being a graduate in that University; and also from the Bar. He was farther sentenced to pay a fine of five thousand pounds, and to endure perpetual imprisonment; but this was not yet all; he was condemned to stand in the Pillory on two successive days, in Westminster and Cheapside, there, on each day, to have an ear cut off. One of the Judges, who represented the Queen's virtues as such that neither oratory nor poetry could do any thing like justice to them, was for making the fine ten thousand pounds; stating, that he knew it was much more than Mr Prynne was worth, yet far less than he deserved to pay; and he wished farther, that his nose should be slit and his forehead burned in addition to the loss of his ears, because he might buy himself a perriwig, and so hide that loss.* The Book, which involved its author in such unprecedented calamities, had actually been licensed, according to the regulations which then obtained for the licensing of Books for publication; but it was stated, that the Licenser had not read the whole of it. Well might Sir Simonds D'Ewes speak of this as a terrifying trial. "Most men," says he, "were affrighted to see, that neither Mr Prynne's Academical nor Barrister's Gown could free him from the infamous loss of his Ears; and all good men conceived this would have been remitted; many asserted it was, till the sad execution of it. I went to see him a while after," continues Sir Simonds, "in the Fleet, to comfort him; and found in him the rare effects of an upright heart, by his serenity of spirit and chearful patience." † The account which Mr Hume gives of this nefarious trial and sentence—dwelling chiefly on the acrimonious and ridiculous parts of the Puritan Prynne's character and Book—wholly passing over the miscreant sycophancy of his Judges, and but gently censuring their appalling and ruthless cruelty—is characteristic enough of

* See Prynne's Trial in the Collection of *State Trials*, Vol. III. of the 8vo Edition.

† See Extracts from *MS.* Journal of D'Ewes's Life, published in Nichols's *Bibliotheca Topographica Britannica*, No. XV.—These Extracts contain some curious scraps of history and anecdote; but it is much to be regretted that the Editor had not the discretion to suppress the atrocious calumny upon Lord Bacon.

his general principles and manner; and well calculated to show, that, with all his penetration, and philosophic spirit, and charms of style, he was still deficient in some qualities of a Historian, without which, History cannot be rendered profitable either to Princes or to People.

VII. *Of Bibliographical Dictionaries and Catalogues.*

The works which fall to be considered under this section, sometimes called *Dictionaries*, sometimes *Catalogues*, and sometimes *Bibliothecæ*, constitute the most generally useful and interesting class of Bibliographical publications. By showing what has been written in all the various branches of human knowledge, in every age and country, they act as useful guides to the inquiries of every class of the learned; while, by pointing out the differences of editions, they constitute manuals of ready information to the professed Bibliographer.

Works of this class are called *General* or *Particular*, according as their object is to indicate Books in all, or in one only, of the departments of Science and Literature. The former only aspire to point out rare or remarkable Books; for no attempt has yet been made, or probably ever will be made, to compile a *universal* Bibliographical Dictionary. On the other hand, it is the object of *particular* Dictionaries to notice all, or the greatest part, of those Books which have been published on the subjects which they embrace; and hence their superior utility to those who are engaged in the study of any particular science or subject.

The works of the former class, which chiefly demand our notice, are the following:—1. *Bibliographie Instructive, ou Traité de la Connoissance des Livres rares et singuliers*, par G. F. De Bure; in seven volumes octavo, published at Paris between 1763 and 1768. The books described in this work are arranged, in appropriate subdivisions, under the five grand classes of *Theology, Jurisprudence, Sciences* and *Arts, Belles Lettres*, and *History;* and the classification which it exemplifies is that generally followed by foreign Bibliographers. The names of the authors in all these classes are arranged alphabetically in the last volume; but it has no index to anonymous works,—a want, however, which was afterwards supplied by another hand, in a thin octavo volume published in 1782, entitled *Bibliographie Instructive, tome dixieme.* This is called the tenth volume, because De Bure had himself published a Supplement of two volumes in 1769. Its title is, *Supplément à la Bibliographie Instructive, ou Catalogue des Livres de Louis Jean Gaignat.* De Bure was a Bookseller at Paris, of great eminence in his profession, but still more distinguished for extensive information in all matters appertaining to Bibliography and Literary History; and, accordingly, his work is still the delight of Bibliographers, though it has been followed by others which indicate a much greater number of Books, and which also, in some particulars, excel it in accuracy. 2. *Dictionnaire Typographique, Historique, et Critique, des Livres rares, estimés et recherchés en tous genres*, par J. B. L. Osmont; 2 vols. 8vo, Paris, 1768. This work is more ample in notices of Italian Books than that of De Bure. 3. *Dictionnaire Bibliographique*, 3 vols. 8vo, Paris, 1790. This work, generally known under the name of Cailleau's *Dictionary*, was compiled, according to M. Barbier and others, by the Abbé Du Clos. It was republished in 1800, with a Supplementary volume, by M. Brunet. It has been already mentioned, that the third volume has a separate alphabet for anonymous Books. 4. *Manuel du Libraire et de l'Amateur de Livres; contenant, 1o, Un nouveau Dictionnaire Bibliographique; 2o, Une Table en forme de Catalogue Raisonné;* par J. C. Brunet. This work was published in three volumes octavo in 1810, and republished with large additions, making in all four volumes, in 1814. It contains a much greater proportion both of English and of German Books, than any of the preceding compilations; and its plan is such as to afford all the advantages both of a Dictionary and a Classed Catalogue; three of the volumes being employed to indicate Books under their names in alphabetical order; and the fourth, to class them, divested of all Bibliographical details, according to the system generally followed. The prices of the rarer Books are given from the principal sales that have taken place of late years in France and other countries; so that, upon the whole, this work, though it has less literary interest than that of De Bure, is probably the best Bibliographical Dictionary extant, for the purposes of the professed Bibliographer.

In the class of *General* Bibliographical Dictionaries we must also place the following work, though its limitation to Books in the learned and Eastern languages, renders it much less general in its plan than those we have described. It is entitled, *A Bibliographical Dictionary, containing a Chronological Account, alphabetically arranged, of the most curious and useful Books in all departments of Learning, published in Latin, Greek, Hebrew, Arabic, and other Eastern languages.* It was published in 1803, in six volumes duodecimo, and the author, we believe, is Dr Adam Clarke. To the principal works noticed in this Dictionary, there are added Biographical Notices and Criticisms; but the author would have judged more wisely, had he included Books in the modern languages, instead of deviating so largely, and with such small pretensions to novelty, into the provinces of Biography and general Criticism. The Supplement, which he published in two duodecimo volumes in 1806, under the title of *The Bibliographical Miscellany*, contains, among other matters, an account of English translations of the Classics and Theological writers; a list of the cities and towns where printing was established in the fifteenth century; and a list of authors on Literary History and Bibliography.

Some writers have complained, particularly M. Camus, that these Bibliographical Dictionaries have been too exclusively devoted to the indication of rare and curious Books; and that they notice but few comparatively, of those whose value consists only in their utility. "Je voudrois," says he, "qu'on suppléât à ce défaut; et que, dans une Bibliographié formée sur un non nouveau plan, on indiquât quels sont, re-

latıvement a chaque genre de connoissance, les livres les plus instructifs." * The *Manuel* of M. Brunet, we may observe, which was published subsequent to the period of this remark, contains the titles of a much greater number of useful Books, than are to be found noticed in any of the other *General* Bibliographical Dictionaries; but it certainly does not, and indeed was not intended, to realize the idea of such a Dictionary as was wished for by M. Camus.

It has sometimes also been alleged, that these Dictionaries, by pointing out so many curious Books, and rare Editions, have contributed greatly to the diffusion of that singular species of disease called the *Bibliomania*. We do not doubt that they may have helped to do so; but the truth is, that this disease has a much deeper root in the vanities of human nature, and is of much more ancient date, than some persons seem to imagine. It gave great offence to Socrates and to Lucian; † and its prevalence among his countrymen had called forth the animadversions of Bruyere, long before the popular work of De Bure gave such an acknowledged zest and pungency to the taste for amassing literary curiosities.

The number of Dictionaries, Catalogues, and *Bibliothecæ*, applicable to particular departments or provinces of Learning, is much too great to permit us to do anything more than to point out a few of the most remarkable and useful among them. Lipenius, a learned German Divine and Professor, born in 1630, and who died in 1692, worn out, as Niceron says, by labour and chagrin, compiled a *Bibliotheca Theologica*, a *Bibliotheca Juridica*, a *Bibliotheca Philosophica*, and a *Bibliotheca Medica*, making in all six volumes folio. The *Bibliotheca Juridica* has been several times reprinted, and two Supplements have been added to it, one by Schott, published at Leipsic in 1775, and the other by Senkenberg, also published there in 1789, making in all four volumes folio. An immense number of Books are indicated in each of these *Bibliothecæ* of Lipenius; of all of which the plan is, to arrange the Books alphabetically according to their subjects, each *Bibliotheca* having also an alphabetical table of the names of the authors whose works are arranged under the alphabet of subjects. The *Bibliotheca Juridica*, owing to the corrections and additions which it has received, forms by much the most valuable part of this series. In regard to Jurisprudence, we may farther mention Bridgman's *Legal Bibliography;* and the valuable work of M. Camus, entitled, *Lettres sur la profession d'Avocat, et Bibliotheque choisi des Livres de Droit.* There are some truly excellent Catalogues of Works in the Sciences, and in Natural History. Such are Dr Young's *Catalogue of Works relating to Natural Philosophy and the Mechanical Arts*, annexed to his *Lectures on Natural Philosophy;* the *Bibliotheca Mathematica* of Murhard; the *Bibliographie Astronomique* of La Lande; and the *Catalogus Bibliothecæ Historiæ Naturalis* JOSEPHI BANKS, by Dr Dryander; which, though the title seems to promise only the catalogue of a private Library, is allowed to furnish the most complete and best arranged view of Books in Natural History, ever published in any country. In the great department of History, there have been published various *Bibliothecæ*, some of them embracing the historical works of all ages and countries, and others, those only which relate to particular countries. The *Bibliotheca Historica* of Meusel, an immense work, consisting of above twenty volumes, and not yet completed, is of the former class. It includes Voyages and Travels; but of Books of this class, there is an excellent separate Catalogue in six volumes octavo, by M. Boucher de La Richarderie; published at Paris in 1808. We must observe, however, that this work would have been better suited to the legitimate ends of such a compilation, had the author confined himself to Bibliographical notices, and wholly refrained from those long extracts by which his Book has been so much enlarged. Of the class of *Bibliothecæ* applicable to the history of particular countries, the *Bibliotheque Historique de la France*, originally published in 1719 in one volume folio, but in the last edition published between 1768 and 1778, extended to five volumes, is by far the most splendid and perfect example. It contains nearly fifty thousand articles as well in Manuscript as Printed, methodically arranged under the different heads of French history to which they relate, and accompanied with a complete set of indexes to authors and subjects.

We must refer such of our readers as are desirous of seeing a fuller list of Catalogues of Books in the different branches of knowledge, to the *Répertoire Bibliographique Universel* of M. Peignot; a useful, but ill arranged Book.

It does not belong to our plan to notice Catalogues of particular Libraries; but we may observe, that *Classed* Catalogues of extensive Collections are justly regarded as rich storehouses of information by all inquirers after Books. We cannot but add, that in this Country, we are greatly, we might with propriety say, shamefully, behind the Continental Nations in this respect. Catalogues of this kind might have been expected from the Directors of the British Museum, and from the great Universities of Oxford and Cambridge, so rich in Books, in leisure, and endowments; but it was a Law Society of Scotland, we believe, namely, the Society of *Writers to his Majesty's Signet*, which set the first example in Britain, of publishing a Catalogue of their Library, so arranged, as to enable every one to turn at once to the class of Books which immediately interests his inquiries.

VIII. *Of the Classification of Books.*

The classing of Books in a Catalogue, so as to furnish a correct systematic view of the contents of an extensive Library, is a task of great difficulty and im-

* *Memoires de l'Institut National.*—Class—Litt. et Beaux Arts. Tom. II.

† Lucian's piece, called in Francklin's translation of his works, *The Illiterate Book-Hunter*, is perhaps the bitterest satire upon Book-Collectors, who are not Book-readers, ever printed.

portance. In order to this, it is necessary to refer every Book to its proper place in the general system of human knowledge; and to do so with precision, it is necessary to have clear and exact ideas of the scope and objects of all the departments and branches of which that system consists. The utility of Catalogues so classed is very great, and consists obviously in this, that the Books upon any subject are found at once by referring to the proper head; whereas in Alphabetical Catalogues, the whole must be perused before we can ascertain what Books they contain upon the subjects which interest us. All who duly consider the matter, therefore, must concur in Dr Middleton's brief and emphatic description of such an undertaking, as *res sané magni momenti, multique sudoris.* *

Whether Classed Catalogues were in use among the ancients, is a piece of information which has not descended to us. The first who is known to have written upon the subject was a German, named Florian Treffer, who published a method of classing Books, at Augsburg, in 1560. Cardona, in 1587, and Scholt, in 1608, published treatises upon this subject; and in 1627, Gabriel Naudé, a writer of no small celebrity in his day, published his *Avis pour dresser une Bibliotheque*, in which he treats of the principles of classification. The Catalogue which he compiled of the Library of the Canon De Cordes, afterwards purchased by Mazarin, was published in 1643, and is esteemed a curiosity among Bibliographers. In the early part of the eighteenth century, Gabriel Martin, a learned Parisian Bookseller, who seems to have been much employed in compiling Catalogues, chalked out a system of arrangement, which, in a great degree, superseded all other systems, and which, in its leading divisions, is still generally followed on the Continent. Various other systems have, however, been proposed by the Bibliographers of France and Germany; but, before proceeding to any particular notice, either of the system of Martin, or of those which differ from it, we must observe, that all who have written upon the subject, seem to have confounded two objects, as we think, perfectly distinct—the arrangement to be followed in the Catalogue of a Library, and that to be followed in placing its Books. They all suppose the same nicety and exactness of classification to be equally necessary, and equally practicable in both. Now, we must remark, that where there is a Classed Catalogue, the grand objects of all arrangement are sufficiently provided for, independently of the location of the Books; and, if there should not be a Classed Catalogue, it seems very clear, that the bulk of those who frequent a public Library, could derive little, if any, benefit from an elaborate classification of the Books on the shelves; even supposing it practicable to effect and maintain it. The chief end of any arrangement that is made on the shelves, ought to be, to aid the memory, and abridge the labour of the Librarians; and all that is useful in this respect, may be accomplished, by means of a much ruder plan, than could be tolerated in any Catalogue pretending to Classification.

The system generally followed, as we have already mentioned, is that of Martin; which divides books into the five great classes of *Theology*, *Jurisprudence*, *Sciences and Arts*, *Belles Lettres*, and *History*. Each of these classes has divisions and subdivisions more or less numerous, according to the number of the branches to be distinguished; and it is in the distribution of these, that the chief differences are found in foreign Catalogues; though the divisions and subdivisions of De Bure, as exemplified in his *Bibliographie Instructive*, are those commonly followed. Some Bibliographers, however, have proposed to alter the order, others to diminish, and some to increase the number of the primitive classes; while a few have proposed systems altogether different, and greatly more refined in their principles of classification. M. Ameilhon, in a paper published in the *Memoirs* of the French Institute, proposes the following leading divisions: Grammar, Logic, Morals, Jurisprudence, Metaphysics, Physics, Arts, Belles Lettres, and History. † In this arrangement, *Theology*, to which he has great objections as a separate class, is transferred, with evident impropriety, to the class of *Metaphysics*. M. Camus has also investigated the principles according to which Books ought to be classed, in another paper in these Memoirs, already quoted; but, as he has not reduced his method, which proceeds on views much too fanciful for the purpose, to specific heads, we can only refer our readers to his paper. Equally remote from the proper objects of a classed Catalogue, are the systems proposed by M. Peignot, and by M. Thiebaut. ‡ The former takes the well known speculations of Bacon and D'Alembert, as to the Genealogy of Knowledge, for the basis of his system; and thus fixes upon three principal heads or classes, under the names of History, Philosophy, and Imagination; with the addition of Bibliography as an introductory class. In the system of the latter, there are, in like manner, only three principal heads, founded upon a division of Knowledge, into knowledge Instrumental, Essential, and Suitable.

Germany has also produced a variety of Bibliographical systems; some of them as absurdly refined as those just mentioned; while others, that of Leibnitz, for example, are better adapted to practical purposes. The classes proposed by this eminent Philosopher are as follows: Theology, Jurisprudence, Medicine, Intellectual Philosophy, Mathematics, Natural

* See his very judicious Tract, entitled, *Bibliothecæ Cantabrigiensis Ordinandæ Methodus*, in the fourth Volume of his Works.

† *Mémoires de l'Institut National.* Class—Litt. et Beaux Arts, T. II.

‡ See *Dictionnaire de Bibliologie*, par G. Peignot, art. Systeme.

Philosophy, Philology, History, and Miscellanies.* Another system, not very remote from this, is that proposed by M. Denis, keeper of the Imperial Library at Vienna; in which books are divided into the classes of Theology, Jurisprudence, Philosophy, Medicine, Mathematics, History, and Philology. This system is developed in his *Introduction to the Knowledge of Books*, to be afterwards described.

Dr Middleton is the only British author, so far as we know, who has written any separate tract on the classification of Books. The classes proposed by him are these: Theology, History, Jurisprudence, Philosophy, Mathematics, Natural History, Medicine, Belles Lettres (*Literæ humaniones*), and Miscellanies. His object in the tract referred to, was to recommend the adoption of this arrangement for a Catalogue of the University Library of Cambridge; and whatever may be its defects, it cannot be questioned that a printed Catalogue of this collection so classed, would have proved of much utility; and would have helped to wipe away that stain of remissness in this particular, which still unfortunately attaches to our great Universities.

Naudé mentions a writer, who proposed to class all sorts of Books under the three heads of Morals, Sciences, and Devotion; and who assigned, as the grounds of this foolish arrangement, these words of the Psalmist, *Disciplinam, Bonitatem, et Scientiam doce me.* We confess, that all such systems as those of M. Peignot and M. Thiebaut, when applied to the formation of Catalogues, appear to us quite as absurd as this system deduced from the *Canticles.* The remark which Naudé applied to it, that it seemed intended "to crucify and torture the memory by its subtilties," is just as applicable to the former. That system, he adds (we use the words of Evelyn's *Translation* of his *Avis pour dresser une Bibliotheque*), "is the best, which is most facile, the least intricate, and the most practised; and which follows the faculties of Theology, Physic, Jurisprudence, Mathematics, Humanity, and others." M. Ameilhon also objects decidedly to all over refined Bibliographical systems, and particularly to those which aspire to follow the genesis and remote affinities of the different branches of knowledge. "L'execution," says he, "en seroit impossible; ou si elle ne l'etoit pas, au moins entraineroit-elle des difficultés, qui ne pourroient être surmontées que par dês hommes profondément réfléches et exercés aux méditations métaphysiques." † The truth is, that when Bibliographers speculate in this field with a view to Catalogue making, they entirely forget their proper province and objects. They have nothing whatever to do with Genealogical Trees of knowledge, or with any mode of classing Books which is founded upon remote and arbitrary abstractions. The whole use and end of a Classed Catalogue is to furnish a ready index to Books, arranged according to their subjects; and that arrangement is therefore to be preferred, which is founded upon the most obviously marked, and generally recognised divisions of those subjects. We may add, that to compile a good Catalogue of an extensive Library, even on this humbler plan, would require more ability, and more correctness of knowledge, than are often likely to be employed in such an undertaking.

Though we are not altogether satisfied with the division and order of the classes in the system commonly followed, we have no doubt, that by means of an additional class, and a correct arrangement of the subdivisions, a Catalogue might be formed, perfectly adequate to every useful purpose. We allude to a class, such as is partly indicated in the schemes both of Leibnitz and Middleton, for the reception of all Encyclopædical works, of Collections of treatises on various subjects, and Works of authors who cannot with propriety be limited to any one division of knowledge. M. Camus thinks, that the latter description of works may be properly enough entered in the class in which their authors most excelled; those of Cicero, for example, among the *Orators*; ‡ but, not to mention the evident incongruity of placing a collection, so multifarious as Cicero's works, under *Oratory*, there may sometimes be room for uncertainty, as to the division under which, according to this rule, an author's works ought to be sought. These incongruities and inconveniences, together with those which must arise from placing Encyclopædias, and General Collections, under any of the common divisions, can only be remedied by a *Miscellaneous Class*; and while this class ought to indicate, in one of its divisions, the Collective Editions of an author's works, his separate treatises ought to be entered under the subjects to which they belong; as, without this, the Classed Catalogue will not fully answer its purpose, of showing what has been written by the authors contained in it, on the different branches of knowledge. Thus, a Catalogue compiled upon this plan, would not only be rendered more consistent in its arrangement, but much more complete as an index to the materials of study.

IX. *Of Bibliography in general.*

It was our object in this article, to institute such a division of the general subject, as should enable us to point out the best sources of instruction and information in regard to all its branches; and in order to complete our view, we have still to notice some of those works which treat generally of all matters appertaining to Bibliography. We do not know any Book that presents a well written, judicious, and comprehensive digest of these matters; but there are several, nevertheless, which contain much curious and useful information in regard to them. 1. *The Introduction to the Knowledge of Books (Einleitung in*

* *Idea* Leibnitiana *Bibliothecæ Publicæ, Secundùm Classes Scientiarum Ordinandæ, fusior, et contractior.* Works Vol. V.

† *Mém. de l'Instit.* Class, Litterat. et Beaux Arts, Tom. I. p. 483.

‡ *Mém. de l'Instit.* Tom. I. Litt. et Beaux Arts.

Bucherkunde), by M. Denis, whose Supplement to Maittaire, and Bibliographical system, we have already mentioned, is of this description. The last edition, published at Vienna in 1796, consists of two volumes quarto. It has never been translated from the original German; and it is to be observed, that though it treats of the substances, forms, and classification of Books, it cannot be considered as a merely Bibliographical work, a large portion of it being devoted to the general History of Learning. The author, who was long principal Librarian of the Imperial Library at Vienna, died in 1808. In Germany he ranks high, not only as a Bibliographer and general Scholar, but as a Poet. He was the first who made his countrymen acquainted with the Poems of Ossian, by means of a poetical translation, which he published in 1768. His own poetry has much of the spirit and manner of the ancient Bards of the North; but he unfortunately chose hexameters for his translation of Ossian,—a form of verse not at all suited to the genius of the poetry which bears the name of that Bard. We are told, that his brother Poet, Alxinger, who died a year or two before him, had bequeathed his Head to augment the craniological stores and science of Dr Gall; a destination which Denis appears not at all to have relished for his own head, and to have feared that it might yet take it; for, by his testament, he enjoined his executors, in very positive terms, to see his body inhumed without dismemberment.* 2. *Manuel Bibliographique*, ou Essai sur la connoissance des livres, des formats, des editions, la maniere de composer une Bibliothèque, etc.; par G. Peignot, published in 1800. 3. *Dictionnaire raisonne de Bibliologie*, contenant l'explication des principaux termes relatifs a la Bibliographie; des notices sur les plus celebres Bibliographes; et l'exposition des differens systemes Bibliographiques: in 3 vols. 8vo; by the same author. Bibliography is certainly indebted to this industrious compiler; but his vague and extravagant notions of its objects and rank have too often led him into confusion in his Books. 4. *Cours de Bibliographie, ou la science du Bibliothecaire*; par C. F. Achard, in 3 vols. 8vo, published at Marseills in 1807. The chief value of this compilation consists in its details of the different systems which have been proposed for classifying Books. We learn from the Introduction, that M. Francois de Neufchateau, when Minister of the Interior, gave orders that the Librarians of all the Departments should deliver Lectures on Bibliography; but that the plan, which indeed savours somewhat of *Bibliomania*, entirely failed; these Librarians having been found quite incapable to prelect upon their vocation. 5. *Introduction to the Study of Bibliography, to which is prefixed a Memoir on the public Libraries of the Ancients*; by Thomas Hartwell Horne, in 2 volumes 8vo, published at London in 1814. This, which is the only English Book of its kind, is chiefly translated and compiled from the French Bibliographical Works, and will be found useful to those who have not access to them. It contains full lists of Writers on Bibliography and Literary History; and the fullest account we have seen of Catalogues of Libraries both British and Foreign. The specimens of early Typography, and of the Vignettes and Monograms of the early Printers, are very neatly executed.

We do not understand what this writer means, when he describes his Book as intended for "an Introduction to the *infant* Science of Bibliography." He seems to have allowed himself to be imposed upon, by the vague *verbiage* of those French Writers, who claim for this branch of knowledge a character of vastness which does not belong to it. Bibliography certainly presents a pretty wide field of inquiry, and in which there is yet room for many useful works; but it must appear evident from the details contained in the present article, that this field has in almost every part been long cultivated; if not always with perfect taste and judgment, yet with great industry, and so as to yield very profitable returns to the Commonwealth of Learning.

BICHAT (Marie François Xavier), celebrated as an Anatomist and Physiologist, was born in France, at a village called Thoirette, on the 11th of November 1771. Great attention was paid to his education by his father, who was himself a physician, and who initiated him at an early age in those studies which were to prepare him more particularly for the profession to which he had destined him. He studied first at the College of Nantua, and afterwards at a seminary at Lyons; and was early distinguished for that activity of mind and facility in acquiring knowledge, which are the sure presage of great attainments at a mature age. In Mathematics and the Physical Sciences more especially dependant on abstract reasoning, for which he showed a remarkable predilection, he made rapid progress. He afterwards became passionately fond of Natural History, and devoted all his time to this new study. He had already made considerable advances in this branch of science, as he had before done in Natural Philosophy and Mathematics, when his ardour was suddenly checked by the reflection that he was engaging in pursuits that were boundless in their object, and that were in danger of leading him too far from his future profession, through which alone he aspired at celebrity. Bidding a-

Bichât.

dieu, therefore, with a singular effort of resolution, to his favourite occupations, he applied himself at once with great diligence to the study of Anatomy and Surgery, under the guidance of Petit, who was chief-surgeon to the Hotel Dieu at Lyons. It is also curious that, some time after he had fully engaged in this course of instruction, he experienced a relapse of his passion for Mathematics to such a degree, that, yielding to the fascination, he resumed his early studies, in which, however, he had sufficient discretion to restrict himself within such limits as did not interfere with his medical pursuits. Petit soon discerned the superior talents of his pupil; and, although he had scarcely attained the age of twenty, employed him constantly as his assistant in his professional labours. The revolutionary disturbances, which raged with so much fury at Lyons, unfortunately interrupted his progress, in the midst of the flattering prospects which were opening to him: and flying from the horrors of the siege, which that devoted city was about to sustain, he took refuge in Paris, about the end of the year 1793. He there resumed the course of his professional studies, and became the assiduous attendant upon the Lectures of the celebrated Dessault; and in this, as in the former instance, became, in no long time, the companion and friend of his instructor. His merit was brought to the notice of Dessault by an accidental circumstance. It had been an established custom in the school, that the substance of the lecture of the preceding day was to be recapitulated, as an exercise, before the whole class, by one of the pupils, selected for this purpose. It happened one day that the pupil on whom this task devolved was absent at the time when he was expected to perform it, and the Professor asked if any one among his auditory would offer himself as a substitute. Bichât boldly came forward to volunteer his services, and acquitted himself to the admiration of all his hearers. The subject he had to explain was the theory and treatment of fractures of the clavicle. The exact analysis which he made of the instructions contained in the lecture, the copiousness and novelty of his illustrations, and the spirit of order and of method which characterized the whole of his exposition, joined to the modesty with which he stated some doubts, as well as some original views which he had taken of the subject, revealed at once the extent and vigour of his genius, and the expectations which might justly be entertained of his future eminence in his profession. Dessault, in particular, was strongly impressed with the superiority he had manifested over all his other pupils; and from that day he became an inmate in his house, and was treated in all respects as an adopted son. The opportunities which fortune thus placed within his reach were eagerly employed; and the favoured pupil showed himself worthy of the protection and confidence which he received. We find him, between the years 1793 and 1795, actively participating in all the labours of Dessault: visiting his patients both at the hospital and in private, accompanying him every where, as his assistant in his operations, and writing the greater part of his letters, in answer to those who consulted him from a distance. His exertions by no means closed with the day; and he passed a great portion of the night in assisting to conduct the experimental researches on the diseases of bones, in which that able surgeon was engaged, and in consulting, previous to each lecture, the works of the ancient authors on the subjects to which they related. Whatever Dessault expressed a desire to have done, and he often required more than an ordinary person would have supposed it possible to perform, was sure to be accomplished within the requisite time by his indefatigable pupil. Notwithstanding these multiplied occupations, Bichât found means to prosecute his own researches in Anatomy and Physiology, to which he devoted every interval of leisure he could seize. The sudden death of Dessault, who was snatched from the world in the meridian of his fame, was a severe stroke of adversity to Bichât; but the event, though it deeply afflicted, did not discourage him: and though it might interrupt for a time, did not eventually relax his efforts at advancement. His first care seems to have been to acquit himself of the obligations he owed his benefactor, by contributing to the support of his widow and her son; and by conducting to a close the fourth volume of Dessault's *Journal de Chirurgie.* To this volume he subjoined a biographical memoir of its author, in which he pays a just tribute to his merit. His next object was to reunite and digest in one body the different surgical doctrines which Dessault had advanced in fugitive papers, published in various periodical works. Of these he, in 1797, composed a work, in two volumes octavo, entitled *Œuvres Chirurgicales de Dessault, ou Tableau de sa Doctrine, et de sa Pratique dans le Traitement des Maladies Externes:* a work in which, although he professes only to explain the ideas of another, he developes them with the clearness and copiousness of one who is in perfect possession of the subject which he treats. He was now at liberty to pursue the full bent of his genius, and soon arrived at those comprehensive and masterly views of Physiology, which, when afterwards developed in his writings, gained him so much applause. Undisturbed by the storms which agitated the political world, he pursued with steadiness the course he had meditated, and directed his more immediate attention to Surgery, which it was then his design to practise. We meet with many proofs of his industry and success, at this period, in the *Recueil de la Société Médicale d'Emulation*, an association of which Bichât was one of the most zealous and active members. Three memoirs which he communicated, were published by the Society in 1796; the first, describing an improvement in the instrument for trepanning; the second, detailing a new process, which he devised for the ligature of polypi; and the third, in the distinction to be observed in fractures of the clavicle, between those cases requiring the assistance of art, and those in which its interference would be of no avail. In 1797, we find him undertaking the arduous task of instructing others, which he commenced by a course of anatomical demonstrations. Not expecting any great number of pupils, he had hired a small room for the purpose; but his merit as a

teacher soon attracted a crowd of auditors; he was obliged to enlarge his theatre, and was also encouraged to extend the plan of his lectures, and to announce what had hitherto never been attempted by one so young and inexperienced, a course of operative surgery. If the boldness of the enterprise was calculated to excite surprise, his success in the execution of it was still more astonishing. His reputation was now fully established, and he was ever after the favourite teacher with the students who resorted to the capital. In the following year, 1798, he gave, in addition to his course on Anatomy and operative Surgery, a separate course of Physiology. But the exertion of speaking, which these numerous courses of lectures, all of which he conducted at the same time, required, was more than his frame could bear; and a dangerous hæmoptysis, with which he was seized in the midst of his labours, obliged him to interrupt them for a time, and warned him that there are limits to human strength. But the danger was no sooner passed, than the lesson seems to have been disregarded; for we find him plunging into new engagements with the same ardour as before. He had now scope in his physiological lectures for a fuller exposition of his original views in the animal economy, which were no sooner made known to his pupils, than they excited much attention in the medical schools at Paris; and he was induced to publish them in a more authentic form. Sketches of these doctrines were given by him in three papers contained in the Memoirs of the *Société Medicale d'Emulation.* The first is on the synovial membranes; in which he gives a more clear description of the organ that secretes synovia, a fluid, the origin of which had been a matter of much controversy. The next contains an account of the membranes of the human body in general, which he considers apart from the organs they invest and support, and which they serve to supply with vessels; and regards as performing offices in the economy distinct from those of the organs with which they are so connected. His last memoir relates to the symmetry, which is so remarkable a feature in all those parts of the body that are the instruments of the animal functions, and which establishes so exact a similarity between the limbs and organs of sense on each side of the body; while, on the other hand, no such regularity can be traced in the forms and dispositions of the viscera, which, like the heart, the stomach, liver, and other organs of assimilation, are subservient to the vital functions. He even assumes this difference as the foundation of a marked distinction between these two classes of functions; the one, being common to all organized beings, he denominates organic; the other, as exclusively pertaining to animality, he denotes by the name of animal functions. The doctrines contained in these memoirs were afterwards more fully developed in his *Traité sur les Membranes,* which appeared in 1800, and which immediately drew the attention of the medical world both at home and abroad. Some time previous to this, he gave to the public a small work, in which he endeavoured to bring together, in a condensed form, the lessons of Dessault relative to the diseases of the urinary passages; in the notes to this volume, we may perceive the germ of many of those views which were peculiar to Bichât.

His next publication was the *Recherches Physiologiques sur la Vie et sur la Mort,* in 1800, which consists of two distinct dissertations. In the first, he explains at still greater length than he had previously done, his classification of functions, and is at pains to trace the distinction between the animal and organic functions in all its bearings. In the second, he investigates the connection between life and the actions of the three central organs, the heart, lungs, and brain, on which its continuance so essentially depends. But the work on which he bestowed the most attention, and which contained the fruits of his most profound and original researches, is the *Anatomie Génerale,* which was published in four volumes octavo in 1801. It is founded on his classification of the parts of the body, according to their intimate structure; in order to establish which, he decomposes the animal machine, not merely into the larger pieces of which it is formed, but into the organic elements that constitute them. Of these elementary parts or textures, as he terms them, into which every organ may be ultimately analyzed, he enumerates twenty-one different species. He conceives each of these textures to possess a peculiar modification of vitality, from which it derives those properties that distinguish it from dead matter, and that give rise to all the phenomena of the animal economy, both in a healthy and diseased state.

Before Bichât had attained the age of eight-and-twenty, he was appointed physician to the Hotel Dieu, a situation which opened an immense field to his ardent spirit of inquiry. In the investigation of diseases, he pursued the same method of diligent observation and scrupulous experiment, which had characterized his researches in physiology. He learned their history, not from books, but by studying them at the bedside of his patients, and by accurate dissection of their bodies after death. He engaged in a long series of examinations, with a view to ascertain the exact changes induced in the various organs by diseases, which he conceived, in every instance, primarily to affect some one of their constituent textures, while the rest did not suffer any change, unless by the supervention of some other disease. In the prosecution of these inquiries, he had, in less than six months, opened above six hundred bodies. As intimately connected with the practical exercise of the healing art, he was anxious also to determine, with more precision than had hitherto been attempted, the effects of remedies on the body. It must be confessed, that our knowledge of the operation of remedies is, for the most part, extremely vague and conjectural; and it appeared to him an object of great importance to rescue this branch of science from the uncertainty in which a multitude of points relating to it were still involved, by applying to it the same methods of inductive reasoning as have, in other sciences, been attended with so much success. The basis of the inquiry was to be laid by collecting a sufficient number of facts to admit of their being compared and generalized. A large hospital could

alone furnish the means of conducting such an investigation; and Bichât eagerly availed himself of the opportunities which his appointment at the Hotel Dieu now afforded him, of instituting on these subjects a series of direct experiments on a very extensive scale. He began by giving singly different medicinal substances, and then watching attentively the phenomena that ensued. He then united them in various ways, first joining two together, then three, and so proceeding to more complicated combinations; and observed the particular changes in their mode of operating, which resulted from their being thus combined. So wide a range of experiments, it is evident, could not have been conducted without assistance; and he selected forty of his young pupils to aid him in collecting the requisite observations. He had already, in this way, procured a vast store of valuable materials for his course of Lectures on the Materia Medica, the completion of which was unfortunately prevented by his untimely death; but a great part of the facts were subsequently published in the inaugural dissertations of his pupils. Latterly, he had also occupied himself with framing a new classification of diseases.

During these arduous vocations, he never lost sight of his anatomical pursuits, and had commenced a new work on the subject, in which the organs were arranged according to his peculiar classification of their functions, under the title of *Anatomie Descriptive.* He lived only to publish the two first volumes of this work. It was, however, continued on the same plan, and completed in three volumes more, by Messrs Buisson and Roux, who had been his most active assistants, and who appear to have been perfectly master of his ideas on the subject. His death was brought on by a fall from a staircase at the Hotel Dieu; and although the accident did not at first appear serious, it excited so great a degree of fever, that his frame, already exhausted by excessive labour, and enfeebled by constantly respiring the tainted air of the dissecting-room, in which he had latterly passed the greater part of his time, sunk under the attack. He died July 22, 1802, universally regretted by his pupils, and attended to the last by the widow of his benefactor, from whom he had never been separated. Every tribute of respect was paid to his memory; his funeral was attended by above six hundred of his pupils, and by a number of the Physicians in Paris. His bust, together with that of Dessault, was placed at the Hotel Dieu by order of the First Consul, in joint commemoration of the man under whose fostering protection so bright a genius was first brought before the public, and of the pupil who nobly emulated the fame of so great a master. We cannot, indeed, refrain from admiration, when we contemplate all that Bichât has done in his profession in so short a period of time, nor sufficiently lament that a career so auspiciously begun, should, at the age of thirty, have been so suddenly and prematurely terminated. (w.)

BILFINGER (George Bernard), born 23d January 1693, at Canstadt in Wurtemburg, acquired considerable celebrity as a Philosopher and Statesman. His father was a Lutheran minister. By a singularity of constitution, hereditary in his family, Bilfinger came into the world with twelve fingers on his hands, and twelve toes. An amputation happily corrected this deformity. Bilfinger, from his earliest years, discovered the greatest inclination to learning, and made himself remarkable by his fondness for meditation. He studied in the schools of Blanbeuern and Bobenhausen, and afterwards entered into the Theological Seminary of Tubingen. The works of Wolf, which he studied in order to learn Mathematics, soon inspired him with a taste for the Wolfean Philosophy, and that of Leibnitz; a passion which made him neglect, for some time, his other studies. Returning to Theology, he wished, at least, to try to connect it with his favourite science of Philosophy, and in this spirit composed a tract, entitled, *De Deo, Anima, et Mundo.* This work, filled with new ideas, met with great success, and contributed to the advancement of the author, who was appointed soon after to the office of Preacher, at the Castle of Tubingen, and of Reader in the school of Theology: but Tubingen was now become too small a theatre for him. He obtained from his friends, in 1719, a supply of money which enabled him to spend some time at Halle, in order to pursue the lessons of Wolf, and after two years of study, he returned to Tubingen, where the Wolfean Philosophy was not yet in favour. He found his protectors there cooled, saw his lectures deserted, and perceived himself shunned, from the dislike of his new doctrines: his ecclesiastical views also suffered from it. This unpleasant situation lasted almost four years, when he received, by the intervention of Wolf, an invitation to go to Petersburg, where Peter I. wished to appoint him Professor of Logic and Metaphysics, and member of his new Academy. He was received in this city, where he arrived in 1725, with the consideration due to his abilities. The Academy of Sciences of Paris having proposed, about this time, the famous problem, on the cause of Gravity, Bilfinger gained the prize, which was a thousand crowns. The reputation of this success was spread abroad among all the learned of Europe. All the journals repeated it; and the Duke Charles Edward of Wurtemburg, finding that the author of this admired Memoir was one of his subjects, hastened to recal him into his dominions. The court of Russia, after having made some useless attempts to detain him, granted him a pension of four hundred florins, and a present of two thousand, in reward of an invention relative to the art of fortification. He quitted Petersburg in 1731. Returned to Tubingen, Bilfinger soon excited considerable attention in that quarter, both by his own lectures, and by the changes which he introduced in the school of Theology. The whole University prospered under his care; and this establishment is conducted to this day according to his excellent regulations. Without overturning any thing in the foundation of Theology, he succeeded in applying his system of Philosophy to this science, exhibiting, it is said, in his deductions, and in his proofs, a method, a justness, and a clearness, which bespoke a mind long exercised in deep and rigorous investigations. The Duke Charles Alexander, who succeeded

Bilfinger. Edward, had already had occasion to appreciate his talents, and put them to use. At the time when he carried on the war in Servia, he maintained a regular correspondence with Bilfinger, who had long been known as an able Engineer, and had, indeed, made some improvements of value in the received system of Fortification. After his return to Tubingen, he had frequent conversations with the Professor on different subjects of administration, and appointed him, in 1735, Privy-Counsellor. This nomination was not a simple honorary title. Bilfinger saw himself raised at once to a power almost unlimited. He resisted some time a promotion, which he did not think himself qualified to sustain. In accepting office, his first care was to acquire all the knowledge necessary to the discharge of its duties. He employed almost two years in assiduous labour to instruct himself thoroughly in the statistics of the country, in considering its political situation, its constitution, its interests, and became, at the end of all this study, one of the most enlightened ministers that his country had yet produced. Bilfinger was placed in a situation too elevated not to excite jealousy and hatred. He felt it, and wished to quit the ministry; but the court refused to receive his resignation, soon after the tender of which, the Duke died. Bilfinger experienced from his successor all the consideration and all the friendship which he had experienced in the beginning of his career. Received into a confidence without bounds, he had the power to realize, without obstacle, those plans of administration with which the most enlightened patriotism had inspired him. Wurtemberg still feels the happy influence of his ministry. Commerce, public instruction, agriculture, were protected and ameliorated by his cares. The culture of the vine, of so much importance in this country, was one of the principal objects of his attention. We ought not to forget that he was the original author of that strict union which has long united Wurtemberg and Prussia, and of the importance to which the hereditary Prince of Wurtemberg was raised at the court of Berlin. In 1737, the Duke nominated him President of his consistory, and Secretary of the grand Order of the Chace. He was also Curator of the University of Tubingen, and member of the Royal Academy of Berlin. All his time was consecrated to some serious occupation, with the exception of one hour in the evening, which he employed in making and receiving visits. His greatest enjoyment was in cultivating his garden. A warm and strong friend, he gave many proofs of gratitude to those protectors, who had generously assisted him in his studies. He has been reproached with being irascible; but in spite of some slight blemishes, the memory of Bilfinger will be always dear to his countrymen, and honoured by all Germans. Wurtemberg reckons him among the greatest men which she has produced, and proposes him as a model to her statesmen and her men of letters. He was never married, and left no issue. He died at Stuttgart the 18th of February 1750. His works, besides various Papers published in the Memoirs of the St Petersburg and Paris Academies of Science, are:

1. *Disputatio de Harmoniâ præstabilitâ*, Tubingen, 1721, in 4to.
2. *De Harmoniâ Animi et Corporis Humani maximè præstabilitâ Commentatio Hypothetica*, Francfort on the Main, 1723, in 8vo. This work was inserted in the Expurgatory Index at Rome in 1734.
3. *De Origine et Permissione Mali, præcipuè Moralis, Commentatio Philosophica*, ibid. 1724, in 8vo.
4. *Specimen Doctrinæ Veterum Sinarum Moralis et Politicæ*, Francf. 1724, in 4to.
5. *Dissertatio Historico-cataptrica de Speculo Archimedis*, Tubingen, 1725, in 4to.
6. *Dilucidationes Philosophicæ de Deo, Animâ Humanâ, Mundo, et Generalibus Rerum Affectionibus*, ibid. 1725, in 4to.
7. *Bilfingeri et Holmanni Epistolæ de Harmoniâ Præstabilitâ*, 1728, in 4to.
8. *Disputatio de Naturâ et Legibus Studii in Theologiâ Thetici*, ibid. 1731, in 4to.
9. *Disputatio de Cultu Dei Rationali*, ibid. 1731.
10. *Notæ Breves in Ben. Spinosæ Methodum Explicandi Scripturas*, Tub. 1732, in 4to.
11. *De Mysteriis Christianæ Fidei Generatim Spectatis Sermo, Recitatus* 1732, Tubingen, 1732, in 4to.
12. *Elementa Physices*, Leipzig, 1742, in 8vo.
13. *La Citadelle Coupée*, Leipzig, 1756, in 4to.

BILLS OF MORTALITY.

Bills of Mortality.

BILLS OF MORTALITY are abstracts from parish registers, showing, as their name imports, the numbers that have died in any parish or place during certain periods of time, as in each week, month, or year; and are, accordingly, denominated weekly, monthly, or yearly bills. They also include the numbers of the baptisms during the same periods, and generally those of the marriages.

What has been advanced on this subject, under the head MORTALITY, BILLS OF, in the *Encyclopædia*, appears to have been taken from Dr Price's *Observations on Reversionary Payments;* and is designed principally, to explain the method of constructing *Tables of Mortality* from such *Bills*, which shall exhibit the law according to which human life wastes at every age, and shall enable us to determine readily, the probability of its continuance from any one age to any other; a subject which will be treated in this *Supplement* under the head MORTALITY, LAW OF.

Objects of this Article.

The objects of the present article are these:—First, to give a brief history of the principal things that have been done in this way, which may suffice for such as are not disposed to go further into the subject, and may, at the same time, indicate the best sources of information to those who take more interest in it.

As both mortuary registers and enumerations of the people are much more valuable when combined than when separate, we shall also notice some of the principal enumerations, the results of which have been published. We shall then point out some of the principal defects in most of the published registers and enumerations; and, lastly, shall submit some forms, according to which, if enumerations be made, and registers kept, they will be easily convertible to useful purposes.

History.

The ancients do not appear to have kept any exact mortuary registers, at least no account of any registers of that kind, with the ages of the deceased, have come down to us; and although, in the Roman *Census*, first established by SERVIUS TULLIUS, both the ages and sexes of the people were distinguished, we have no exact account of these particulars in any one of their enumerations.

Indeed, the principal object of the *census* among that warlike people, was the levying of men and money for the purposes of conquest; the duration of human life appears to have occupied very little of their attention, and their proficiency in the science of quantity was not sufficient either to show them what the necessary *data* were, or to enable them to draw just inferences from them, had they been in their possession.

A good account of what the ancient Romans did in this way, with references to the original authorities, may be found in the Italian translation of M. Demoivre's *Treatise of Annuities on Lives*, by Gaeta and Fontana, which was published at *Milan*, in 8vo, in the year 1776. (*Discorso Preliminare, Parte* 2.)

The keeping of parish registers commenced in England in the year 1538, in consequence of an injunction issued in that year by Thomas Cromwell, who, after the abolition of the Pope's authority in this kingdom, in the reign of Henry VIII., had been appointed the King's vicegerent in ecclesiastical affairs.

Some parish registers in Germany appear to have commenced with the sixteenth century; and in the *Göttliche Ordnung* of Süssmilch (T. 3. S. 23.), we are informed, that at the time of Lord Cromwell's injunction, they had already old registers of that kind, both at Augsburgh and Breslaw. However, the extracts he has given from the Augsburgh registers do not go back further than the year 1501, nor those for Breslaw beyond 1555. About the beginning of the seventeenth century, such registers appear to have been established in most parts of Europe; but it was not until the year 1662 that they began to attract public notice, and to be considered as the sources of valuable and interesting information.

Mr Graunt.

In that year, John Graunt, a citizen of London (afterwards an officer in the trained bands of the city, and a Fellow of the Royal Society), published his *Natural and Political Observations on the Bills of Mortality*, principally those for London. The London bills, or accounts of baptisms and burials, appear to have been occasioned by the plague, and to have been begun in the year 1592, a time of great mortality. They were afterwards discontinued, but were resumed in 1603, after the great plague of that year. They have ever since been continued weekly, and an annual bill also has been regularly published. In 1629, the number of deaths by the different diseases and casualties, were first inserted in them, also the distinction of the sexes; and these have been continued ever since. But it is in the totals only of the baptisms and burials that the sexes are distinguished in these bills. They do not show how many of each sex died of each disease, neither have they, since 1728, when the distinction of the ages of the dead was first introduced, shown how many of each sex died in each interval of age, but only the total number of both sexes.

This book of Graunt's, although the first, is also one of the best that have been published on the subject. It contains many judicious observations on the imperfections of the bills, on the proportions of the deaths from different diseases and casualties, and on their increase and decrease, with the probable causes of such fluctuations. He also observed, that "the more sickly the years are, the less fecund or fruitful of children also they be."

Besides the London bills, he gave one for a country parish in Hampshire, in the first edition of his

Bills of Mortality.

book; and, in an appendix to the later editions, two others, one for Tiverton, the other for Cranbrook in Kent, with a few observations on foreign bills. He almost always reasons justly from his *data*; but, as these were very imperfect, in his endeavours to draw more information from them than they could supply, he has sometimes fallen into error.

Even in this enlightened age, when a much greater proportion of the people devote a portion of their leisure to the acquisition of knowledge than in Graunt's time, subjects of this kind have but few attractions for the generality even of reading men, who cannot endure the fatigue of thinking closely for any length of time. The author, accordingly, expected his readers to be rather select than numerous, and was ambitious of that distinction, as appears by the motto he prefixed to his work,

——Non, me ut miretur Turba, laboro,
Contentus paucis Lectoribus.——

The book was, however, favourably received by the public, and went through five editions in fifteen years, the two first in 4to, the three others in 8vo; the last of them, published in 1676, two years after the author's death, was edited by his friend, *Sir William Petty*, who, in consequence of having sometimes spoken of this edition as his own, has by some writers been erroneously considered as the author.

Graunt's observations, like all others of a similar kind, by showing the usefulness of parish registers and bills of mortality, contributed to form a taste for these inquiries among thinking men; and, consequently, to improve both the registers and the bills derived from them; so that, from his time, the subject has been continually cultivated more and more. Parish registers, in most parts of Europe, have been kept with more care; and a succession of works of considerable merit have been published on the subject, containing an important part of the natural and political history of our species, and affording valuable materials for the science of political economy.

The principal of these works we proceed to give a short account of, in the order of their publication.

As the ages at which the deaths took place were not inserted in the London bills till 1728, Captain Graunt could not avail himself of that important information, but made a fruitless attempt to determine the law of mortality without it.

Halley.

The Breslaw bills appear to have been the first wherein the ages at which the deaths took place were inserted, and the most important information which Bills of Mortality can afford, was first drawn from them by Dr Halley; who, in 1692, constructed a table of mortality for Breslaw from these bills for the five preceding years, and inserted a paper on the subject in the *Philosophical Transactions*, No. 196.

Davenant and Gregory King.

In 1699, Dr Davenant, in *An Essay upon the probable Methods of making a People Gainers in the Ballance of Trade*, published some extracts from *Natural and Political Observations and Conclusions upon the State and Condition of England*, by permission of their author, Gregory King, Esq. Lancaster herald, who had completed them in 1696, though they still remained in manuscript; and the whole of this very curious production was published by Mr Chambers at the end of his *Estimate* in 1802. Mr King derived his information from the poll-books; from actual observations in particular places; from the assessments on marriages, births, and burials; and from the parish registers. Many of his conclusions agree surprisingly well, considering the time he wrote, with those which are the results of a hundred years of further observations and inquiries. He had access to much better *data* than Graunt, and his conclusions are more accurate; but he does not explain so fully how he arrived at them.

M. Kerseboom.

From the publication of Davenant's essay, above mentioned, nearly forty years had elapsed without any thing further being done in this way, when M. Kerseboom published an essay, in the Dutch language, on the probable number of people in Holland and West Friesland, which he deduced from the Bills of Mortality (Hague, 1738, 4to); and two others in 1740 and 1742: an account of the first of these three essays may be seen in the *Philosophical Transactions*, No. 450, and of the two others in No. 468.

J. P. Süssmilch.

In 1742 was published the first edition of the celebrated work, entitled *Die Göttliche Ordnung in den Veränderungen des menschlichen Geschlechts aus der Geburt, dem Tode und der Fortpflanzung desselben erwiesen von* Johann Peter Süssmilch. The second edition appeared in 1761, enriched with the materials which had been laid before the public through various channels in the interim; the third in 1765, and in 1775 a fourth edition of the two volumes of Süssmilch was published by Christian Jacob Baumann, to which this editor himself added, in 1776, a third volume, consisting of additions to the other two, and remarks upon them, with many new tables, and a copious index. The last edition of this work was published in 1798, but it does not appear to have been augmented or improved since 1776. It contains long dissertations on every thing not mathematical connected with the subject, and, besides original information, includes the substance of all the other publications on it previous to 1776; with an immense collection of materials, which, when borrowed, are often better arranged and rendered more convenient for reference, than they will be found to be in the works they were extracted from; besides, the original sources of information are always referred to, and these advantages, with that of a full index, render it a valuable work for occasional reference. The three thick 8vo volumes contain upwards of 2300 pages, closely printed with a small type, and the tables alone occupy 330 pages.

J. Baumann.

M. Deparcieux.

In 1746 was published the *Essai* of M. Deparcieux, which has been already mentioned in the historical introduction to the article ANNUITIES in this Supplement: information much wanted on this subject, was there given in a very clear and popular manner, and the work no doubt contributed greatly to the advancement of the science. It probably had some influence in promoting the establishment of what is called the *Tabellvärket* in Sweden, which

Bills of Mortality.

took place in 1749, and of which we shall have occasion to take further notice presently.

Dr Short.

In 1750 appeared, in 8vo, *New Observations natural, moral, civil, political, and medical, on City, Town, and Country Bills of Mortality; to which are added, large and clear Abstracts of the best Authors who have written on that subject; with an Appendix of the Weather and Meteors*, by Thomas Short, M.D. which he had "had on the anvil" for eighteen years, as he informs us in the Preface to his *History of Air, Weather*, &c. This author, with incredible labour, collected extracts from the mortuary and baptismal registers in a great many market-towns and country parishes in England, chiefly in the northern counties, in almost every variety of soil and situation, and reduced them into tables in various ways, so as to enable him to draw useful inferences from them.

He informs us that Lord Cromwell's injunction in 1538 was but little regarded in many places till the year 1559, when another was issued for the same purpose by Queen Elizabeth; nevertheless, he had procured several exact country registers, commencing with 1538, and continued, without one chasm, for more than two hundred years; and the registers before 1644, he considered to be much more valuable than afterwards, on account of the increase of dissenters from that time. He likewise procured both the numbers of families and of souls in seven of the market-towns, and fifty-four of the country parishes, for which he had registers; and thus arrived at satisfactory information on several points, which, till then, had been very imperfectly understood. But the sexes were not distinguished in his enumerations; neither were the ages, in any of the enumerations or registers he has given accounts of, except in the London Bills of Mortality, and what he has taken from Dr Halley, respecting those for Breslaw.

Although Dr Short took so much trouble in collecting materials, and has generally reasoned well upon them, he has shown but little skill, and does not appear to have taken much pains in communicating his information to his readers; so that it costs them considerable labour to find what they want, especially in his tables; and when found, to understand it.

Mr Morris.

In 1751 was first printed a tract by Corbyn Morris, entitled, *Observations on the past growth and present state of the City of London*, with the most convenient and instructive tables of the London bills that have been printed: they contained the annual baptisms and burials from the year 1603, the number of annual deaths by each disease from 1675, and of each age from 1728; all brought down to the year 1750. This tract was reprinted in 1758, with a continuation of the tables to the end of 1757; these also contain useful annual averages and proportions. Mr Morris's observations are generally very judicious, but he was one of those authors who appear to have laboured under much misconception with regard to the evils to be apprehended from the mortality of London, and what they considered to be its baneful effects in drawing recruits from the country. These writers did not perceive, or did not sufficiently consider, that the natural procreative power is much more than adequate to supply any waste of that kind, and that the real obstacle to the increase of the people, is the limited means of subsistence. This had been observed by Dr Halley in his *Further Considerations on the Breslaw Bills of Mortality* (*Phil. Trans.* 1693), though it there also appears, that he had not sufficiently considered the mode of its operation: this was first fully illustrated by Dr Franklin in his excellent *Observations on the Increase of Mankind, Peopling of Countries*, &c. written in Philadelphia in 1751, the same year in which Mr Morris's pamphlet was first published. The author also pointed out in that pamphlet, material defects in the Bills of Mortality, and proposed a better method of keeping them, not only in London, but throughout the kingdom. This gave occasion to a paper by Mr James Dodson, which was inserted in the *Philosophical Transactions* for that year (1751), wherein he showed the importance of their being so kept as to afford the means of valuing annuities on lives, and proposed other alterations which appeared to him calculated to fit them for the purpose.

Mr Dodson.

Nicolaas Struyck.

Nicolaas Struyck of Amsterdam, who, in his *Introduction to General Geography*, published there in 1740, had inserted *(Gissingen over den staat van 't Menschelyk Geslagt) Conjectures on the State of the Human Species*; published at the same place in 1753, a quarto volume, the first half of which is astronomical, the other (216 pages) is entitled *(Nader Ontdekkingen noopens den staat van het Menschelyk Geslagt), Further Discoveries concerning the State of the Human Species.* It contains statements of actual enumerations of the people in many Dutch villages, principally in North Holland, wherein the sexes are distinguished, and the numbers in childhood, celibacy, marriage, and widowhood; but with respect to their ages, it is only stated for each sex, how many were under ten years, and how many of the unmarried were above that age; except in two instances, wherein the number of each sex is given in each interval of five years of age, from birth to the extremity of life: they amount altogether to 2728, of whom not one was above the age of 85, and only four above 80.

He generally gives, for each place, the names and professions or occupations of the persons who made the enumeration, and the precise day on which it was made; or if it occupied the parties more days than one, those on which it was commenced and completed are given; a practice which shows a laudable solicitude about particulars, and a title to our confidence, the want of which we have great cause to lament in too many other writers.

Extracts from many parish registers are also given; in these, too, the ages are seldom noticed; but in a few cases they are given very minutely, especially in that of Westzaandam, for which, the numbers who died in each interval of five years of age, from birth to the extremity of life, are given; also the number in each year of age under fifteen, the number in each month of the first year of age, even the number that died in the first hour from birth, in the first twenty-four hours, and in each day of the first week of their age. During a term of nineteen years, the whole number of deaths thus registered was 3328;

but the sexes were not distinguished under fifteen years of age, which Struyck himself lamented. The work also contains much information respecting the population and parish registers of *Amsterdam*, *Haarlem*, &c. with some accounts of other countries, and of other works on the subject.

Dr Birch.

In 1759 was published, at London, in 4to, *A Collection of the Yearly Bills of Mortality, from* 1657 *to* 1758 *inclusive, together with several other Bills of an earlier date;* to which were subjoined Captain Graunt's *Observations; Another Essay in Political Arithmetic,* by Sir William Petty; the *Observations of Corbyn Morris, Esq.;* and *A Comparative View of the Diseases and Ages, with a Table of the Probabilities of Life for the last thirty years,* by J. P. Esq. F. R. S. This is a valuable compilation, and has been generally attributed to Dr Birch, the Secretary and Historian of the Royal Society; the preface is very judicious, and contains a good deal of information. For the following history of this publication, the author of the present article is indebted to the kindness of Dr Heberden :—

"The bills were collected into a volume by his father, the late Dr Heberden. He procured likewise, observations from several of his friends, rectors of some large parishes, or others likely to give him information; particularly from Bishop Moss, Bishop Green, Bishop Squire, and Dr Birch. These, together with some of his own remarks, were thrown into the form of a preface; and the whole was committed to the care of Dr Birch. To make the calculations which appear at the end of the book, Dr Heberden employed James Postlethwayt, Esq. a very distinguished arithmetician."

M. Messance.

In the year 1766, this branch of knowledge was enriched with new materials, of more value than all that had previously been laid before the public. These were contained in three publications, of which we shall first notice the *Recherches sur la Population des généralités d'Auvergne, de Lyon, de Rouen, et de quelques Provinces et Villes du Royaume. Par M. Messance, Receveur des Tailles de l'Election de Saint Etienne.*

Most of the political writers in France, for some years previous to the date of this publication, had asserted confidently that the kingdom was depopulated, but without producing any proofs. The object of M. Messance was, to enable his readers to judge of the merit of such assertions, and to pronounce less vaguely on a subject in itself so interesting, the knowledge of which can only be obtained by a great number of facts and actual observations. The work, accordingly, is filled with tables, exhibiting the results of actual enumerations of the people, and of extracts from the parish registers. They show, for each sex, how many were under 14, or in celibacy above that age; those in the states of marriage and of widowhood; and the number of domestic servants. The numbers of families are also stated; and the enumerations of the ecclesiastics, properly classed, are given separately; but no other information respecting the ages of the living is given than that mentioned above. A great many statements are also inserted of the numbers that died in different parishes, and more extensive districts, under 5 years of age, between 5 and 10, and in each interval of 10 years, from thence to the age of 100; during different periods of from 10 to 40 years, or more, generally ending about the year 1760; but in these the sexes are not distinguished.

In all cases, he has given the general results of his tables, and the proportions they afford, very distinctly stated; and among these results, the increase of the population during the preceding 60 years, to which his researches were generally limited, is clearly ascertained.

The work also contains many interesting tables, in which the rate of mortality, and the produce of manufacturing labour, are compared with the contemporaneous prices of grain, in various places, generally for periods of 20 years each.

M. Muret.

In the same year was published, at Yverdon, in 8vo, the work entitled *Mémoire sur l'état de la Population, dans le Pays de Vaud, qui a obtenu la prix proposé par la Société œconomique de Berne. Par M. Muret, premier Pasteur à Vevey, et Secretaire de la Société Œconomique de Vevey.*

The Pays de Vaud contains 112 parishes, and the population at that time was about 113,000 souls. M. Muret wrote for information to all the clergymen in the country, who made him returns of the numbers of baptisms and burials in their respective parishes, for different periods, from 10 to 40 years, in many of which both the ages and sexes were distinguished; and from about two-thirds of them he obtained also the numbers of marriages and families actually subsisting; also the number of souls, "or at least of communicants," in their parishes: but neither the ages nor sexes were distinguished in any of the enumerations of the living.

This performance does much credit both to the author's industry and judgment, but it has also material defects. He gave upwards of 50 tables, by which he intended to show the probabilities and expectations of life till five years of age, and at every fifth year after that, in different parishes and places, under various circumstances of soil and situation, and for people of different habits and occupations; also for the two sexes separately. These must have cost him a good deal of labour, and would have been extremely valuable had they been correct; but, unfortunately, he did not understand the construction of such tables, and they are not to be depended upon. He also took considerable pains to determine the rates of mortality among married and single women, considered separately, and thought he had proved that it was less among the married; but the proofs he adduced were not conclusive. Some of his observations on the state of the population, and the plans he recommended for increasing it, also show, that he did not understand the principle on which its progress depends.

It is with much reluctance that we make, on so respectable an author, remarks which apply equally to almost all his predecessors in these inquiries; but this we consider to be rendered necessary, by the *Memoir* generally, and the Tables in particular, having been praised for their extreme accuracy, in a

Bills of Mortality. very good abridgment of them, inserted in the second volume of a book, entitled *De Re Rustica, or the Repository*, 8vo, London, 1770.

The disadvantages of her soil and climate necessarily keep Sweden thinly peopled in comparison with the countries which, in these respects, are more happily circumstanced; and since the year 1748, the state of the population has been an object of anxious solicitude with the government; which, in 1749, established what, in this country, would probably be called a Board of Population (but is there denominated *Tabellvärket*), for reducing into convenient forms the extracts from the parish registers, and the returns from the magistrates of the numbers of the people, which the governors of the different provinces are required to state to the commissioners appointed for these purposes. The extracts from the registers are made and transmitted annually, but the enumerations only once in three years.

Printed forms, with proper blanks, distinguishing the ages and sexes, both of the living and the dead, with the diseases the deaths were occasioned by, are distributed throughout the country, to enable the people to make these returns correctly and uniformly; and the information thus acquired, respecting the state of population and mortality, is much more correct and satisfactory than what has been obtained in any other place of considerable extent; but from causes which we have not room to explain here, the results were not laid before the public until some years after the returns were made.

M. Wargentin. M. Wargentin, who was one of the Commissioners of the Tabellvärket, inserted in the *Transactions of the Royal Academy of Sciences at Stockholm, for the years* 1754 *and* 1755, papers on the usefulness of annual registers of births and deaths in a country; which, like all his other productions, were written with much judgment and modesty; but, to illustrate the subject, he was generally under the necessity of borrowing materials from the writings of others; as, at that time, he was only in possession of the results of the Swedish returns for the single year 1749. In the same *Transactions*, for the year 1766, he inserted a paper on the mortality in Sweden, wherein he gave tables exhibiting the number of the living of each sex in each interval of age, in the years 1757, 1760, and 1763; also the number of annual deaths of each age and sex during a period of nine years, commencing with 1755, both for all Sweden and Finland, and for Stockholm separately; with other interesting results of the registers and enumerations, and many judicious observations upon them.

This paper of M. Wargentin's is more valuable than all that had previously been published on the subject; it is also to be found in the French abridgment of the Stockholm *Transactions*, in the eleventh volume of the *Collection Académique* (*partie étrangere*), which abridgment was also published separately, at Paris, in 1772.

In 1767, Dr Short published, in 4to, *A Comparative History of the Increase and Decrease of Mankind*, in which the tables are printed more intelligibly, and there is more information respecting foreign Bills of Mortality, than in his *New Observations*.

Dr Price. The first edition of Dr Price's *Observations on Reversionary Payments* appeared in 1771, and contained "observations on the expectations of lives, the increase of mankind, the number of inhabitants in London, and the influence of great towns on health and population," which had been published in the *Philosophical Transactions* for 1769, and added considerably to the information on those subjects which had been previously before the public; also observations on the proper methods of constructing tables of mortality, mentioned at the commencement of this article, and which we shall have occasion to notice again.

Dr Haygarth. In the *Philosophical Transactions* for the years 1774 and 1775, were inserted two excellent papers by Dr Haygarth of Chester, wherein he gave the Bills of Mortality for that city, for the years 1772 and 1773 respectively, in a form calculated to exhibit, at one view, the most useful and interesting information such bills can afford without calculation, and presenting to the calculator *data* that are essential to the solution of the most important questions respecting the state of the population. Three papers by Dr Percival (also of considerable merit) appeared in the same *Transactions* about this time, relating principally to the population of Manchester and its neighbourhood.

Dr Percival.

M. Moheau. In 1778 was published, at Paris, in 8vo, the work entitled *Recherches et Considérations sur la Population de la France*, par M. Moheau. This book is agreeably written, in a way entirely popular, and will probably be perused with more pleasure, therefore, also with more profit, by the generality of readers, than any other on the subject of population. It contains a great number of tables, for many of which he was indebted to other writers, especially to M. Messance; but he has also given many that are original, derived from the Bills of Mortality and actual enumerations of the people, though, without explaining in a satisfactory manner how he obtained his information, which, if it be correct, must have cost great labour. In his preface he says, "*il est tel page de ce livre qui a coûté nécessairement deux mois de travail, et un volume de chiffres.*"

The fourth edition of Dr Price's *Observations on Reversionary Payments* appeared in 1783, and contained much new and valuable information on these subjects, as has already been observed in the historical introduction to the article ANNUITIES in this *Supplement*.

M. Krafft. In 1786 was published, at Petersburgh, in the *Acts of the Academy of Sciences* there, for the year 1782, an essay by M. Krafft, on the marriages, births, and burials, at St Petersburgh, during a period of 17 years, from 1764 to 1780, preceded by a general exposition of the uses such tables might be applied to, if the observations they record were extended over entire governments in Russia. This paper contains seventeen tables, which show the number of deaths at each age, and by each of the principal diseases, together with the numbers of marriages and baptisms; the numbers in each case, being given for each of the 17 years separately, as well as for the whole term; and the sexes are always distinguished; as are likewise foreigners from the native Russians.

These tables would have been rendered very valuable, had they been accompanied by statements of the numbers of the living of each sex in the different intervals of age; but for want of this information, it is difficult to apply them to any useful purpose, and many of the inferences M. Krafft has drawn from them are very uncertain.

Heysham.

During a period of nine years, commencing with 1779, and ending with 1787, Dr Heysham of Carlisle kept accurate registers of the births, and of the deaths at all ages, in the two parishes which comprehend that city and its environs; also the diseases or casualties which the deaths at each age were occasioned by; and the sexes were in all cases distinguished. These excellent registers were kept with great care and skill on the plan of Dr Haygarth above-mentioned, and included all dissenters within the two parishes. Dr Heysham published them from year to year as they were made, and accompanied them with valuable observations on the state of the weather and diseases in each year. Their value was greatly enhanced by two enumerations of the people within the two parishes, the one made in January 1780, the other in December 1787, in both of which the ages were distinguished, but not the sexes of each age, though the totals of each sex were. These documents, printed in convenient forms, with further information respecting them, and many useful tables deduced from them, may be found in Mr Milne's *Treatise on Annuities*.

Barton.

In the third volume of the *Transactions of the American Philosophical Society*, published in 1793, were inserted *Observations on the probabilities of the duration of human life, and on the progress of population in the United States of America*, contained in a letter from Mr Barton, which had been read to the Society in March 1791; also a postscript to that letter, read in December following; the returns of an actual enumeration of the people in the United States having been made in the mean time. The information there given from the parish registers is of little value. In the enumerations, the sexes were distinguished, but not the ages, except the numbers of free white males under and above sixteen; but even that information with regard to the population of America is very interesting, whether we contrast the early with the more recently settled counties, or the whole of the United States with the population of Europe.

Nicander.

In the years 1799, 1800, and 1801, M. Nicander inserted eight different memoirs among those of the Royal Academy of Sciences at Stockholm, exhibiting the state of population and mortality in all Sweden and Finland, from the year 1772 to 1795 inclusive. These contain a great number of tables, which present the most interesting results of the *Tabellvärket* during that period; the ages and sexes, both of the living and the dead, are distinguished with sufficient minuteness, and the number of deaths of each sex by every disease is given. The information in these papers is much more complete and satisfactory than any other yet collected respecting the state of the population of a whole kingdom, or even of any particular part of it, if we except the observations of Dr Heysham, which were confined to Carlisle and its neighbourhood. M. Nicander was a Member of the Royal Academy of Sciences at Stockholm, also one of the Commissioners of the *Tabellvärket*, and their secretary. We are sorry to announce his death, which took place in the summer of 1815.

M. Mourgue.

In the year 1800 was published, at Paris, in 8vo, under the title of *Essai de Statistique*, a memoir by J. A. Mourgue, on the births, marriages, and deaths, that took place in Montpellier during a period of 21 years, ending with 1792, with the ages at which the deaths happened, the sexes are also distinguished, and the population of the place appears to have been nearly stationary. The tables and observations of M. Mourgue appear to be more valuable than any others relative to the population of France, that have yet been published, except those of M. Deparcieux, which related only to select orders of the people. This memoir was read at a meeting of the French National Institute in 1795, and printed in the *Mém. des Sav. Etr. an.* 14.

Spanish Registers.

An enumeration of the people in Spain was made by royal authority in the years 1768 and 1769, and again in 1787; a minute account of this last was printed at Madrid, showing for each province separately, the numbers of parishes, cities, towns, villages, &c. &c. with the number of people in each class according to their ranks, professions, occupations, &c. and the monastic orders of both sexes were particularly distinguished: to these was prefixed a summary of the census of 1768 and 1769. In these two enumerations, the ages of the people were not distinguished with sufficient minuteness; they only showed how many were under 7, between 7 and 16, 16 and 25, 25 and 40, 40 and 50, and above 50. In both enumerations, together with the ages, the distinction of the sexes was given; in the first, the married were only distinguished from the single; but that of 1787 showed how many of each sex, and in each interval of age, were in the states of celibacy, marriage, and widowhood.

A third enumeration of the people in Spain and the Spanish possessions in Europe and Africa, including the Canary Islands, was made in 1797; and a full account of it, occupying nearly 50 large tables, was printed at Madrid in 1801. The distinction of the ages in this enumeration was still not sufficiently minute; under 40 it was the same as in the two preceding, but after that age, the number of the living in each interval of 10 years to 100 was given, and the number above 100.

No information from the parish registers in Spain was given in any of these cases; although satisfactory extracts from them all, distinguishing the ages and sexes of the deceased, or even from those only which could be most depended upon, during the ten years that intervened between the two last enumerations, would have rendered the results of these incomparably more valuable, provided that the population of the places for which correct registers were given, could be distinguished from the rest. Those to whom the superintendence of these measures were entrusted in Spain, seem to have been well aware of this, and to have actually entered upon the formation of these necessary supplements to the enumerations,

Bills of Mortality.

as appears by the following passage extracted from the introduction to the printed statement of the last census:—

"*Interin que se forman las tablas necrológicas, las de nacidos y casados, en que entiende el ministerio de Estado, y que son muy útiles para valuar casi geométricamente el total de la poblacion del Reyno, debemos contentarnos con las noticias que nos proporcionen los censos executados por el método que el presente.*" But the author of this article has not yet succeeded in his endeavours to procure further information as to these tables of births, deaths, and marriages.

Dr Heberden.

In 1801 were published (in 4to), *Observations on the Increase and Decrease of different Diseases, and particularly of the Plague*, by William Heberden junior, M.D. F.R.S. containing some tables, chiefly deduced from the London bills. In the advertisement prefixed to this valuable tract, we are informed that it had been intended to be subjoined to a new edition of the Bills of Moitality; which edition, however, was not published. We are also indebted to the same ingenious physician for other interesting observations on the mortality in London, inserted in the *Philosophical Transactions of the Royal Society* (for 1796), and in those of the *London College of Physicians*, Vol. IV.

Dr Willan.

In the same year (1801) was published (in 12mo) another valuable work, entitled, *Reports on the Diseases in London, particularly during the years* 1796, 1797, 1798, 1799, *and* 1800, by Robert Willan, M.D. F.A.S. part of which had been previously inserted in some periodical publications; the author's observations were made both on the Bills of Mortality, and on the cases that occurred in his own practice.

In reading the writings of the physicians who have treated these subjects, it is impossible not to regret, that they have been so little attended to by the medical profession in general, and that Bills of Mortality have not been more generally kept in such a way, as to throw the lights which they alone can, on the causes of the increase and decrease of different diseases, and of the great differences that are found between the degrees of mortality in different situations, and among different classes of the people. The information of this kind already before the public clearly shows, that the general causes which tend to shorten life do also embitter it; and that where the people are the most happy, useful, and respectable in their several stations, there also, *cæteris paribus*, they are the longest lived. And these inquiries, we think, are of more importance to governments, and better worth their attention, than statesmen are generally aware of.

In the sixth volume of the *American Philosophical Transactions*, published in 1809, two tables were given, showing the number that died of each disease in each interval of age, during the years 1807 and 1808 separately, in the city and liberties of Philadelphia, which were communicated by the Board of Health; the numbers both of adults and of children who died in each month of each of these two years, are also given; and it is modestly added, that any suggestions for further improvements will be thankfully received. We therefore beg to suggest, that the distinction of the sexes, which has not been made, would be a material improvement; and it might also be useful to state, what year the Board consider to be the limit between childhood and adultage. If, in addition to this, the number of the people in each interval of age within the city and liberties, be determined at regular intervals, as every 5th or 10th year, and the registers of deaths, with the diseases and ages, be regularly continued for several such periods, the annual births of each sex being also given, they cannot fail to become very valuable.

Bills of Mortality.

Observations on British Population Acts.

In pursuance of an act of Parliament (41st Geo. III. cap. 15.), an enumeration of the people in Great Britain was made in 1801: also returns of the baptisms and burials in England and Wales, during the year 1700, and every tenth year after that till 1780, then for every year to 1800 inclusive, with the number of marriages in each year from the commencement of 1754 to the end of 1800. Large and clear abstracts of the answers and returns to this act were printed by order of the House of Commons in 1802, and occupy more than 1000 pages folio. In 1811, another act (51st Geo. III. cap. 6.) was passed, "for taking an account of the population of Great Britain, and the increase or diminution thereof;" in consequence of which, returns were that year made to Parliament, of the number of persons in every part of Great Britain; also of the numbers of baptisms, burials, and marriages in England and Wales, during each of the preceding ten years; very satisfactory abstracts of these were also printed by order of Parliament, in 1812, with some preliminary observations, in which corrections of the preceding returns are given.

Acts.

The sexes were distinguished both in these enumerations and extracts from the registers, but the ages in none of them; and the proportions of males to females among the living are not to be depended upon, a number of males in the army and navy, which it is difficult to estimate, not being natives of Great Britain, nor usually resident there. The returns of baptisms and burials were also defective, but few registers of dissenters having been included in them.

These abstracts are, however, with respect to the objects they extend to, more minute and satisfactory, than any other accounts of the same kind that have been published; and it is very desirable that such returns should continue to be made, and abstracts of them printed at regular intervals; for nothing is so well calculated to show the influence of different causes on the prosperity of a nation, as the comparison of the different states of the population, and the rate of its progress or declension, under different circumstances: besides, the value of the abstracts we already have, will be much enhanced by the publication of others of a similar kind hereafter.

It is much to be regretted, that no information as to the ages of the living, or those at which the deaths took place, was required by either of the acts above referred to; nor any encouragement or facility afforded to those who might be disposed to collect such information; and, consequently, that none was given in the returns.

Without better regulations for the keeping of mortuary registers than those at present in force, with-

out such as should extend to dissenters of every denomination, it would probably be better not to require returns of the ages of the deceased from all parts of the kingdom; for defective or inaccurate returns would only mislead, and, not to mention the difficulty and expense of procuring returns of the ages of all the living, they would be comparatively of little use, where those of the dead were wanting.

But if government were to print forms for making returns both of the numbers of the living and of the annual deaths in proper intervals of age, throughout the extent of life; only sending such forms along with those now in use, to such as should apply for them,—then, persons who take an interest in such inquiries, and have the means of making correct returns, might do so with advantage. And a summary of all of that kind made from different parts of the kingdom, would convey much important information. Returns also, from such places only as were similarly circumstanced, might be collected into as many summaries as there were material varieties in the circumstances; and thus would afford the means of determining the different modifications of the law of mortality, which different circumstances produce. If the diseases that occasioned the deaths were also inserted, the greater prevalence of particular diseases in some circumstances than in others, would be apparent, with their effects, and the probable means of preventing them, or lessening their mortality.

But, *the population enumerated must always be precisely that which produces the deaths registered; the grand desideratum being, to determine the number of annual deaths at each age, which takes place among a given number of the living at the same age.*

Milne.

Mr Milne's *Treatise on Annuities and Assurances* was published in 1815, and contains clear abstracts of the most important statements of this kind that have been published since Dr Price's time; these will, we believe, be found to be much more valuable than any thing of the kind that was extant when that ingenious author wrote, whose work has been generally referred to for the best information on such subjects.

Observations on the forms of Bills of Mortality.

Of all the statements derived from bills of mortality and enumerations of the people, which we have mentioned, only those for Sweden and Finland, and Dr Heysham's for Carlisle, have been given in the proper form, and with sufficient correctness to afford the information, which is the most important object of them all,—that which is necessary for determining the law of mortality.

To effect this, it is only necessary to know the mean number of the living and of the annual deaths, in sufficiently small intervals of age, throughout the extent of life, for a period of time sufficient to allow of the accidental fluctuations arising from more or less fruitful years, and other causes, compensating each other: such periods, probably, should not be less than eight or ten years; but the necessary length will depend upon the climate, the number of the people, their general modes of life, and their political circumstances.

These *data* being obtained, it is not difficult to determine the proportion of the annual deaths to the number of the living in each year of age. Then, assuming any number of births, as 1000 or 10,000, it is easy to show how many would die in each year of their age; and, consequently, how many would survive that year; which numbers of survivors and of annual deaths, when arranged in the order of the ages, constitute the desired table of mortality, by which all the most important questions respecting the duration of human life may be easily resolved.

For want of understanding the principles upon which the proper construction of such tables depends, most of the writers on this subject, many of them men of great merit and industry, have taken much pains to little purpose, and after excessive labour, have arrived at false conclusions. Hardly any of them appear to have been aware of the necessity of obtaining the number of the living, as well as of the annual deaths in each interval of age, or that that would greatly enhance the value of Bills of Mortality, by extending their useful applications.

Dr Price's *Essay on the proper Method of constructing Tables of Mortality*, already twice mentioned in this article, was intended to show how such tables might be constructed from registers of the *deaths only* at all ages; but the hypotheses he proceeded upon can hardly obtain in any real case; and even if they did, his method would only determine the number of the living in the place, at every age; therefore, if it could be put in practice (which it never can), it would only supersede the necessity of actual enumerations; and, with the numbers so obtained, we should have to proceed as above.

That *Essay* of Dr Price was an amplification of what Mr Simpson had previously advanced on the subject, with his accustomed accuracy, and contains many just observations on the defects of the tables of mortality that had previously been published; but so far as it contributed to induce a belief that the determination of the number of the living in every interval of age, by actual enumeration, was not necessary to the construction of accurate tables, it must have done harm.

What is here stated will be found demonstrated in the third chapter of Mr Milne's *Treatise on Annuities*.

We come now to the

FORMS SUBMITTED

FOR BILLS OF MORTALITY AND FECUNDITY.

It is desirable that a bill should be published for each year separately, to show how the rates, both of mortality and fecundity, vary with the circumstances of the people in different years; and, from these yearly bills, nothing is more easy than to derive others for longer periods.

According to the form A, the births of both sexes in each year will be distinguished, and the born alive from the still-born; the number of marriages will also be given.

In this, and all other cases where those who undertake the formation of such bills are either unable or unwilling to distinguish all the particulars indicated, the reasons for the omissions should be inserted in the spaces set apart for the numbers omitted. But,

where the still-born are not distinguished *as such*, they should be omitted entirely, and the number of births stated should be that of the children born alive.

The numbers of deaths of the two sexes in each interval of age, during any year, may, as they are collected from the registers, be conveniently disposed according to the form B; the intervals between 5 years of age and 100, being each 5 years; and the number dying at each age above 100 should be particularly specified. It would, indeed, be much better to give a separate statement of the number of each sex dying in each year of age above 90; for the whole number is never very great, and any error committed at the greater ages, in constructing a table of mortality, affects all the preceding numbers in the table.

But some persons, who would not take the trouble of forming bills of mortality in which the ages are to be so minutely distinguished, might yet be willing to furnish them with the requisite care, according to the form b, which might still be very useful; and, indeed, from 20 to 60 years of age, intervals of 10 years each might do very well.

The value of Bills of Mortality would be greatly enhanced, by inserting in them the contemporaneous wages of labourers in agriculture, and of the workmen employed in the more common kinds of trade and manufacture carried on among the people they relate to; also the prices of the necessaries of life which persons of these descriptions consume the most of; together with any thing uncommon in the seasons or the crops, and every material change in the circumstances of the people.

Enumerations.

The number of the people in the several intervals of age, which we have stated above to be of so much importance, may be disposed in tables exactly similar to B or b, recommended for the deaths; but it is not necessary that the duration of life should be divided into the same intervals for the living as the dead. It is always desirable that the intervals should, in both cases, be small; but yet not so small, as, by the increase of labour, to occasion the numbers being determined with less exactness, or to deter many from engaging in the work. Such intervals should not, however, exceed ten years.

When the bills are given for a certain period, if there be but one enumeration of the people, it should be made at the middle of the period; if two, at its extremities; and if more than two, it is desirable that they should be made at equal intervals of time throughout the period.

We give no forms here of Bills of Mortality and Fecundity, designed to distinguish legitimate from illegitimate children, or the mortality or fecundity of each month of the year, nor the number of women delivered annually at the different periods of life, nor the diseases the deaths were occasioned by. Neither are the forms here recommended for enumerations of the people, calculated to distinguish the numbers in the different states of childhood, celibacy, marriage, or widowhood; nor the ranks, or professions, or occupations of the people. All these things are curious, and of some use, although, if we except the diseases which the deaths of each sex at the different ages were occasioned by, they are of little value in comparison with the information the forms here given are calculated to convey. And it is of so much importance that that information should be given correctly, that we would willingly forego these minor objects, to avoid dividing and fatiguing the attention of those who undertake the more important part of the task, which is of itself sufficiently laborious.

And those who may be disposed to keep registers, and form bills and enumerations, on a scale so much extended as to include all these particulars, or most of them, and have also the requisite qualifications, will find no great difficulty in preparing the most convenient forms of tables for the purpose. Several forms of that description, with references to others, will be found in Mr Milne's *Treatise on Annuities*

See Mortality, Law of, in this *Supplement*. (u.)

ack Sea. Boundaries.

BLACK SEA, or EUXINE SEA, *Pontus Euxinus* of the ancients, is a large inland sea, bounded on the west by Roumelia, Bulgaria, and Bossarabia; on the north by Russian Tartary; on the east by Mingrelia, Circassia, and Georgia; and on the south by Anatolia. It is entered from the Mediterranean through the channel of the Dardanelles, the ancient *Hellespont*, the Sea of Marmora, *Propontis*, and the channel of Constantinople, *Thracian Bosphorus;* and it is connected with the Sea of Azoph, *Palus Mæotis*, by the strait between the Crimea and the isle of Taman, the ancient *Cimmerian Bosphorus*, known by the various modern names of the Strait of Caffa, of Yenikale, and of Taman.

ogress've ography.

Till within the last thirty years, the extent of the Black Sea, and the position of several of its principal capes, gulfs, and ports, were very imperfectly ascertained. Soon after the commencement of the French Revolution, the National Institute sent M. Beauchamp to examine this sea, and especially its southern shores. In this enterprise he was much impeded by the jealousy of the Turks; nevertheless, he ascertained that Cape Kerempe, *Carambis*, was placed in the charts too far to the south; that the Gulf of Sansoun, *Amisenus Sinus*, was deeper than represented; and that Tribizond, Tarabagan of the Turks, *Trapezus*, was five or six leagues further to the west than it appeared in the charts. Recent travellers have discovered that even the Parisian charts are inaccurate. According to Dr Clarke, the Isle of Serpents, Ulan-Adassi of the Turks, Fidonisi of the modern Greeks, the ancient *Leuce*, lies 15 minutes, and the port of Odessa 27 minutes, too far towards the north (Clarke's *Travels*, I. 653); and Mr Macgill ascertained, from two very good observations of his own, compared with those of some captains who had navigated this sea, that, in the French charts, even Cape Kerempe is not accurately placed, it being set down 15 miles too far north, while Cape Aria, or Careza, *Criu-Metopon*, in the Crimea, is placed 22 miles too far south. This, of course, makes a difference in the width of the sea at this place of 27 miles (Macgill's *Travels*, I. 195).

tent.

According to the best authorities, which Mr Arrowsmith has followed in his maps of this sea, it lies between 41 and 46½ degrees of north latitude, the bottom of the bay of Sansoun penetrating nearly to the 40th degree, and Cape Kerempe stretching out nearly to the 42d; and between 28 and 41½ degrees of east longitude from Greenwich. This will give for its breadth, from Cape Baba in Anatolia to Odessa, about 380 miles; and for its length, from the coast of Roumelia to the mouth of the Phasis, 932 miles. The Black Sea, however, may be considered as divided into two parts, by Cape Aria on the south of the Crimea, and Cape Kerempe on the coast of Paphlagonia, the former lying in about 44½, and the latter in about 42 degrees of latitude. Both these capes being high land, vessels sailing between them can discover the coast on either side. The circumference of the Black Sea is about 3800 miles.

ame.

It derives its modern name either from the dense fogs which frequently cover it, or from the dangers of its navigation arising from these fogs; the sudden and violent storms to which it is exposed; and the shallows hitherto unnoticed in any chart. The origin of its ancient name is given in the *Encyclopædia*, under the article EUXINE.

Black Sea.

Former State.

The opinion of the ancients, that the Black Sea was formerly much more extensive than it is at present, and that it did not originally communicate with the Mediterranean, is embraced by many modern authors of note, particularly Tournefort, Buffon, Pallas, and Dr Clarke, and seems to be confirmed by several circumstances. Immense strata of limestone, consisting almost entirely of mineralized sea-shells, may be traced the whole way from the Black Sea towards the north, as far as the 48th degree of latitude; and Pallas, in the third and seventh volumes of his *Travels*, has pointed out traces of its former extent over all the desert of Astracan and Jaik. The evidences derived from the appearance of the present coast of this sea, are still less equivocal in support of the diminution of its waters. Pliny expressly states, that *Taurica*, the Crimea, was not only once surrounded by the sea, but that the sea covered all the champaign part of it. Now, there are layers of marine shells all the way from the mouths of the Dnieper to those of the Don; and if we suppose the waters of the Black Sea to be restored only to the level of these layers, the Crimea will appear again an island. The alluvial nature of more than three-fourths of the soil of Crimea Proper to the north, the numerous salt lakes and marshes, and the remains of marine productions of various kinds which are found there, sufficiently confirm the latter part of Pliny's statement.

Bursting of the Thracian Bosphorus.

The ancients believed that the communication between the Black Sea and the Mediterranean, and the consequent diminution of the waters of the former, was effected by the bursting of the Thracian Bosphorus, at the period of the deluge which inundated Greece; and this tradition is confirmed by a reference to existing natural phenomena. The cliffs and hills at the mouth of the Bosphorus, are composed of enormous pebbles, which appear to have undergone the action of fire, and afterwards to have been rounded by long contact in water. On the points of the European light-house, there are immense rocks of hard and compact lava; and the rock of which the Cyanean Isles consist, appears to have been more or less modified by fire, and to have been cemented during the boiling of a volcano. On the Asiatic side of the strait, a little to the east of the Anatolian light-house, there is a range of basaltic pillars, exhibiting very regular prismatic forms. From the consideration of all these observations, and comparing events recorded in history with the phenomena of nature, Dr Clarke considers it more than a conjectural position, "that the bursting of the Thracian Bosphorus, the deluge mentioned by Diodorus Siculus, and the draining of the waters, which once united the Black Sea to the Caspian, and covered the great oriental plain of Tartary, were all the consequence of earthquakes caused by subterranean fires, described as still burning at the time of the passage of the Argonauts, and whose effects are visible even at this hour." (I. 680.) It is proper to mention,

that Olivier does not coincide with other naturalists respecting the former extent of the Black Sea, or the bursting of the Thracian Bosphorus.

Changes in its Coasts.

The north and west coasts of this sea have undergone, and are still undergoing, considerable changes: the southern coast, consisting chiefly of calcareous rocks, is nearly in the same state in which it was in the time of the ancients. According to Valerius Flaccus, the gulfs and bays in the north and west coasts were extremely deep; most of these are now all either entirely filled up, or much contracted. In proof that the Black Sea and the Sea of Azoph are still sustaining a diminution of their waters, it may be stated, that ships which formerly sailed to Taganrock and the mouths of the Don, are now unable to approach either the one or the other; that the Sea of Azoph has become so shallow, that, during certain winds, a passage may be effected by land from Taganrock to Azoph, through the bed of the sea; and that the isthmus connecting the Cyanean Isles with the Continent, which does not appear to have existed in the time of Strabo, appears to be increasing. On the southern coast of the Black Sea, there is, as far as we know, only one instance of a recession of the waters: the channel which formerly divided the village of Amasrah, *Amastris*, is now filled up, and forms a low isthmus.

Currents.

A rapid current, which generally flows at the rate of a league an hour, the influence of which is felt at the distance of ten miles from land, when it begins to take another direction, sets from the Black Sea into the Bosphorus. Sometimes, however, the long continuance of a strong south-west wind effectually counteracts this current. The Black Sea, from its particular form, being like a basin, into which many large rivers pour their streams, is full of currents, particularly in summer, when the rivers are increased by the melting of the snows: when strong winds act against these currents, a high sea is produced.

Winds.

North-east winds prevail from June to August inclusive; the most prevalent winds, at other seasons of the year, are from the south and south-west.

Climate.

The general climate of the Black Sea is cold and humid; the winters are long and frequently very severe, but the navigation is free of impediment from ice till the beginning of November, and often much later. The quantity of fresh water conveyed into this sea renders it brackish, and liable to freeze with a moderate degree of cold. It is calculated by some authors, particularly Tournefort (II. 404), and the Abbé Barthelemy (*Voyage d'Anacharse*, Tom. I. c. 1), that what it receives is much more than what it discharges into the Mediterranean. Dr Clarke, however, is of opinion, that the rivers which fall into the Black Sea and the Sea of Azoph, do not communicate more water than flows through the canal of Constantinople; hence he concludes, that, admitting the effect of evaporation, the level of the Black Sea insensibly falls (I. 628).

Rivers.

The Black Sea receives a considerable portion of the fresh waters of Europe, as well as of Asia Minor. The Danube collects the waters of a great part of Germany, Hungary, Bosnia, Servia, &c. The Dniester, Bog, Don, and Dnieper, discharge into it those of a part of Russia and Poland. The Phasis collects those of Mingrelia; and the Sangaris, and Kisil Irmak, *Halys*, part of those of Anatolia.

Fish.

In the Black Sea are found the tunny fish, which enters it to spawn; sturgeon, sterlet, porpoise, mackarel, soal, turbot, whiting, &c. It abounds with a species of sea-worm, four or five inches long; its head is like an arrow, and its body consists of a whitish mucilage: these worms are very destructive to ships.

Coasts and Ports of Roumelia.

We shall begin our survey of the coasts and ports of this sea, at its entrance from the Bosphorus, and proceed along its western shores. Off each point of the entrance of the Bosphorus from the Black Sea is a group of rocky islets, which retain their ancient name, Cyanean Islands. These have been already described. From the Bosphorus to Kara-Kerman, which lies within a few miles of the southernmost branch of the Danube, the coast is lined by the mountainous ridge of Balkan, *Hæmus*, which terminates at Cape Emeniah, *Hæmi extrema*. The valleys between these mountains form little coves, where vessels are laden with the timber of Hæmus for Constantinople. The forest of Belgrad, which takes its name from a village near Constantinople, extends along the south-west corner of the Black Sea, for about 100 miles.

Incada.

Incada, *Thenias*, lies on this coast in 41° 52′ north latitude. On the north side of the harbour there is good anchorage; it is only exposed to winds from the east and south-east, and is sufficiently spacious to contain a fleet; a heavy sea, however, enters it, when those winds blow to which it is exposed: Its chief export is charcoal to Constantinople.

Burgos.

At the head of the Gulf of Foros, which is bounded on the south by Cape Emeniah, is four or five leagues wide, and runs into the land nearly the same distance, is Burgos, which exports a considerable quantity of wool, iron, corn, butter, cheese, &c. to Constantinople. There are several roads in this gulf fit for the largest ships.

Coast and Ports of Bulgaria.

On the coast of Bulgaria is Varna, at the mouth of a river, which forms a large lake and extensive marshes; hence provisions are sent to Constantinople. Kara-Kerman, *Istropolis*, is a large village on the beach; several shoals lie off it, which oblige vessels to anchor a league to the south. Its principal export is corn.

Mouths of the Danube.

From Kara-Kerman to Actiar, in the Crimea, the coast is very low, and the shoals formed by the rivers run off a considerable distance. The Danube empties itself into the Black Sea, between Bulgaria and Bossarabia, by seven mouths, among swampy islands and shifting banks. The most frequented mouth is 100 fathoms wide and 3 fathoms deep; its stream runs out at the rate of three miles an hour. So great is the extent over which the waters of this river diffuse themselves, from the shallowness of the sea, that at the distance of three leagues from its mouth the water is almost sweet, and within one league it is perfectly fit for use. A very singular appearance takes place in the mouths of the Danube;—the porpoise, which every where else exhibits a dark colour, is there perfectly white; hence, as soon as the Greek mariners descry the white por-

poise, they have no doubt that they are in the current of the Danube, although in 30 fathoms water, and many leagues distant from its mouth. Opposite the mouths of this river is Serpents Island, already noticed. Kilia-nova, belonging to Austria, is a port of small consequence, at one of the mouths; it might, however, be rendered highly important, by vending the productions of Hungary, if the navigation of the river were not obstructed by the jealousy of the Turks.

The Russian province of Cherson is divided from Bossarabia by the Dniester Tyras. A bank before it, forms two channels; that on the west, called the channel of Constantinople, is 150 fathoms broad; and that on the east, called the channel of Ockzakoff, 80; neither have more than eight feet water. Akerman, on the south bank of this river, has some export trade in corn, wool, wine, wood, hides, and butter. Between the Dniester and Dnieper stands Odessa, the most flourishing port in the Black Sea. It owes its prosperity, not so much to any natural advantages, as to the wise administration of the Duke of Richelieu, while he was governor of this province. It is situate close to the coast, which is here very lofty, and much exposed to the winds, especially to the east. In order to render it a safe and commodious port, the Duke caused a harbour to be formed, in which ships of no small burden may ride secure from every storm. He also built a large mole, extending half a werst into the sea; several smaller ones, and a handsome quay, one werst and a half long. The roads without the port are safe in summer, and the anchorage good. Odessa labours under the want of a navigable river, and a great scarcity of fresh water. In the year 1805, 595 vessels were entered at this port, of which 27 were under the English flag; 264 were Austrians, owned by the merchants of Trieste, but employed as the carriers of Spain and Portugal. In the year 1816, up to the 28th of June, 498 ships had entered Odessa, bringing merchandize to the value of one and a half million of rubles, besides a very large quantity of specie. During the same period, there sailed 246 ships laden with Russian produce, to the amount of 15,220,000 rubles, including above 324,000 quarters of wheat. The principal imports are wine, chiefly French, some rum, raw silk, coffee, sugar, oil, soap, sulphur, fruit, linen cloth, &c. but all in very limited quantities. The great article of export is wheat, which, however, in the opinion of Mr Macgill, is very far inferior to that of Taganrock, being soft, and apt to heat; besides this, grain, rye, barley, oats, tallow, and tallow candles, beeswax, iron, hemp, &c. are exported.

The Dnieper, *Borysthenes*, which separates the Russian provinces of Cherson and Taurida, forms, near its mouth, a shallow and marshy lake, two and a half miles broad, a-breast of Ockzakoff, but more at the confluence of the Bog. The entrance is almost closed by shifting sand banks, between which, there is seldom more than five feet water. The Bog, *Hypanis*, falls into the gulf of Leman, or estuary of the Dnieper. There is a very small island opposite the mouth of the latter river, almost inaccessible on account of its perpendicular cliffs of rock and clay. Ockzakoff is a small port, lying at the junction of these rivers; its harbour is perfectly secure, but the little trade it formerly possessed, has been drawn away to Odessa. Opposite to Ockzakoff is Kinburn, which, before the building of Cherson, was intended by the Russians as the principal depôt for the merchandize sent from the provinces bordering on the Dnieper. The extension of the Russian dominions on the west, has caused even Cherson, on the right bank of the Dnieper, to be superseded by Odessa. Yet corn, hemp, and other articles of exportation, are so much cheaper, and more plentiful here, that many foreign vessels still prefer this port, though they are obliged first to perform quarantine, and unload their cargoes at Odessa. The Dnieper is five miles wide at Cherson, but only vessels that draw six feet can ascend to it. The Russians, however, have a large arsenal here, and build line-of-battle ships, which are floated down the river on machines, and afterwards conveyed to Ockzakoff to be equipped. Nicolaef, on the Bog, a fine river, without bar or cataract, with deep, still water, is the station for vessels when built, and here they are laid up to be repaired. It has extensive marine arsenals, being the seat of the Russian marine administration on the Black Sea.

The southern coast of the Crimea is lofty and precipitous; the mountains beginning at Balaclara, *Symboli*, and extending to Caffa, *Theodosia*. Some of these are celebrated in antiquity, and are no less remarkable for their formation and appearance. The mountain Tchedirdagh, *Trapezus*, rises rapidly from the coast about Alusta to the height of 1200 or 1300 feet; it exhibits a mass of limestone very compact, of a grey colour, and according to Pallas, upon friction, slightly fœtid. The remarkable headlands of the Crimea are Cape Tarchanskoi, called by the Tartars Aya-Burun, or the Sacred Promontory, probably the *Parthenium* of Strabo; one of the loftiest mountains in the Crimea, terminating abruptly in the sea, and forming the west point of the Peninsula. It consists of marble. On the south point is Cape Aria, *Criu-Metopon*, formerly noticed.

The first port of note on the west coast of the Crimea is Kosloff, or Eupatoria, from which, in 1793, 176 vessels were freighted with corn, salt, and leather; but at present, its commerce is nearly annihilated. Sevastopel, formerly Actiar, *Ctenus*, is the chief station of the Russian Black Sea fleet, no merchant ship being allowed to enter it, except in distress. The natural advantages of this harbour are very great. The largest vessels lie within a cable's length of the shore. The harbour is divided into three coves, something resembling that of Malta. The principal branch runs east, and is terminated by the valley and little river of Inkerman. Here the fleets of the world might ride secure, and have convenient anchorage; and in any of the ports, vessels find from 21 to 70 feet depth of water, and good anchorage. On a tongue of high land between the two southern creeks stands the Admiralty and storehouses. The great bay of Actiar also bears the name of the Roads, and here the Russian fleet is frequently at anchor. The port of Balaclara is separated from that of Actiar by a narrow peninsula. It

Black Sea. is one of the most remarkable in the Crimea, appearing from the town landlocked by high precipitous mountains. Its entrance is so extremely narrow, that only one ship can pass at a time; but within the port, it is three quarters of a mile long, and 400 yards broad; it is secure in all weather from storms; and ships of war of any burden may find in it sufficient depth of water. The mountains which surround it are of red and white marble, and the shore in some parts is covered with gold coloured mica, in a state of extreme division. This port is closed against the vessels of all nations, not excepting Prussians, to prevent smuggling. Caffa lies on a bay, capable of containing several hundred merchant vessels, but exposed to the east and southwest. It formerly carried on the most extensive trade in the Black Sea; but it is now of very little consequence. Kertchi, *Ponticapium*, on a peninsula, *Chersonesus Cimmeria*, stretching into the strait of Taman, and Yenikale, at the extremity of the same peninsula, are small ports chiefly inhabited by fishermen.

Caffa.

Coast of Anatolia.

The coast of Anatolia, on the Black Sea, extends to the Kesil-Irmak, which falls into this sea a little to the west of the Gulf of Sansoun. It is lined by high mountains, terminating in lofty promontories. It is steep and clean, with numerous little coves, into most of which small rivulets fall. The most remarkable headlands are Cape Kili-Mili, east of Erekli; Cape Kerenipe, the north point of Asia Minor, very high land, with breakers off it; and Cape Indjee, a low point to the west of Sinope. The principal rivers on this coast, besides the Kisil-Irmak, *Halays*, and the Sakaria, *Sangarius*, already noticed, are the Falios, *Bettæus*, and the Barthin, Parthenius. The only port of consequence is Sinope, strongly situate on the narrow and low isthmus of a rocky peninsula. The mole which formed its port is nearly in ruins. The depth of water is 12 feet. There is, however, a good road for the largest ships; and Turkish vessels of war are built here. Sinope is the nearest port on the Black Sea to Angora, the only place hitherto known that supplies the fine goats' hair.

Coast of Roum;

The coast from the Kisil-Irmak to Vona is named Roum by the Turks. The chief places are Sansoun, *Amisus*, on the Jekyl Irmak, which falls into the deep Gulf of Sansoun. Fatsa, *Polemonium*, at the mouth of the Sidemus, Budjiah and Vona, *Boona*, on the Cape of the same name.

of the Laziens.

From Vona, the coast takes the name of the tribes that inhabit it. The Laziens, *Lazi*, occupy the coast from Vona to the Batouni. The principal port on this coast is Trebizond. Though it can receive only small vessels, it has a considerable trade. One hundred and fifty or two hundred small craft annually sail to Taganrock, with *nardek*, a marmalade of grapes, and *beckmiss*, a syrup made for the use of the distilleries there.

Trebizond.

Coast of the Gurions.

Next to the Laziens, the Gurions occupy the coast, as far as the Rioni, *Phasis*. At its mouth this river is 60 fathoms deep, and half a league broad; but a small island lies in the midst of its channel. The only port in the country of the Gurions is Poti, to which the merchants of Georgia resort; the Mingrelians occupying the country of the ancient *Colchi*. In this tract there is no port of consequence. The Abasses occupy the coast from Isgarur to the Strait of Yenikale, as far as Anaffa. This coast is very elevated, the Caucassian mountains approaching close to the sea. Near Sondjuk is a very lofty promontory called Varda. From Anaffa to the Straits, the coast is low. Some small vessels are built at Anaffa by the Turks. The Kuban, *Hypanis*, receives most of the waters of the western side of Caucasus. Near its mouth it divides into two branches, one of which falls into the Sea of Azoph, and the other into the Black Sea. The marshy isle of Taman is formed by it. On this island is Fana Jona, a place of some trade.

Black Sea. Coast of Mingrelia.

The Kuban.

History of the Commerce of the Black Sea.

The commerce of the Black Sea, in ancient times, was successively in the possession of the Phœnicians, Egyptians, Greeks, and Romans. From the last it passed to the Greeks of the Lower Empire; from them to the Venetians and the Genoese. Caffa was the principal city of the commerce of the Genoese with the east; and the port at which was deposited all the merchandize which had been transported to the Black Sea. By the capture of Constantinople in 1453, this commerce was nearly destroyed; and by the capture of Caffa, in 1476, it was completely annihilated. One of the favourite objects of Peter the Great was to obtain a share in the commerce of this sea, which the subjects of the Porte alone were permitted to navigate. In 1699, he succeeded in subduing Azoph and the country round it; but, by the unfortunate battle of Pruth, in 1711, he was compelled to relinquish his conquests. His successors, and especially Catherine II. aimed at the same object. This enterprising sovereign, by the treaty of Kainardgy, in 1774, and afterwards by the treaty of Jassy, in 1791, completely accomplished her object; the Turks being obliged to surrender a part of Lesser Tartary and the Crimea, to allow the Russians to establish a navy in the Black Sea, and to permit their flag a free passage through the Dardanelles. In 1784, the Porte granted the privilege of navigating the Black Sea to the Court of Vienna. No other European nation obtained this privilege, though the French carried on a considerable trade under the Russian and Imperial flags, till after the conquest of Egypt by the French, when a treaty was concluded between the French government and the Porte, by which the latter granted the free navigation of this Sea. At the peace of Amiens, the navigation was opened to the Prussian, Spanish, Neapolitan, Dutch, Ragusan, and English merchant flags; and all these nations were allowed to have resident Consuls in the Turkish ports of this Sea. The English, however, by secret treaties with the Turks, in the reign of James I. and Charles, were granted the navigation of this Sea; and, in 1799, it was again granted.

Soon after the peace of Amiens, the commerce of this Sea increased considerably: so that, in 1803, 815 vessels entered the Russian ports from the Mediterranean. Most of them came in ballast, and returned with corn. Of these 815 vessels, there were,

ck Sea.

Flags.	Loaded at.	Destination.
421 Austrians	552 Odessa	186 Trieste
329 Russians	210 Taganrock	144 Messina
18 Ragusans	23 Caffa	103 Caphalonia
16 Ionian Islands	19 Kosloff	72 Genoa
15 French	7 Serastopil	57 Leghorn
7 English	4 Cherson	26 Corfu
6 Hydriots		24 Barcelona
3 Spaniards	815	19 Marseilles
		10 Naples
815		8 Malta
		7 Tchesmé
		4 Zante
		155 sailed without declaring their destination, on account of the war.
		815

From these 815, the 210 which loaded at Taganrock ought to be deducted, in order to give an accurate view of the commerce of the Black Sea at this period.

The Russian exports from and imports to this Sea were, in

	Exports.	Imports.
1802	3,000,000 rubles	2,055,000
1804	5,000,000	4,200,000
1805	7,400,000	5,356,000

In the year 1802, 36 vessels, and 266 small craft, were employed by Russia, in the coasting trade of this Sea. There is also a considerable trade between the Russian ports and Constantinople and Smyrna, carried on entirely by Greek vessels under Russian colours.

ussian eet.

In 1807, the Russian Black Sea fleet consisted of 12 sail of the line, 4 frigates, 7 brigs and cutters, and 18 small craft; and the Black Sea flotilla consisted of 40 gunboats and 80 falconets.

rincipal rticles of ommerce.

The principal articles of commerce afforded by the countries on the Black Sea, are wheat, rice, tobacco, hides, tallow, iron, hare-skins, honey, wax, and yellow grains for dyeing, from Roumelia and Bulgaria, by the ports of Varna and Burgos. The same articles, with the addition of wool, butter, hemp, masts, ship-timber, and pitch, from Moldavia and Wallachia, by Rudjuk and Galatz on the Danube. From Bessarabia, by Ovidopel, and from the province of Cherson, by Odessa, Akerman, and Cherson, corn, oak-timber, hides, tallow, tar, shagreen, wax, honey, hemp, sail-cloth, and wool. From the Crimea, by the ports of Actiar, Kosloff, and Caffa, corn, wool, wax, honey, dried and salted hides, deer-skins, morocco-leather, sheep-skins, salted and dried fish, potash, felt, caviar, wine, silk, and saltpetre. From Anatolia, by the ports of Erekli, Amasrah, and Sinope, hides, dried fruits, linens, linen-thread, wax, honey, hemp, copper, and ship-timber. From the countries of the Laziens and Gurions, principally by Trebizond, all the above articles, except ship-timber. From Mingrelia, and the country of the Abasses, principally by Sudjuk and Anaffa, slaves, timber, box-wood, wool, silk, furs, butter, hides, wax, honey, &c. The trade to these coasts is entirely carried on by a few Greeks of Constantinople, and is very insignificant.

Black Sea || Blasting.

See *Essai sur le Commerce, &c. de la Mer Noire*, Paris, 1805; Oddy's *European Commerce*, p. 169; Clarke's *Travels*, Vol. I. 4to edition; Macgill's *Travels in Turkey*, &c. Vol. I.; Coxe's *Travels*, Vol. III. 8vo edition; Tuckey's *Maritime Statistics*, Vol. II. (c.)

BLASTING, is a term used by the Engineer and Miner, to denote the application of the explosive force of gunpowder, in opening or rending rocks, indurated clay, consolidated earth, and the walls of old buildings. In quarrying sandstone, consisting of regular layers, the work is performed chiefly by means of the *pick*, the *wedge*, the *hammer*, and the *pinch* or *lever*; recourse being seldom had to the more violent and irregular effects of gunpowder. But for many kinds of limestone, and for greenstone and basalt, blasting is always resorted to; and some of the rocks called *primitive*, such as *granite*, *gneiss*, and *sienite*, could scarcely be torn asunder by any other means.

At what period blasting with gunpowder was first resorted to as a *power in mechanics*, is uncertain. Gunpowder was applied to military engines in 1330, but there is reason to believe that its application to the peaceful arts is of a much later date. It may seem strange at this day to propose the *expansive or explosive force* of gunpowder as a new *mechanical power*; but when the lever and the wedge become ineffectual to the purposes of the artificer, he must naturally attach a high value, and be disposed to give an elevated term, to that instrument or means by which he is enabled, in a very simple manner, to effect his purpose, and overcome the greatest obstructions to his operations. One could almost, therefore, wish it dignified with such a title as the EXPLOSIVE POWER.

This agent is no less simple in its application, than it is powerful in its effects. It is considered as the result of the sudden extrication of a *permanently elastic fluid* by the ignition of the gunpowder, the extricated gas occupying perhaps 1000 times more space than the grains of the powder. Some authors are of opinion, that the powder contains only atmospheric air in a state of great condensation, and that, when this fluid is set at liberty, being at the same time highly rarified by the heat, from the inflammation of the powder, it produces the wonderful effects already mentioned. By others, it is supposed that the air contained in the nitre of the gunpowder is about 244 times denser than atmospheric air, and that, when exploded, it produces an effect proportioned to its condensation; the elastic fluid expanding with a velocity which has been calculated at the rate of about 10,000 feet *per* second; and its pressure or force, when thus expanding, having been estimated as equal to a *thousand atmospheres*, or as a

thousand times greater than the atmospheric pressure upon a base of the same extent. If we apply this product to the pressure of the atmosphere, or at the rate of $14\frac{3}{4}$ pounds to the square inch, we shall find that the elastic fluid of gunpowder, at the moment of explosion, exerts a force equivalent to $6\frac{1}{2}$ tons upon the square inch of surface exposed to its force; and that with a velocity which even the imagination can hardly follow. Count Rumford, indeed, estimated this force at 10,000 atmospheres; but we have rather followed the calculations of Hutton, whose opportunities of experiment, connected with the Military College of Woolwich, have been unquestionably great.

The progress of quarrying and blasting rocks has, of late years, made great advancement in this country. In Europe, the art of mining was long chiefly confined to Sweden and Germany; but, since the disappearance of our thickly wooded forests, and the universal introduction of pit-coal for fuel, and of cast-iron in the arts, Britain has made rapid strides to improvement in the art of Mining, and now rivals her Continental neighbours. Here we may allude to the Coalworks of Northumberland and Durham, of Cumberland and the western counties of England and Wales. We may also notice the great extent of the like works in the south-eastern and south-western districts of Scotland. Much of this kind of work is done with the pick and shovel; but without the aid of the expansive force of gunpowder, these operations must have been of a very limited extent. Other works, of no less magnitude than those of Coal Mines, have been executed in Great Britain, almost wholly by the force of gunpowder, particularly in Canal and Road-works. To illustrate more fully the use of gunpowder in mining operations, we may mention the extensive works in Tunnelling, for preserving the level of canals through mountainous districts of country, instead of forming Locks, or following a circuitous line of navigation. The bold attempt of blasting rocks, under such circumstances, was, in this country, reserved for Mr Brindley, Engineer upon the Duke of Bridgewater's canals. In 1776, this celebrated Engineer completed the first navigable tunnel, at Harecastle in Staffordshire, which is upwards of one mile in length. Since that period, many other works of a similar nature, and even of much greater extent, have been executed in various parts of Europe. By the art of blasting, immense excavations have been made upon the Great Canal in Sweden. In France, a tunnel of about seven miles in length has lately been made; and, in our own country, at Sapperton, on the canal joining the rivers Severn and Thames, and at Marsdenhill, there is a tunnel, upwards of three miles in length, forced entirely through rock, by the use of gunpowder. We may also instance the great national work of the Caledonian Canal. In all of these works, in road-making, and many others intimately connected with the prosperity of commerce, the extension of the arts, our domestic comfort, and national importance, it is most evident, that, but for the simple process of applying the expansive force of gunpowder, we must have been deprived of innumerable advantages and accommodations.

Method of Blasting Rocks.

When a perforation or hole is to be made in a rock for the purpose of blasting with gunpowder, the prudent quarrier considers the nature of the rock, and the inclination or dip of the strata, and from these determines the calibre, and the depth and direction of the bore or recipient for the gunpowder. According to circumstances, the diameter of the hole varies from half an inch to $2\frac{1}{2}$ inches, the depth from a few inches to many feet, and the direction varies to all the angles from the perpendicular to the horizontal. The implements for the performance of this operation are rude, and so extremely simple and familiar, as hardly to require description; and the whole operation of boring and blasting rocks is so easily performed, that, in the space of a few weeks, an intelligent labourer may become an expert quarrier. The tools are few in number, and, as just said, are simple in their construction. The chisel, or *jumper*, as it is technically called, varies in its length and other dimensions according to the work to be performed, and its edge is more or less pointed to suit the hardness or tenacity of the rock to be bored. If the cylindrical hole to be drilled is of small diameter and of no great depth, or the work fixed to a confined position, as often happens, the operation of boring is performed by a single person; with one hand he manages the chisel or jumper, which he keeps constantly turning, and with the other he strikes the jumper with a hammer of 6 or 8 lb. weight. But when the hole is of larger dimensions, and of a depth exceeding a foot, it generally becomes the business of one man, in a sitting posture, to hold and direct the jumper,—to keep it constantly turning,—to supply the hole with water, and occasionally to clean it out; while two and even three men, with hammers of 10 or 12 lb. weight, strike successive blows upon the jumper, until the rock is perforated to the desired depth. To prevent annoyance to the quarriers from the squirting up of the water, a small rope of straw or hemp is simply twisted round the jumper, and kept resting on the orifice of the hole. When the perforations are to be made to a greater depth than about 30 inches, it is now common to use a chisel or jumper, varying in length from 6 to 8 feet, pointed at both ends, having a bulbous part in the middle for the convenience of holding it; it thus becomes a kind of double jumper, and is used without a hammer, with either end put into the hole at pleasure. When a bore of considerable depth is to be made, after the hole has been perforated a few inches with the common jumper, the quarriers lay it and their hammers aside, and collect round the *long jumper*, in a standing posture, and lay hold of it by the bulbous part, lifting and letting it drop into the hole by its own gravity; in this manner, by the successive strokes or falling of the long jumper, a hole to the depth of five feet and upwards is perforated, with much ease to the workmen, and with wonderful expedition. When the boring of the hole is completed, the *debris* and moisture are then carefully cleaned out, and a proper

charge of powder is put into it. In practice, there is no very precise rule for the charge or quantity of gunpowder, this being regulated at the discretion of the quarrier, according to the tenacity and mass of the rock to be removed; and these circumstances having been previously considered, in the dimensions of the bore, it is customary to fill it in the proportion of about one half with gunpowder.

The charge being introduced into the cylindrical hole bored or drilled in the rock, a long iron called the *pricker* is inserted amongst the powder, to be afterwards withdrawn when the priming powder is introduced. While this rod remains, the process of *ramming* or *stemming* the hole is performed by forcing burnt clay, fragments of pounded brick, stone, or any other substance less liable than another to produce sparks of fire on being struck with iron. After a layer or stratum of such matter has been pressed down upon the powder, the remaining depth of the hole is filled with pounded stone or earthy matters of any kind, forced down with an iron punch or rammer of such dimensions that it nearly fills the hole, but having a groove in it to receive the pricker; the rammer being flat at the end which enters the hole, the fragments of stone are pounded by it round the pricker, which must be occasionally turned to prevent it from being too firmly fixed, and thereby prevented from being drawn. This wadding or matter, laid immediately over the powder, is gently forced down at first, to prevent, as much as possible, the danger of premature explosion; but as the hole is more and more filled up, the quarrier strikes down the stemmer with more violence and less care, and consolidates the wadding as much as possible, with a view to produce a greater effect by the shot. In this operation consists the chief danger attending the process of blasting with gunpowder; for it must be obvious, that, unless the utmost care be taken in forcing down the first portions of the wadding above the powder, there is great danger of such a collision taking place, between the stemmer and the pricker, or between either of these and the rock or sides of the hole, as may elicit a spark of fire, and produce unintentioned explosion. From this cause, indeed, the most unfortunate and distressing accidents have sometimes happened to quarriers. A recent case occurred under the notice of the writer of this article, from which an experienced workman lost the sight of both eyes, and had his legs and arms much shattered. It is necessary, as before noticed, frequently to turn the pricker during the process of stemming the shot, in order to prevent its being so bound by the wadding as to prevent its being withdrawn; and it has been known that, by the friction produced in the mere act of turning it unguardedly, the shot has been fired off. To prevent accident in this way, copper prickers, or, to save expence, prickers composed partly of copper and partly of iron, have been introduced, instead of those formed wholly of iron. The copper pricker is certainly much less liable to accident; but notwithstanding that this fact is self-evident, and has been clearly established in quarries where copper and iron prickers have been used at the same time, yet, from the greater expence of the copper, and its being more liable to twist and break, it has by no means come into general use.

The hole being now fully charged with the powder and wadding, the pricker is drawn out. The small tubular space, which it leaves, is sometimes wholly filled with powder, but with a view to save that expensive article, it is now common to insert wheaten or oaten straws filled with powder. These straw tubes may be joined so as to reach any necessary depth; the lower straw always terminating in the root part where a natural obstruction occurs, or it is artificially stopped with clay, to prevent the powder from being lost. The lower part of the priming straw is pared quite thin, so as to insure the inflammation of the charge of powder in the hole. This being done, a *slow match*, consisting generally of a bit of soft paper, prepared by dipping it into a solution of saltpetre, is carefully applied to the priming powder. When this match is touched with fire, the quarriers give the alarm to all around, to retire to a sufficient distance, so as to avoid accident from the expected explosion. This commonly takes place in about a minute. The priming first explodes, attended only with flame; a short interval of suspense commonly ensues; the eyes of the byestanders being anxiously directed towards the spot; the rock is instantly seen to open, when a sharp report, or a detonating noise, takes place, and numerous fragments of stone are observed to spring into the air, and fly about in all directions, from amidst a cloud of smoke. The quarrier then returns with alacrity to the scene of his operations. When blasting with gunpowder is carried on in coal-pits or in sinking wells, where the workmen cannot get speedily out of the reach of the shot, or in any situation where adjoining houses, &c. may be in danger of being injured, it is common to load or cover up part of the rock to be blasted, with a quantity of furze or brushwood, to prevent the fragments of blasted rock from being driven to a distance.

Use of Sand in Blasting.

The simplicity of this operation, so important to our means of quarrying or prying into the bowels of the earth, is, perhaps, one cause of so little attention having been paid to it by persons of science; while the personal risk attending it may have also operated, in some measure, to prevent particular inquiries regarding it. It was an extremely natural conclusion for the quarrier to suppose, that the more firmly the shot was rammed home, the more powerful would be the effect of the explosion. This, we know, was long the conviction of military Engineers; and was also a principle invariably adopted by miners, to the great personal hazard of the artificer. In many places, this notion still prevails, and we cannot enough lament the force, and stubbornness of custom in this instance; as it has been fully established, that a wadding of loose sand, or of any earthy matter in a dry state, answers all the purposes of the firmest ramming or wadding. Now, as it is in the operation of ramming, that accidents most commonly befall the quarrier, and which the use of the copper pricker cannot altogether prevent, it is not

Blasting.

a little surprising, that the use of sand does not become universal.

To the common-labourer, indeed, it naturally seems somewhat paradoxical to say, that particles of loose sand can produce an effect equal to stemming a shot with an iron punch and hammer; but those who are better informed, should insist on the use of sand, whereby the person of the quarrier would be much less exposed, and much time and trouble would be saved. It may be noticed, that in several works this is observed, particularly at Lord Elgin's extensive mining operations at Charlestown in Scotland, where much attention is paid to the security and comfort of the artificer, as well as to every thing interesting to science. The practice of using loose sand instead of pounded stone rammed with force, has been in use at these works for several years (it is believed since about the year 1810). The writer of this article has also had considerable opportunities of trying the accuracy of these statements, *as to the efficiency* of sand, at the extensive quarrying operations which lately became necessary in cutting down a part of the Caltonhill, in forming the new approach to the city of Edinburgh, where upwards of 100,000 cubic yards of rocky matters were removed, and gunpowder to the value of nearly L. 1000 Sterling, was expended, chiefly in blasting rock, consisting of whinstone, or greenstone, much traversed by calcareous spar. The holes at this work were bored of various dimensions, both as to calibre and depth, and also at all the angles of inclination, from the perpendicular to the horizontal. Trials were here made with holes from three to seven or eight feet in depth, and of a diameter from an inch to two and a half inches in diameter; when it was invariably found, that when the powder was wadded with sand, the effect in tearing or blasting the rock was as great as when the more commonly followed method, of ramming with pounded stone was adopted. In the judgment of the *Contractors*, the fragments of rock had a greater tendency to fly to a distance when sand only was employed; but there was as great a bulk of the rock raised by the shot wadded with sand as by that which was rammed in the usual way; and in practice it was found that the shots with sand were not more liable to fail, *or blow*, without doing execution, than those which were rammed. It is a fact perhaps as curious and interesting as any connected with the subject, that in both ways the shots fail, and at times blow out, without producing any effect, or being occasioned by any apparent cause. Reasoning from the simultaneous effects of the sudden extrication of the elastic fluid of gunpowder, whether a wadding of loose sand or of firmly pounded stone be employed, trial was made of gunpowder without any wadding, but the effect produced by this method was rather to shake or rend the upper part, near the orifice of the hole or surface of the rock, than at the bottom of the hole. This fact, however, favours the conclusion that the explosive force of gunpowder is in proportion to the surface upon which it acts; and that the effect is so instantaneous, that it seems a matter not essentially connected with the operation, in what manner the wadding is effected, provided that the atmospheric air is not in immediate contact with the powder; as otherwise the fluid appears to divide, and its effects to be lost in space, without being applied chiefly at the bottom of the hole, where the greatest execution is wished to be done.

It may be noticed, that although the use of *sand* for blasting in mining operations is by no means general, yet so much of this practice has obtained, that the quarrier is now only at pains to *ram* an inch or two of the lower wadding firmly home; the upper parts are done loosely, with little attention either to the stuff employed, or to the ramming of it; he merely consolidates it in such a manner, that the broken particles shall not fall into the charge amongst the powder, when he withdraws the pricker. In so far, this is a saving of time; but unfortunately he still undergoes much personal risk, the chief danger being in ramming at first, or in the turning or withdrawing of the pricker, where the wadding is firm. When sand is used immediately above the powder, both the pricker and the rammer are wholly unnecessary; the *primed straw* being inserted into the powder, the sand is poured into the hole, and the shot is ready for the match. A difficulty occurs in the use of sand, which, though easily surmounted, it may be proper to notice in this place. When the hole or perforation in the rock happens to be horizontal, or at more than an angle of 45° from the perpendicular, the priming straw is apt to be injured in filling the hole with sand, an evil to which the pricker is not liable; but this is easily got over by inserting the priming straw into a small cylindrical tube of sheet-iron or copper, while the sand is gently pressed into the hole; the small tube which is open at both ends is afterwards withdrawn. By this means, the operation of the horizontal shot is rendered not less sure, and is attended with no more expence, and little more trouble, than when the bore is perpendicular.

Inflammation of the Powder.

It has been supposed by some, that a more complete inflammation of the powder would take place, if it were ignited at the bottom of the hole; but it has been found by experience, that this is not essential. It even appears from experiment, that gunpowder is more fully inflamed by applying the fire near the top, for in firing *Ordnance*, considerable quantities of the uninflamed grains of the powder have been collected, by placing a piece of cloth at a distance from the gun, and allowing the shot to pass through it.

Use of Quick-Lime.

Quick-lime, suddenly slacked, has been suggested, as a mode of rending rocks; but this process would in practice be found very defective. In some situations where the explosive effects of gunpowder could not be applied with safety, as in the interior of a building, or for such like purposes, this mode may be resorted to with good effect.

Blasting under Water.

Blasting with gunpowder, under water, is necessarily performed in various operations of the Engineer, particularly in the excavation of the foundations of piers, and in deepening the entrances of harbours. This is performed by inserting the charge of powder into the perforated rock, by means of a

case or *cartridge* made of *tin-plate*. The lower part is made to fit the bore in the rock, as nearly as may be; from this a small pipe of the same metal is carried to the surface of the water, with the priming powder. Here wadding is unnecessary, the pressure of the water upon the tin case superseding the necessity of any; and the explosive effects are generally greater, in proportion to the charge, than those in the open air. It may here be observed, that explosions under water have, in some instances, been proposed as a mode of attack in marine warfare; and it is presumed, that explosions, at considerable depths, might occasion such an impression on the water, and so disturb the equilibrium of the atmospheric pressure, as to be capable of sinking large ships, or floating batteries.

Blasting Screw. It may also be mentioned, that a new instrument, called the *Blasting Screw*, has been lately applied with considerable success to the rending or splitting of large trees and logs of timber. It consists of a screw which is wrought into an auger-hole, bored in the centre of the timber; here the charge of powder is inserted, and the orifice of the hole in the log is then shut up or closed with the screw, when a match, or piece of cord, prepared with saltpetre, is introduced into a small hole left in the screw for this purpose, by which the powder is ignited. The application of this screw to the purposes of blasting is not very obviously necessary, because, from what we have seen, it would appear that the auger-hole being charged with powder and sand, would answer every purpose. One great objection to the process of blasting applied to the rending of timber is, the irregular and uncertain direction of the fracture, by which great waste is sometimes occasioned. It may, however, be necessary to resort to this mode of breaking up large trees, when cut down and left in inaccessible situations, where a great force of men and of implements cannot easily be procured or applied.

See *Treatise of Artillery* by John Muller; Hutton's *Mathematical Dictionary*; and Nicholson's *Journal*, Vols. XII. and XIII. (H. H.)

BLEACHING.

BLEACHING is the art of whitening thread and cloth. It has been treated at considerable length in the *Encyclopædia*. Our business here is merely to supply the defects of that article. These are chiefly two; namely, 1. A very incomplete historical detail of the improvements in bleaching, at least as far as this country is concerned; and, 2. The omission of any description of the present mode of bleaching, as practised by the most enlightened manufacturers of Great Britain.

History. I. The Ancients, especially in Egypt, where white linen was a common article of clothing, must at an early period have been acquainted with the method of bleaching that substance, but none of their writers have left us any details on the subject. We know, however, from Pliny, that different plants, and likewise the ashes of plants, which no doubt contained alkali, were employed as detergents. Pliny mentions particularly the *struthium* as much used for bleaching in Greece. This plant has been considered by some as the *gypsophila struthium*. But as it does not appear from Sibthorp's *Flora Græca*, published by Sir James Smith, that this species is a native of Greece, Dr Sibthorp's conjecture that the *struthium* of the Ancients was the *saponaria officinalis*, a plant common in Greece, is certainly more probable. Mr Parkes, in his *Essay on Bleaching* (*Chemical Essay*, Vol. IV. p. 7), says, that Theophrastus states that lime was used by the ancients in bleaching; and that a ship, partly loaded with linen, and partly with lime for bleaching it, was destroyed by the accidental access of water to the lime. We endeavoured, with some pains, to verify this quotation; and, for this purpose, turned over all the writings of Theophrastus with which we are acquainted, without being able to find any thing bearing the least allusion to it. We have doubts whether lime could be employed as a detergent of linen, without injuring the texture of the cloth; and, on that account, it would have gratified us exceedingly to have found such a statement in so respectable and correct a writer as Theophrastus.

About sixty or seventy years ago, the art of bleaching was scarcely known in Great Britain. It was customary to send all the brown linen manufactured in Scotland to Holland to be bleached. It was sent away in the month of March, and not returned till the end of October, being out of the hands of the merchant more than half a year. The principal Dutch bleaching-grounds were in the neighbourhood of Haerlem; and the great success of their bleachings was ascribed to the superior efficacy of their water, which, according to the fashionable theory of the time, was sea-water filtered and rendered sweet, by passing through their sand-downs. Indeed, it was long a prejudice on the Continent, that no water was efficacious for bleaching but sea-water.

The Dutch mode of bleaching was to steep the linen for about a week in a potash ley poured over it boiling hot. The cloth being taken out of this ley, and washed, was next put into wooden vessels containing butter-milk, in which it lay under a pressure for five or six days. After this it was spread upon the grass, and kept wet for several months, exposed to the sunshine of summer.

In the year 1749, as we are informed by Mr Parkes (*Chemical Essays*, Vol. IV. p. 26), an Irishman, who had learned something of the art of bleaching, settled in the north of Scotland, and ex-

Bleaching. tablished a bleaching manufactory. On applying to the principal Scotch makers of linen, they readily furnished him with a quantity of goods; but after keeping them a whole year, he failed in all his endeavours to bleach them, and the proprietors were obliged to send them to Holland to get the process completed. Next summer his efforts were not more successful; the linen was considerably injured, and even rendered tender by his management, but it was not whitened. Nevertheless, this man by perseverance became in a few years an excellent practical bleacher. He had the merit of introducing the art into Great Britain, and his descendants at this day figure among the higher ranks in the metropolis.

The bleaching process, as at that time performed, was very tedious, occupying a complete summer. It consisted in steeping the cloth in alkaline leys for several days, washing it clean, and spreading it upon the grass for some weeks. The steeping in alkaline leys, called *bucking*, and the bleaching on the grass, called *crofting*, were repeated alternately for five or six times. The cloth was then steeped for some days in sour milk, washed clean, and crofted. These processes were repeated, diminishing every time the strength of the alkaline ley, till the linen had acquired the requisite whiteness.

For the first improvement in this tedious process, which was faithfully copied from the Dutch bleachfields, manufacturers were indebted to Dr Home of Edinburgh, who proposed to substitute water, acidulated with sulphuric acid, for the sour milk previously employed. This suggestion was in consequence of the new mode of making sulphuric acid, contrived some time before by Dr Roebuck, which reduced the price of that acid to less than one-third of what it had formerly been. It is curious, that when this change was first adopted by the bleachers, there was the same outcry against its corrosive effects as we have seen some years ago, when oxymuriatic acid was substituted for crofting. No allegation, however, could be worse founded, and it was completely destroyed by the publication of Dr Home (*Essay on Bleaching*), who demonstrated the perfect innocence and the superior efficacy and cheapness of sulphuric acid, when properly applied, over sour milk. Another advantage resulted from the use of sulphuric acid, which was of the greatest importance to the merchant. A souring with sulphuric acid required at the longest only twenty-four hours, and often not more than twelve; whereas, when sour milk was employed, six weeks, or even two months, were requisite, according to the state of the weather. In consequence of this improvement, the process of bleaching was shortened from eight months to four, which enabled the merchant to dispose of his goods so much the sooner, and consequently to trade with so much less capital.

The bleaching art remained in this state, or nearly so, till the year 1787, when a most important change began to take place in it, in consequence of a discovery which originated in Sweden about thirteen years before. In the year 1774, there appeared in the *Memoirs of the Royal Academy of Stockholm* a paper on manganese, by Mr Scheele. Among other experiments to which he subjected this mineral, he mixed it with muriatic acid, put the mixture in a retort, and applied heat. He perceived a smell similar to that of aqua regia. This induced him to collect what came over in a receiver, and he found it to be muriatic acid, altered in a remarkable manner by the action of the manganese on it. Its smell was greatly heightened, it was become less soluble in water, and it possessed the property of destroying those vegetable colours on which it was allowed to act. M. Berthollet repeated the experiments of Scheele on this new acid in 1785, and added considerably to the facts already known. He showed that this new acid (called by Scheele *dephlogisticated muriatic acid*) is a gas soluble in water, to which it gives a yellowish green colour, an astringent taste, and the peculiar smell by which the acid is distinguished. When water, impregnated with this acid, is exposed to sunshine, it gradually loses its colour, while, at the same time, a quantity of oxygen gas is disengaged from the water. If the liquid be now examined, it will be found to contain, not the new acid, but common muriatic acid. This experiment Berthollet considered as exhibiting an analysis of the new acid, and as demonstrating that it is a compound of muriatic acid and oxygen. On that account, he gave it the name of *oxygenated muriatic acid*, which was afterwards shortened into *oxymuriatic acid*, an appellation by which it is still known among bleachers.

The property which oxymuriatic acid possesses of destroying vegetable colours, led Berthollet to suspect, that it might be introduced with advantage into the art of bleaching, and that it would enable practical bleachers greatly to shorten their processes. At what time these ideas first struck his mind, we do not exactly know; but at the end of a paper on dephlogisticated muriatic acid, read before the Academy of Sciences at Paris in April 1785, and published in the *Journal de Physique* for May of the same year (Vol. XXVI. p. 325), he mentions that he had tried the effect of the acid in bleaching cloth, and found that it answered perfectly. This idea is developed still farther in a paper on the same acid, published in the *Journal de Physique* for 1786. In 1786, he exhibited the experiment to Mr Watt, who, immediately upon his return to England, commenced a practical examination of the subject, and was accordingly the person who first introduced the new method of bleaching into Great Britain.

Mr Parkes, in his *Chemical Essays*, published in 1815, has mentioned some facts upon this subject, which it will be proper to state. In the early part of the year 1787, Professor Copland of Aberdeen accompanied the present Duke of Gordon to Geneva, and he was shown the discolouring property of oxymuriatic acid by M. de Saussure. Mr Copland was much struck with the importance of the experiment, and on his return to Aberdeen in July 1787, mentioned the circumstance, and repeated the experiment before some eminent bleachers in his own neighbourhood. These gentlemen were Messrs Milnes of the house of Gordon, Barron, and Company, Aberdeen. They immediately began the application of the process to the bleaching of linen on

a great scale; and Mr Parkes assures us that they were the first persons who applied the new process to practical bleaching in Great Britain.

New Process introduced into Britain by Watt.

But this statement, though it may appear plausible at first sight, is quite incorrect. The writer of this article took the liberty of applying to Mr Watt himself for information on the subject. Mr Watt has preserved copies of all his letters since the year 1782, taken by means of his copying machine. He allowed the writer of this article to peruse such of them as bore any reference to this subject. Now, two letters were found, which entirely set the matter at rest. The first of these is to his father-in-law, Mr Macgregor, dated Birmingham, March 19, 1787. In this letter he gives a particular detail of the new bleaching process, states its advantages, and says that he had sent Mr Macgregor a quantity of the whitening liquor. The second letter is to Berthollet, and is dated Birmingham, May 9, 1787. The following is a part of that letter, which we have transcribed verbatim: "Je ne sais pas si j'ai encore fait la liqueur acid si fort que vous avez fait, mais je vous donnerois les moyens de juger. Je trouve que 4 onces de mon acide melé avec la quantité necessaire d'alkali de pearl-ash peut blanchir un gros de toile brune, telle comme j'ai vu chez vous. Il est vrai qu'il ne la fait tout a fait blanc; mais il le fait aussi blanc, que je puis le faire, meme en ajoutant une second dose d'acide. Je bouille la toile par avance dans une solution d'alkali faible; et à mi blanc, je la bouille une second fois. Je trouve que le savon est meilleur que l'alkali pur pour la second bouillon. J'ai blanchi toute à fait le coton, mais je ne suis encore parvenu à blanchir *parfaitement* la toile de lin." The reader will observe, that the date of both of these letters is some months before Mr Copland's return from the Continent. M. Berthollet had published his process in 1785, and as Watt had brought it to England in the end of 1786, and had put it in practice, and introduced it into Mr Macgregor's bleachfield, near Glasgow, in the month of March 1787, it is clear that Saussure has no claim to the original discovery, nor Mr Copland to the first introduction of the new process into Great Britain.

Dr Henry quotes a letter of Mr Watt, dated 1788, February 23, in which he says, "I have *for more than a twelvemonth* been in possession *and practice* of a method of preparing a liquor from common salt, which possesses bleaching qualities in an eminent degree; but not being the inventor, I have not attempted to get a patent or exclusive privilege for it." (*Annals of Philosophy*, VI. 423.) This letter alone is sufficient to show, that Mr Watt's experiments were of an earlier date than those of Messrs Milnes. He says, farther, that "at that very time 1500 yards of linen were bleaching by the new process, under his directions." This great experiment was conducted in the bleachfield of his father-in-law, Mr Macgregor, near Glasgow; where, as he wrote to M. Berthollet, soon after, 500 pieces were bleached by the new method, and Mr Macgregor was so satisfied of the importance of the new process, that he resolved to continue it. Mr Watt made several improvements in the method of M. Berthollet. Instead of employing muriatic acid and manganese, as had been done by Scheele and Berthollet, he had recourse to the cheaper mode of a mixture of common salt, black oxide of manganese, and sulphuric acid. He made use of wooden vessels to hold the water, which was to be impregnated with the oxymuriatic gas, coating them within with a mixture of wax and pitch, which rendered the air light, and prevented the gas from acting on the wood. Mr Watt likewise contrived a test to indicate the strength of the water impregnated with oxymuriatic acid, as far as its bleaching effects were concerned. He took a determinate quantity of the infusion of cochineal, and ascertained how much of the bleaching liquor was necessary to destroy the colour. The strength of the bleaching liquor was obviously inversely as the quantity necessary to destroy the colour. But M. Welter hit upon another method about the same time, which has been considered as preferable, and has in consequence come into general use. He employed a solution of indigo in sulphuric acid instead of the infusion of cochineal. In other respects the two methods were the same.

Mr Thomas Henry of Manchester began his experiments on bleaching, by means of oxymuriatic acid, nearly as early as Mr Watt, and without any previous knowledge of what he had done. He was very assiduous, and very successful in his trials. At a meeting of the bleachers, held at Manchester, early in 1788, he exhibited half a yard of calico, bleached by the new method, which was considered as superior in whiteness to half a piece of calico, bleached by the same process by Messrs Cooper, Baker, and Charles Taylor. In consequence of this exhibition he was applied to by Mr Ridgway of Horwich, to be instructed in the new process. And the instructions which he accordingly received, were the first step of a series of improvements carried on by Mr Ridgway and his Son, with an ability and spirit of enterprise, which have raised their establishment to its present extent and importance. (See *Annals of Philosophy*, VI. 423.) These two gentlemen, Messrs Watt and Henry, had the chief merit of introducing the new mode of bleaching into Lancashire, and the neighbourhood of Glasgow.

In the year 1789, M. Berthollet published a memoir on the subject, in the second volume of the *Annales de Chimie* (p. 151). In this memoir, which constituted the first publication on the mode of bleaching by means of oxymuriatic acid, Berthollet gives a detail of the progress of his experiments, and states the attempts that had been made to introduce the new mode of bleaching into France. M. Bonjour, who had assisted him in his experiments, associated himself with M. Constant, a manufacturer of cloth at Valenciennes, to form a bleaching establishment in that city upon the new plan. But their project was prevented by the prejudices of the inhabitants, and by the jealousy of the bleachers, who were afraid of being injured by the introduction of any new improvements. M. le Comte de Bellaing, however, who approved of the project, granted a piece of ground possessed of all the requisite conve-

niences; but rather at too great a distance from Valenciennes. M. Bonjour applied to the Board of Commerce for the exclusive privilege of bleaching for some years, according to the new method in Valenciennes and Cambray, and for two leagues around these places, offering at the same time to explain the new process in all its details to those who wished to make themselves acquainted with it. But the request was refused.

It does not appear, from Berthollet's account, that the new mode of bleaching had been able to establish itself in any manufactory in France, before the publication of his Memoir. One of the great difficulties in the way of applying oxymuriatic acid to bleaching was the very disagreeable and noxious odour which characterizes it, and which rendered it not only very offensive, but highly injurious to the health of the workmen. He describes, at considerable length, a vessel contrived for impregnating water with it, by M. Welter, and likewise the mode of preparing the gas from common salt, black oxide of manganese, and sulphuric acid. But his improvements, though considerable, were far from obviating the inconveniences complained of. Some method was wanted which should deprive water impregnated with this gas of its smell, without depriving it of its bleaching qualities. The first attempt to accomplish this object originated from M. Berthollet himself.

When he first began to bleach, by means of water impregnated with oxymuriatic acid, he employed that liquid as concentrated as possible; but he found that the texture of the cloth steeped in this liquid was considerably injured. To prevent this effect, he at first added a little alkali to the liquid, to saturate a portion of the acid. But he found afterwards that it was better to dilute the liquid with water. Before this last method occurred to him, he was requested to go to Javelle, to show the bleachers there, the method of preparing the oxymuriatic acid, and making the bleaching liquor. He went twice in consequence, prepared the liquor before the bleachers, and added some potash to prevent the acid from injuring the texture of the cloth. Sometime after the manufacturers of Javelle announced in the different journals that they had discovered a peculiar liquid which they called *Lessive de Javelle*, and which possessed the property of bleaching cloth immersed in it for a few hours. This liquid they prepared by dissolving potash in the water which they were going to impregnate with oxymuriatic acid. The consequence was, that the liquid absorbed a much greater quantity of gas, and might be diluted with a considerable proportion of water, without losing its bleaching quality.

Being disappointed in their attempts to introduce this liquor among the French bleachers, they came over to England, and applied to Parliament for the exclusive privilege of supplying the British bleachers with this liquid. The patent was to be given to MM. Bourbollon de Bonnueil and Company. In consequence of this application, a meeting of the bleachers of Lancashire was advertised, in the beginning of the year 1788. It was at this meeting that Mr Henry exhibited the half yard of calico bleached according to the new method. Mr Watt had written a letter to Dr Percival on the subject, which was communicated to the meeting. He stated in it that he had been in possession of a new method of bleaching, by means of oxymuriatic acid, for above a year; that he had learned it from Berthollet, and that he had every reason to believe that the liquor of MM. Bourbollon de Bonnueil and Company, consisted of oxymuriatic acid, or of some proportion of it. In consequence of this meeting, the county members of Parliament were requested to oppose the intended monoply. Mr Watt also exerted all his influence; and Mr Parkes informs us likewise, that one of the Messrs Milnes of Aberdeen, who had been informed of the use of oxymuriatic acid by Mr Copland, happened to be in the gallery of the House of Commons when this application in favour of these gentlemen was made. He took immediate measures to inform the principal members that this was not a new process; that he himself had long ago prepared an article equally advantageous, and that he was ready to substantiate the truth of his statement when required. (Parkes's *Chemical Essays*, IV. 62.) In consequence of the united exertions of all these different gentlemen, the bill was thrown out, and the monopoly prevented.

It seems to have been partly in consequence of this application of the French gentlemen that Mr Henry of Manchester was induced to attempt bleaching in the large way with oxymuriatic acid. His attention had been first drawn to the subject by the papers of Berthollet, published in the *Journal de Physique*, during the years 1785 and 1786. He was at that time engaged in a course of lectures on Dyeing, Printing, and Bleaching. An acquaintance with the properties of oxymuriatic acid, which he had repeatedly had occasion to exhibit in his course of lectures, and the general hints previously throwu out by Berthollet, led him to conclude, that the liquor of Bourbollon and Company could be nothing else than oxymuriatic acid, or some compound of it. His first operations on the large scale consisted in exposing the goods, in a moist state, in air-tight chambers, to the action of oxymuriatic acid gas. He likewise began to prepare for sale a bleaching liquor, in which the gas was condensed in a very weak solution of potash; which, as we learn from Berthollet, was the very same with the *Lessive de Javelle*. This liquid possessed two advantages over water simply impregnated with oxymuriatic gas. Its smell was less noxious, and it might be employed to whiten printed calicos without destroying the colours which had been dyed upon the cloth. But these advantages were much more than counterbalanced by equivalent disadvantages. It was found not to go nearly so far as water impregnated with oxymuriatic acid, and when kept for some time, it lost its bleaching properties altogether. The reason of this last alteration is now sufficiently understood; the oxymuriatic acid in the liquid was gradually destroyed, and converted into common muriatic acid and chloric acid; the water containing merely common muriate of potash and chlorate of potash. In conse-

quence of these disadvantages, the addition of potash to the bleaching liquid was soon laid aside.

The next attempt to destroy the noxious smell of the liquid, without destroying its bleaching property, was the addition of lime to the liquid. Mr Henry of Manchester was one of the first persons who thought of this addition. On the floor of his air-tight chambers rested a stratum of thin cream of lime, through which the goods were passed by means of a wince; and were afterwards exposed, on quitting the liquor, to oxymuriatic acid gas. Hence the oxymuriate of lime was formed upon the cloth. But this method was objectionable in the case of some coloured goods, the colours of which were injured or destroyed by that earth. It admitted, therefore, of only a partial application.

Other persons made similar attempts, but none of them appear to have been attended with success. But Mr Tennant of Glasgow, after a great deal of most laborious and acute investigation, hit upon the method of making a saturated liquid of oxymuriate of lime, which was found to answer perfectly all the purposes of the bleacher. This was certainly a most important improvement. Without it, the prodigious extent of business carried on by some of our bleachers could not possibly have been transacted. To give some idea of the rapidity with which bleaching is conducted according to the new process, we may mention the following fact, which we state on what we consider as very good authority. A bleacher in Lancashire received 1400 pieces of grey muslin on a Tuesday, which on the Thursday immediately following were returned bleached to the manufacturers, at the distance of 16 miles, and they were packed up and sent off on that very day to a foreign market. The quick return of capital which is thus made is a benefit entirely to be ascribed to the new mode of bleaching.

In the year 1798, Mr Tennant took out a patent for his new invention, and offered the use of it to practical bleachers, for a fair and reasonable portion of the savings made by its substitution for potash, then in general use. Many of the bleachers, however, used it without paying him, and a combination was formed to resist the right of the patentees. In December 1802, Mr Tennant and Company brought an action for damages against Messrs Slater and Varley, the nominal defendants; but who, in fact, were backed and supported by a combination of almost all the bleachers in Lancashire. In consequence of this action, the patent right was set aside by the verdict of a jury and the decision of Lord Ellenborough, who used very strong language against the patentees. The grounds of this decision were, that the patent included a mode of *bucking* with quicklime and water, which was not a new invention. It was decided that, because one part of the patent was not new, therefore the whole must be set aside. Had the writer of this article constituted the jury, the verdict would have been very different. Lime was indeed used previous to the patent of Mr Tennant; but it was employed in a quite different manner from his, and he would have allowed all of them to continue their peculiar method without any objection or injury to his emolument. If the very same process as that of Mr Tennant was employed before he took out his patent, there could be no doubt that the process originated with him, and that those who used it had been induced to do so from the information which they derived from him. In the opinion of the writer of this article, Mr Tennant was hardly used, and the words employed by Lord Ellenborough were quite inapplicable to him. But when a very powerful combination is formed against any individual, the sentiments with which they are actuated propagate themselves with rapidity, and it is difficult for the most upright jury to avoid being swayed by prejudices so much the more formidable, because their existence is not perceived.

In consequence of this decision, the use of liquid oxymuriate of lime in bleaching was thrown open to all, and appears now to be universally employed by all the great bleachers in Britain. Mr Tennant, thus deprived of the fruits of several years of anxious and laborious investigation, advanced a step farther, to what may be considered as the completion of the new method. This consisted in impregnating quicklime in a dry state with oxymuriatic acid. He had taken out a patent for this on the 13th of April 1799, and his right fortunately was not contested. He began his manufactory of solid oxymuriate of lime at first upon a small scale, which has been ever since gradually extending, and is now very considerable indeed. During the whole period of the duration of his patent, he laboured under great disadvantages. The oxymuriatic acid gas with which the lime was impregnated, was obtained from common salt. Now, his patent did not extend to Ireland, in consequence of which, manufactures of dry oxymuriate of lime were established in that kingdom. In Ireland, the manufacturer obtained his salt-duty free, while in Scotland Mr Tennant was obliged to pay a duty of 7s. 6d. *per* bushel. Such, however, was the superiority of the methods employed by Mr Tennant, that he was able to compete with the Irish manufacturers in their own country.

In the year 1815, in consequence of the joint application of the bleachers, the duty on common salt, formerly charged upon all bleachers and others who employed that article in the preparation of a bleaching liquid, was taken off, and they were henceforth allowed to use it duty free. But this act, while it affords great advantages to bleachers on a large scale, precludes those who only work on a small scale, from making their own oxymuriate of lime; the consumption of the powder, therefore, is likely to increase very much among the little bleachers and calico printers. Its use is also considerable in partially discharging the colour of Turkey red cloth. The method was originally a French invention; but a patent has been lately granted to Mr Thomson, a Lancashire bleacher, for the process, which, we believe, he imported from Iony. The method is this: An acid paste, consisting of citric acid, or any other acid thickened with gum, is first printed on the Turkey red cloth, which is then passed through liquid oxymuriate of lime. It becomes white only where the acid was applied. On this bleached part any

Bleaching. other colour may be applied, and the combinations produced are exceedingly beautiful and striking.*

Such, as far as we are acquainted with the subject, is the history of the progress of the new method of bleaching in Great Britain. We have said nothing of the Irish bleachers, because we are not particularly acquainted with the progress of the new method in that country; though we believe that oxymuriatic acid was tried by the Irish bleachers almost as early as it was in Great Britain. Mr Parkes supposes that Mr Kirwan might have proposed the trial of the new reagent, in consequence of some suggestion from Scheele or Saussure. (Parkes's *Chemical Essays*, IV. 43.) But we have no evidence that this was the case. Indeed, it would be quite unreasonable to attempt, by such vague suspicions, to detract from the merit due to Berthollet for his original suggestion of the application of oxymuriatic acid to bleaching,—a merit which he has enjoyed without a competitor for 30 years. Scheele was dead before any one attempted to introduce the new acid into bleaching, either in Great Britain or Ireland. And there is every reason for believing that Saussure's knowledge of the bleaching qualities of oxymuriatic acid, originated from Berthollet's publications on the subject in 1785 and 1786.

There are three different ways of employing oxymuriatic acid in bleaching, still followed by different manufacturers; the first, the simplest, and we may add, the most economical and efficacious mode, is to impregnate water with oxymuriatic acid, and to use this liquid without any addition in a sufficiently diluted state. Mr Rupp, long ago, demonstrated the superior economy of this process, and even at present it is used by the great house of Oberkampf, Widmer, and Company, of Jony, near Versailles, who have contrived a very ingenious apparatus for its preparation. The only objection to this mode of using the gas, is its suffocating odour, which renders it injurious to the health of the workmen employed.

But the method universally employed by the great bleachers of Britain and Ireland, is to form a liquid oxymuriate of lime, and to immerse the goods in it. The gas is always obtained from common salt, by the joint action of sulphuric acid and black oxide of manganese. Various proportions of these ingredients have been recommended by different persons; but none of them seem to have founded their numbers on scientific considerations. Berthollet, in his dissertation on this subject, published in 1789 (*Annales de Chimie*, II. 165), recommends the following proportions as the best:

6 parts of black oxide of manganese,
16 parts of common salt,
12 parts of sulphuric acid,
8 or 12 parts of water.

Boullon La-Grange, in his Elementary Chemical work, recommends

3 parts of common salt,
2 parts sulphuric acid,
1 part of black oxide of manganese,
2 parts of water.

Mr Rupp directed

3 parts of manganese,
8 parts of common salt,
6 parts of sulphuric acid,
12 parts of water.

Mr Tennant of Glasgow directs

3 parts common salt,
3 parts of manganese,
3 parts of sulphuric acid,
3 parts, by measure, of water.

The usual proportions in France are,

3 parts manganese,
10 parts common salt,
7 parts sulphuric acid,
9 parts water.

The numbers recommended by Mr Dalton, as agreeing with the atomic theory, are,

100 sulphuric acid of the specific gravity 1.850,
76 water,
40 common salt,
35 black oxide of manganese.

These numbers are founded on the supposition, that two atoms of sulphuric arid are requisite to disengage one atom of muriatic acid from common salt, which, at the common temperature of the atmosphere, or when the heat of boiling water is only applied, is probably true; though at higher temperatures we know, that one atom of sulphuric acid will drive off one atom of muriatic acid. If we consider the state of the common salt, as it is employed, and the frequent impurity of the oxide of manganese used, pro-

* We may notice here, what we consider as a very improper restriction in the new act of Parliament, which takes off the duty on the common salt used by bleachers. They are prohibited from using the rock-salt as it is dug out of the mine, but must employ what has been refined, and which, of course, amounts to four times the price. Surely the framers of the act might have easily seen that, if it was their object to prevent smuggling, it would have been answered much better by prohibiting the use of refined salt, than by restricting the bleachers to it. It would be impossible to smuggle rock-salt without actually refining it, which no bleacher could do without the certainty of detection. Indeed, such a smuggling trade could only be followed on a scale totally below the attention of a bleacher.

Since the preceding note was written, this absurd restriction has been withdrawn, and the use of rock-salt permitted.

bably the bleachers would find the following proportions the most economical and advantageous:

2 parts sulphuric acid,
2 parts water,
1 part common salt,
1 part black oxide of manganese.

At present there can be no doubt that the proportion of common salt used by the bleachers is too great. It is well known, that what remains in the stills after the process, contains still a considerable proportion of muriatic acid. Thus Mr Wilson found the salt which crystallized in the liquid residuum, after distillation, was composed of

Sulphate of soda,	55.47
Muriate of manganese,	26.79
Muriate of lead, -	1.52
Water, - -	16.22
	100.00

This residue was obtained from a mixture of

3 parts common salt,
1 part black oxide of manganese,
4 parts sulphuric acid of the sp. gr. 1.500.

See *Annals of Philosophy*, I. 365.

Dr Henry of Manchester found very large proportions of common salt and muriate of manganese in the residue left after distillation; and he informed the writer of this article, that he had known a bleacher, when in want of common salt, to work twice from the same ingredients, by adding fresh manganese and oil of vitrol. This is a sufficient proof that vastly too much common salt is employed. Indeed, the consumption of common salt by the bleachers is enormous. One bleacher in Lancashire, for example, uses, every six weeks, four waggon loads of common salt, each load containing 3 tons 13 cwt. This is almost at the rate of two tons and a half of salt *per* week. He employs, for his process, 22 leaden stills, each 22 inches deep, and about 2 feet 4 inches in diameter. Eleven of these are worked on alternate days.

The temperature of steam, under the pressure of the atmosphere, is sufficient to expel the whole of the oxymuriatic acid, and nothing is gained by employing a stronger heat. Accordingly, the stills are universally heated by steam. The calculation is, that 25 square feet of surface in the boiler, is sufficient to heat six stills of the dimensions given above, into each of which are put 112 lbs. of common salt. The gas is received into cream of lime, in which the lime is kept suspended by mechanical agitation. When the process is finished, the undissolved lime is allowed to subside, and the clear liquid is drawn off. Its specific gravity is, generally, about 1.0125. Liquid of this strength is usually mixed with five or six times its bulk of water, before the goods are immersed in it. It has been said, that muriate of lime always injures the texture of cloth immersed in it. But this is true only when the solution is concentrated, and when it is used boiling hot; but by no means applies to the processes of the bleacher.

The third state in which the oxymuriatic acid is employed by bleachers, is combined with lime, constituting dry oxymuriate of lime. Hitherto the manufacture of this salt in Great Britain has been confined to Mr Tennant of Glasgow, the inventor of the process. But his patent being now at an end, other persons have begun to make it in the neighbourhood of Manchester. For the manufacture of this salt, leaden stills are employed similar to those used in making liquid oxymuriate of lime, and likewise cast-iron stills. The gas is conveyed into a close wooden vessel, on the bottom of which is spread some quicklime, newly slaked and sifted. As the gas passes over, it combines with the lime, and gradually forms the salt required. It is a soft white powder, possessing little smell. When heated it gives out oxygen gas; but if it be mixed with sulphuric acid, oxymuriatic gas is given out when the heat of a lamp is applied. It is partially soluble in water, and the solution gradually disengages bubbles of oxygen gas, while the salt is changed into common muriate of lime. This change appears to take place gradually, even when the salt is kept in a dry state. Mr Dalton has analyzed this salt, and found it composed of

Oxymuriatic acid,	23	or 1 atom,
Lime, -	38	or 2 atoms,
Water, -	39	or 6 atoms.
	100	

When the salt is dissolved in water, one-half of the lime is precipitated, so that the compound which was formerly a subchloride of lime, is now converted into a chloride. Its constituents are,

Oxymuriatic acid,	54.7	or 1 atom,
Lime, -	45.3	or 1 atom.
	100.0	

When a current of oxymuriatic gas is passed to saturation through water in which lime is suspended, a bichloride of lime is formed. It is composed of

Oxymuriatic acid,	70.7	or 2 atoms,
Lime, -	29.3	or 1 atom.
	000.0	

See *Annals of Philosophy*, I. 15, and II. 6.

From Mr Dalton's experiments, the oxymuriate of lime of commerce contains one-third of its weight of common muriate of lime; but this portion varies according to the age of the salt, always increasing, till at last the whole is converted into common muriate of lime.

Present Method of Bleaching.

II. In the article Bleaching in the *Encyclopædia*, very copious extracts have been given from Kirwan, Berthollet, Decharmes, Oreilly, Rupp, &c. with descriptions and drawings of the different apparatus recommended by them. But the reader of that article will be at a loss to form any idea of the method

of bleaching at present employed by the most enlightened bleachers in Great Britain On that account, we conceive that it will be requisite to give a concise sketch of the different processes as they occur in a practical bleachfield. We shall omit most of the descriptions of apparatus, which would oblige us to repeat many things contained in the article to which this is a supplement. The bleaching apparatus is sufficiently simple to be easily conceived by the reader without many particular descriptions. Cotton being much more easily bleached than linen, it will be requisite (though the processes are nearly the same) to give the method of bleaching each separately, because the quantity of materials employed differ for each.

1. *Bleaching of Linen.*

It would appear from the new process of Mr Lee, who separates the woody matter from the fibre of flax without steeping it, by means of mechanical action, and then bleaches his flax by simply washing it in warm water, that the colouring matter is not chemically combined with the fibrous matter, while the plant is vegetating, or after it is pulled, but that the chemical combination takes place while the plant is steeped in water. The object of this steeping is to induce a fermentation, which loosens and destroys a cement which bound the fibres of flax to each other and to the wood. This fermentation weakens considerably the strength of the flax fibres, and even destroys many of them. Mr Lee's process, therefore, if it be practicable on a large scale, would be a prodigious improvement. It would render the flax fibres much stronger, it would increase their quantity, and it would save the expence of the materials employed in bleaching the linen. The writer of this article has been informed that Mr Lee's process has uniformly failed of success, when tried in Ireland. If this account be true, it is extremely difficult to explain it. We have seen Mr Lee's process performed by workmen under his own direction at Old Bow, near London, with the most complete success; not merely upon handfuls of flax, but upon whole fields of it. Indeed, the whole is so extremely simple, that we cannot well see how it should fail, if properly conducted. We cannot, therefore, help suspecting that the prejudices of the Irish, with which it would have to contend, have been too powerful for it; but that, as soon as it shall meet with fair play, it will be found just as practicable, and certainly much cheaper and better, than the methods at present in use.

It is during the steep, then, that flax acquires its permanent dark colour; and four processes, which we shall now briefly describe, are requisite to restore it to its original white colour, or to separate the colouring matter, which is chemically combined with the fibres of the flax.

1. When the flax is converted into thread, it is repeatedly moistened with the saliva of the spinner, which leaves attached to it a quantity of albumen. When the thread is woven into linen, it is covered with the weaver's dressing, which consists of a paste, made of flour and water. The first step of the bleacher's process is to remove these foreign bodies, that the colouring matter of the flax itself may be laid open to his subsequent operations. For this purpose, the goods are immersed in warm water, or in a warm alkaline ley, which has already been used in the bleaching processes to be described immediately. In this situation they are allowed to remain till some degree of fermentation appears on the surface of the liquid with which they are covered. This appearance takes place sooner or later, according to the nature of the goods and the heat of the weather, and it is allowed to continue longer or shorter according to circumstances. The goods are then taken out, and well washed in pure water, which now removes all the foreign matter added during the spinning and weaving.

2. The second process consists in exposing the goods to the action of alkaline leys.

The alkali universally employed by the bleachers in Great Britain is Russian or American potash, which contains about two-thirds of its weight of caustic potash, according to the experiments of Vauquelin (*Annales de Chemie*, XL. 273). The other ingredients are sulphate of potash, muriate of potash, carbonic acid, and siliceous earth. It has been alleged that the potash of commerce is often adulterated artificially with common salt. This the bleacher should always ascertain before employing it. Indeed, every bleacher, who wishes to be exact, ought to be in possession of a mode of determining the exact quantity of potash which the alkali that he intends to use contains. There are two methods which may be employed for this purpose. The first is to dissolve a certain quantity of the potash in water, and to try how much acid of a known strength is requisite to saturate the alkali contained in this solution. Ample directions for reducing this method to practice, are contained in the dissertation of Vauquelin above referred to. The second mode of testing the alkali is more rapid; but would be less convenient for the bleacher, unless he were in possession of a mercurial pneumatic trough; but if he is supplied with this part of chemical apparatus, the method is very easy; and, perhaps, in the hands of persons not very conversant with chemical experiments, more to be depended on than the first described method. It is this. A glass tube of the capacity of 10 or 12 cubic inches, shut at one end, and flat at the other, so as to stand on the mercurial trough when filled with mercury, is to be graduated into cubic inches and tenths. The tube, when the strength of the alkali is to be tried, is to be filled with mercury, and placed inverted on the trough. Then let up 20 grains of the alkali to be examined, which will rise to the top of the tube. Add now about 50 grains of sulphuric acid. As soon as the acid comes in contact with the potash, an effervescence takes place, and the carbonic acid is extricated. Observe the number of cubic inches and tenths of this gas extricated, taking care to sink the tube so far in the trough that the mercury in the tube and trough are upon the same level. Multiply the bulk of the carbonic acid by the number 0.46313; the product is the weight of carbonic acid present in grains. Multiply this weight by 2.18; the product is the weight in grains of real potash contained in 20 grains of the pearl ashes under examination.

6

This last method is founded upon several chemical facts which have been sufficiently established. The potash, as it exists in American or Russian potash, is combined with carbonic acid in such a proportion, that one atom of acid is combined with one atom of alkali. An atom of carbonic acid weighs 2.750, and an atom of potash 6. The weight of a cubic inch of carbonic acid gas is 0.46313 grains. Hence, if we multiply the bulk of carbonic acid in cubic inches and tenths, by 0.46313, we obtain its weight in grains. The numbers 2.750 and 6, are very nearly to each other as 1 to 2.18. Hence, if we multiply the weight of carbonic acid, found by 2.18, we obtain the weight of potash with which it was combined. It is proper to know, that this method will give the proportion of potash rather below the truth, because, a little of the carbonic acid will be held in solution by the acid employed. If we add such a quantity of sulphuric acid, that, after the expulsion of the gas, the whole shall remain in a liquid state, the result will be almost perfectly exact, if the bulk of the liquid be added to that of the gaseous product, and the whole be considered as carbonic acid gas.

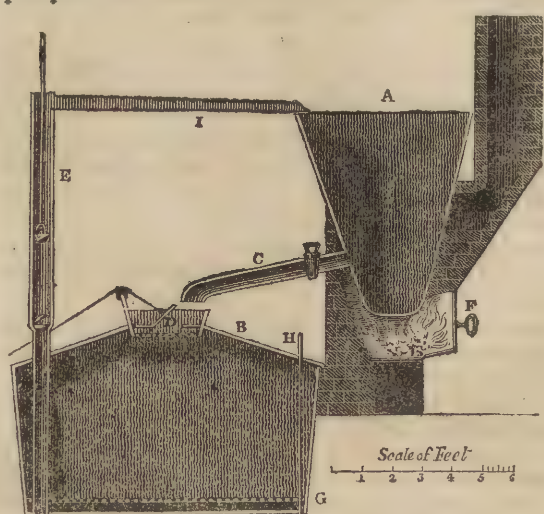
Formerly, the Irish bleachers were in the habit of using barilla instead of potash. But there are two objections to the use of this alkali. In the first place, the weight of real alkali contained in the same proportion of barilla, is much smaller than in pearl-ash; and, in the second place, the weight of an atom of soda being greater than that of an atom of potash, it is probable, that the second will go farther in bleaching than the former. When to this fact we add the difference of the price, which is always in favour of potash, there can be no hesitation in affirming, that no bleacher who studies the principles of economy, would make use of barilla if he can be supplied with pearl-ash. In trying the strength of barilla, the second of the two methods above described cannot be employed, because barilla contains both carbonate of lime and carbonate of magnesia. Hence the quantity of carbonic acid will always be much greater than it would be, if barilla contained only carbonate of soda. According to the experiments of Kirwan, a great proportion of the soda in barilla is in a caustic state. But if we attend to the way in which this substance is procured by burning the *salcola* vermiculata, we shall scarcely be induced to adopt this opinion. For, during the combustion of vegetable substances, carbonic acid is always evolved in considerable quantities, this acid would, of course, combine with the alkali, and the heat of the combustion is insufficient to decompose the carbonate of soda when once formed.

Two methods of applying pearl-ash to the purposes of bleaching, are generally followed. These methods are called *Boiling* and *Bucking*.

Boiling needs no description. The alkaline ley and the goods are put together into a boiler, and the whole kept at the boiling temperature for the requisite length of time.

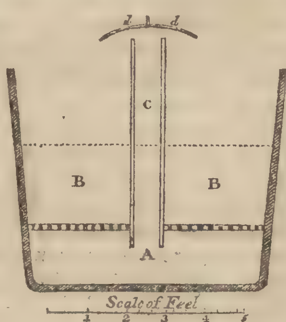
Bucking is somewhat more complicated. It consists in making the alkaline ley, raised to a boiling heat, to pass repeatedly through the goods. Various modes of performing this process are followed in different bleaching-houses. But they may be all reduced to one or other of the following three: 1. The goods are placed loosely in a proper vessel, the heated ley is made to run upon them, and to pass through them. As it comes to the bottom of the vessel containing the goods, it is pumped back again into the boiler, where it is heated a second time, and then made to pass through the goods as before. This process is repeated as often as is thought requisite. 2. The alkaline solution is put into the bottom of a large boiler, having a platform of wood, with holes through it, placed a little way above the surface of the ley. Through the middle of this platform there passes a pipe of a convenient size, the lower end of which reaches nearly to the bottom of the boiler, being immersed deep in the ley, while the upper end rises as high as the mouth of the boiler. The goods are placed upon the platform, and round the tube within the boiler to a convenient height. When heat is applied to the boiler, the steam generated is prevented from making its escape by the wooden platform and the goods. It, therefore, acts upon the surface of the ley, and forces it to ascend through the tube. A kind of umbrella is suspended over the top of the tube, which assists in spreading the ley over the surface of the goods. By this contrivance, it is made to spread over and trickle down through the goods, till it gets again to the bottom of the boiler, to be heated and forced up by the steam as formerly. This method is more efficacious than simple boiling, because the temperature of the ley is heated some degrees higher than 212°, which has a considerable effect upon the goods.

The following are sections of the vessels used for these two different methods of bucking: This figure shows the vessels employed, when the ley is simply pumped back into the boiler. A is the boiler



for heating the alkaline ley. B is the large wooden vessel in which the goods are placed. C the cock and pipe, by means of which the ley is conveyed upon the goods. D a square box designed for spreading the ley over the goods within the vessel B. E the pump for raising the liquor again out of the vessel B, from which it is conveyed by the

spout I back again into the boiler. F is the furnace for heating the ley. G represents the false bottom of the wooden vessel, full of holes, for the passage of the ley when it has run through the goods. H is a round wooden staff, which completely fits a hole at the bottom of the bucking vessel. It is called a duck, and is intended to be pulled up whenever the spent alkaline liquor is to be run off.



This figure represents the second kind of bucking apparatus. A is a metallic boiler to be fixed in brick work, as in the preceding figure. BB is the top part of wood, called a crib, with the bottom full of holes. In this, the goods are placed one above another, often amounting to many hundred pieces at one operation. C is the pipe through which the leys boil up, and *dd* is the umbrella suspended over the pipe, for the purpose of spreading the ley more effectually over the goods.

The third method of bucking is a modification of the second. It is considered as preferable, and is perhaps most generally used by experienced and extensive bleachers. The platform and its ascending pipe are placed, not in the boiler, but in a convenient tub or cistern. The requisite quantity of ley is put into the cistern below the platform. A tube passes into it, which conveys steam from a steam-boiler, in such quantity as first to heat up the ley to the boiling point, and then to force it up through the central tube, to be deposited over the surface of the goods, and to filter through them into the space below the platform. This method of bucking so nearly resembles the last, that the nature of the vessel employed will be easily understood without a figure.

The quantity of pearl-ash required for bleaching linen in general, amounts to $\frac{1}{10}$th or $\frac{1}{12}$th of the weight of the goods to be bleached. This quantity, however, is not to be used all at once; but is to be divided into six or eight portions, to be employed each in as many bucking processes. When the goods are boiled in an alkaline ley, the boiling is usually continued for four or six hours. In bucking, the process is generally continued till the liquor is so far evaporated, that the whole of it which remains is retained by the goods themselves. This generally requires from six to eight hours.

Heavy yarns for making ducks and similar fabrics are most advantageously bleached before being woven into cloth. These yarns are usually boiled with from 16 to 20 *per cent.* of their weight of pearl-ash, divided among two, three, and sometimes four boils, in proportion to the nature of the fabric, and the degree of whiteness required. When two boils are required, $\frac{1}{12}$th of the weight of the goods may be used in the first, and $\frac{1}{20}$th in the second boil. If the goods are difficult to bleach, or if a greater degree of whiteness be required, it is sometimes customary to give them a third, or even a fourth boil, diminishing the allowance of potash each time. In the last boil, one-third or one-half of the potash is frequently kept out, and its place supplied by an equal quantity of soft soap. When the weather is favourable, the goods are sometimes exposed on the grass after each boiling.

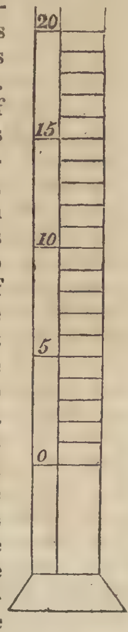
3. The third process is to expose the goods to the action of oxymuriatic acid in some one of the three states described in a preceding part of this article,—namely, dissolved in water, combined with lime in the state of liquid oxymuriate of lime, or in the state of solid oxymuriate of lime. The first of these states is the most economical; but its very noxious odour renders its application scarcely practicable on a great scale. The second state consists of two atoms of oxymuriatic acid, combined with one atom of lime, or it is a bichloride of lime; and the third state, or the dry powder, is a compound of one atom of oxymuriatic acid and one atom of lime, or it is a chloride of lime. Of these two last substances there can be little doubt that the first, or the one made in the liquid way, is the most efficacious. But we shall suppose the dry chloride of lime to be the substance used; as its employment is likely to increase very much, especially among those bleachers who are the most likely to require instructions. Besides, it is not difficult to apply the observations made on chloride of lime to the liquid bichloride.

The quantity of oxymuriate of lime required for bleaching linen varies considerably, according to the nature of the linen operated upon,—according to the season of the year, and the degree of exposure on the grass,—and according to the whiteness required. But we may state the average quantity as varying between $\frac{1}{12}$th and $\frac{1}{20}$th of the weight of the goods employed. This quantity may be divided into three or four processes. If three processes be reckoned sufficient, $\frac{5}{12}$ths of the oxymuriate may be expended on the first operation, $\frac{4}{12}$ths in the second, and $\frac{3}{12}$ths in the third. If four processes are considered as requisite, then $\frac{4}{12}$ths of the oxymuriate should be used in the first operation, $\frac{3}{12}$ths in the second, $\frac{3}{12}$ths in the third, and $\frac{2}{12}$ths in the fourth. Two wine pipes may be employed for the solution of the bleaching powder. They should be placed on one end, the other end being open; and a plug-hole should be made in each, about 10 or 12 inches above the bottom. From 20 lbs. to 100 lbs. of the bleaching powder is to be put into a small tub or bucket, where it is to be well bruised and mixed with a little water. This mixture is to be thrown into one of the wine pipes, more water is to be added, and the whole carefully stirred together for a few minutes. A cover is then to be put upon the pipe, and the whole is allowed to stand till the insoluble part of the powder, consisting of quicklime, subsides below the plug-hole. The clear solution, called *stock-liquor,* is now to be drawn off through the plug-hole, and may either be used immediately, which is most expedient, or it may be kept under a close cover till wanted.

Repeated portions of powder may, in this manner, be dissolved in the same pipe, till the sediment ac-

cumulate to the height of the plug-hole. When this happens, fresh stock-liquor must be prepared in the other pipe. But instead of using pure water, as in the first operation, the sediment in the first pipe should be repeatedly washed, by filling up the pipe with water,—stirring the sediment well,—allowing it to settle, and then drawing off the clear liquor by the plug-hole. These washings, as long as they show any bleaching power, are to be used in the second pipe, instead of pure water, for preparing stock-liquor. The sediment, in every future operation, should be exhausted in a similar manner.

The strength of this liquor is determined by means of the graduated glass tube, figured in the margin, which is known by the name of the *Test-tube*. The method is as follows: One part of the best indigo is dissolved in nine parts of strong sulphuric acid, and the solution is mixed with 990 parts of water, making a solution, $\frac{1}{1000}$th part of which is indigo. Of this liquid a quantity is to be poured into the test-tube, so as to fill it up to 0, or the commencement of the scale. The bleaching liquor, whose power is to be tried, is then to be dropt gradually in and mixed with the blue liquor, by shaking the tube from time to time, till the blue is changed into a clear brown. As soon as this takes place, the degree of the scale to which the mixture reaches is observed, and the figure marked at that degree indicates the strength of the steep-liquor. The lowest on the scale is, of course, the strongest in bleaching power, being capable of destroying most colour. The liquor, whose strength is thus ascertained, is denominated Steep-liquor, of 1, 2, 3, 4, 5, and 6 degrees; the last of which is the weakest ever used for any kind of goods. By adding stock-liquor, when the steep-liquor is too weak, and water when too strong, this liquor may be obtained of any strength which is required.



The bleacher's operations should go on in regular rotation. The whitest goods are put into the clean fresh steeps. As these goods do not exhaust the bleaching power of the liquor, its strength is restored after they are taken out, by the addition of fresh stock-liquor. It is then used for goods in a less advanced state of whiteness. If the second operation has not exhausted its bleaching powers, or rendered it foul, it may be used a third time by another addition of stock-liquor. But if it has been rendered very foul, and indicates only 12 or 15 degrees in the test-tube, it is not worth preserving or using.

One pound of the bleaching powder, as it is prepared by Mr Tennant and Company of Glasgow, is capable of forming from ten to twelve gallons of liquor of one degree.

The exposure of the goods to the action of the oxymuriate of lime should not commence till after the third boil or buck, if they are to be exposed three times to the action of this substance; and after the second, if they are to be exposed to four operations, with muriate of lime. These operations should alternate with the last bucks or boils. In all cases, the oxymuriate of lime must be dissolved in such a proportion of water as to allow the goods immersed in it to float loosely and easily in the solution, that the liquid may come into free contact with every part of them.

Though the method of immersion or steeping the goods in the solution of oxymuriate of lime is most generally used, yet, in some cases, great advantage is obtained by *wincing* the goods through the solution, instead of allowing them to rest for any length of time in it. When the method of wincing is followed, a solution of twice or thrice the ordinary strength may be safely used, and much time in consequence saved. When the goods are coarse and heavy, such as yarn for ducks, this last method is almost universally preferred. These heavy yarns require from $\frac{1}{12}$th to $\frac{1}{15}$th of their weight of oxymuriate of lime, divided into a number of operations corresponding to that of the boils, and following these boils, or these boils with exposure on the grass, when such exposures are employed. In the first oxymuriatic operation, they are winced through a strong solution, produced by adding about three or four ounces of dry oxymuriate of lime to each gallon of water. The yarns are hung over a roller fixed in the mouth of the trough or tub that contains the solution, which covers part of its surface. This roller being then turned rapidly round by means of a crank fixed on one of its ends, the yarn is made to pass rapidly and repeatedly through the liquor for the space of thirty or forty minutes. Fresh parcels of yarn are, in succession, passed through the liquor, its strength being restored by additions of oxymuriate when necessary, and the whole changed when exhausted of bleaching powers and foul. In this way, a very powerful bleaching effect is produced, and yarns which have undergone one process in this way, may receive the remaining oxymuriatic processes to which they are to be exposed in the ordinary way of immersion, which is less expensive in point of labour, though less efficacious.

The oxymuriatic process then is repeated three or four times, beginning after the second or third boil or buck, and alternating with every subsequent boil or buck. The time during which the goods are exposed to the oxymuriatic solution during each process, is from six to twelve hours.

4. The fourth process consists in steeping the goods in an acid solution. This is called the acid process. We have already observed, that the acid at first used for this purpose was sour milk; but that, when Dr Roebuck contrived his new method of preparing sulphuric acid, Dr Home proposed this acid as a substitute for sour milk; that it speedily came into general use, and very much improved and shortened the tedious bleaching processes at that time in general use. This steeping in sulphuric acid is repeated twice, and sometimes thrice, once after each of the last two or three immersions in the oxymuriate of lime. For this purpose, a quantity of strong sulphuric acid is taken, amounting to about $\frac{1}{40}$th or $\frac{1}{50}$th of the weight of the goods to be immersed. This acid is diluted with 60 or 80 times its weight

of water, which reduces it to the specific gravity of about 1.015. Now, sulphuric acid of this specific gravity contains about $1\frac{1}{2}$ per cent. of its weight of real sulphuric acid. In this liquid they are steeped from eight to twelve hours. When linen fabrics are intended for printing, they require two or three additional processes in alkali, and one in acid, and the solution of the sulphuric acid is generally made one-third stronger when the goods are intended for the madder copper.

Such are the different processes at present followed by the practical bleachers in Great Britain. After each of them, whether boiling or bucking in an alkaline solution, immersion in oxymuriate of lime, or steeping in sulphuric acid, the goods must be carefully washed in pure water, either by machinery or otherwise, till all the materials employed are completely washed out of them. Upon this much of the economy and success of bleaching depends. It is likewise of great advantage to free the goods from the water which they contain after each washing, before subjecting them to the next operation. For this purpose, Bramah's press is employed in almost all the large bleaching-houses, and constitutes one of the greatest improvements introduced of late years.

2. *Bleaching of Cottons.*

Cotton is a kind of down which fills the seed pods of various species of plants, particularly the *Gossypium herbaceum, hirsutum,* and *arboreum,* from all of which it is extracted in considerable quantity for the purposes of manufacturers. This substance was known to the ancients, and made by them into thread and cloth. Cotton cloth appears to have been generally worn in Egypt and the neighbouring countries at a very early period; and no doubt the plant was cultivated in India and China for similar purposes before the time at which the history of these nations, as far as we are acquainted with it, commences. Pliny gives a short description of the *gossypium* which grew in Upper Egypt, which is sufficient to show us that it was the same with our cotton plant. "Superior pars Ægypti in Arabiam vergens gignit fruticem, quem aliqui *gossipion* vocant, plures *xylon*, et ideo lina inde facta *xylina*. Parvus est, similemque barbatæ nucis defert fructum, cujus ex interiore bombyce lanugo netur. Nec ulla sunt eis in candore mollitiave præferenda." (*Plinii, Natur. Hist.* Lib. xix. c. 2.) The *byssus* mentioned in the same chapter was probably likewise a species of cotton; though the account of it given by Pliny is not sufficiently precise to enable us to make out the point with certainty.

Since the discovery and colonization of America and the West Indies, and our great connection with East India, cotton has become a very common article of clothing in Europe. The manufacture of cotton cloth in consequence has increased prodigiously, and in Great Britain constitutes one of the great branches of manufacturing industry. As it does not go through the complicated processes of flax and hemp, and is naturally (for the most part at least) of a lighter colour, the art of bleaching it is much more easy and less expensive. The processes are nearly the same as those for linen; but it will be requisite to go over them shortly, in order to point out the difference in the proportions of the ingredients employed, and some other little circumstances which ought to be generally known.

1. The first, or fermenting process, is the same for cottons as for linens. This must be the case, because the weaver's dressing, which it is the object of the process to remove, is the same in both cases.

2. But there is a difference in the second process, which consists in exposing the goods to the action of alkaline leys.

Cotton goods are generally exposed to the action of lime diffused through water, so as to constitute what is called *milk of lime*. The liquid is heated to the temperature of 200°, and the cloth is kept in it from four to six hours. Two or three alkaline processes will be required after this, and the quantity of potash which ought to be used should amount to $\frac{1}{30}$th of the weight of the goods. When the application is to be made at twice, the first of the operations should have $\frac{5}{8}$ths, and the second $\frac{3}{8}$ths of the whole potash. If three processes are to be gone through, the first and second should have $\frac{3}{8}$ths each, and the third $\frac{2}{8}$ths of the potash.

When heavy cottons are bleached, either boiling or bucking may be employed, as described under the head of linens. When the cotton fabrics are light, or contain dyed colours, boiling is generally preferred, and the proportion of alkali diminished one-third, while a quantity of hard or soft soap, equal to the diminution of the alkali, is added to the ley.

3. The third, or oxymuriatic process, is nearly the same for cottons as for linens. The quantity of oxymuriate of lime used, should amount to $\frac{1}{20}$th or $\frac{1}{30}$th of the weight of the cotton cloth to be bleached. This quantity is divided among two or three operations, an oxymuriatic process following each alkaline process. When three operations are to be performed, the first must have $\frac{5}{12}$ths, the second $\frac{4}{12}$ths, and the third $\frac{3}{12}$ths of the whole oxymuriate of lime. When only two operations are to be performed, the first should contain two-thirds, and the last one-third of the whole. The duration of each steep should be from six to twelve hours, but not longer. If wincing through the solution be preferred, a stronger liquor may be used, and the operation may be finished in fifteen or twenty minutes.

4. The fourth, or acid process, is pretty much the same for cottons as for linens; the quantity of sulphuric acid should amount to about $\frac{1}{60}$th or $\frac{1}{80}$th of the weight of the cotton goods. It must be diluted with water till its specific gravity be reduced to 1.010. A steep in this diluted acid from six to twelve hours after each of the two last oxymuriatic processes is generally made use of.

When the fabrics are very light, or contain dyed colours, the souring is only once used, and the strength of the acid is reduced to 1.008. This souring is applied after the last oxymuriatic process. In this case thorough washing or rinsing in water, is most strictly to be attended to before exposure to the sulphuric acid in souring. When cotton fabrics

Bleaching.

are intended for printing with madder colours, they require one or two additional bucks or boils, and the sours should be one-third stronger.

The intermediate washings in pure water, and the proper draining of the goods after washing, must be observed with as much care in bleaching cotton as in bleaching linen. It is only in the bleaching of those goods intended for printing, that any exposure to the light and air is now used, and that but seldom even in this case.

3. *Bleaching of Rags for the Papermaker.*

The rags to be whitened should be well washed in the engine, and when reduced to what is called half-stuff, the water should be run off, leaving just enough to allow them to be easily turned. While the rags are thus preparing, a solution of the bleaching-powder is to be got ready, by putting the powder into a pitcher or other convenient vessel, and pouring upon it two or three gallons of water, stirring and bruising it well, till every thing soluble is taken up. After it has stood some time to allow the insoluble sediment to fall down, it is fit for use, and the pure solution should be poured into the engine. The sediment may be repeatedly washed with fresh portions of water to exhaust any remains of soluble matter, which alone is useful in the whitening process. While this last operation is going on, the engine is to be kept moving, and to continue so for about an hour, which will generally be sufficient to produce the requisite degree of whiteness. The water may now be returned upon the engine, and the washing continued as usual till the process be completed. The quantity of powder usually allowed, is from two pounds to four pounds for every hundred weight of rags, in proportion to the whiteness required, and the difficulty of whitening the stuff.

Rags containing dyed colours, to be discharged, should be well washed and reduced to half-stuff. They are then removed from the engine and put into a puncheon, made water tight, but having a sufficient opening in the side to admit with ease the putting in and taking out of the stuff, and capable of being shut up so as to retain the water. Having put the stuff into this puncheon, take for every cwt. of the rags a solution containing from five to eight pounds of bleaching powder, according to the strength and fixedness of the colours to be discharged. Pour the solution into the puncheon among the stuff, allowing liquid enough to let the stuff float easily, and for each pound of powder used, add half a pound of sulphuric acid. Then shut up and secure the opening so as to make the puncheon air tight; then turn the puncheon round upon its axis, by means of a crank fixed at one end of it. Moving it in this manner gives facility and uniformity to the discharging process.

We have now finished the sketch which we proposed to give of the processes at present followed by the practical bleachers of Great Britain. For several other applications of the same operations, we refer to the article BLEACHING in the *Encyclopædia*. But probably a few words will be expected from us on the theory of the art. Upon this subject, the following observations are all we have to offer:

Theory of Bleaching.

The fibres of hemp, linen, and cotton, are naturally white; but, before bleaching, they are combined with a substance which gives them their grey or brown colour. The object of bleaching is to remove this substance. From the experiments which have been made upon the subject, it would appear that this substance is partly in the state of resin, and partly in a state analogous to that of the volatile oils. Resins dissolve readily in the alkalies, which they neutralize and convert into a species of soap. But this is not the case with the colouring matter, which is in a state analogous to that of volatile oil. After the weaver's dressing has been removed, the cloth is boiled or bucked repeatedly in alkaline leys, which dissolve and separate the whole of the colouring matter, which possesses the characters of resin. The alkaline ley, after this process, is turbid, has a brownish red colour, a strong smell, and has lost its alkaline properties. When muriatic acid is poured into it, a copious flocky precipitate subsides, consisting of the colouring matter. This substance, when properly edulcorated, has a greenish grey colour, which it retains when separated from the water by the filter. But, when dry, it becomes blackish externally, though it retains internally its greenish tint. It is soluble in alcohol, insoluble in oil of turpentine, but dissolves readily in the alkalies. It tinges the strong acids, but does not readily dissolve in them. When thrown upon a red-hot iron, it burns with a yellow flame and a black smoke, leaving a charry residuum. These properties, for the knowledge of which we are indebted to Mr Kirwan,* are sufficient to show us that the substance which the alkalies separate from linen is analogous to the resins.

By repeated boiling in alkaline leys the cloth is rendered whiter. But it is not yet bleached; because a colouring matter still remains, which the alkalies are incapable of dissolving. The action of oxymuriatic acid, or exposure to the air and light, produces a change on this colouring matter, and renders it capable of being dissolved in alkalies. In short, by these processes it is converted into a resinous matter, similar to that which the alkalies had previously removed. There can be no doubt that this change is produced by the union of the colouring matter with oxygen. When the oxymuriatic acid is used, the oxygen is supplied by the water which is decomposed by the mutual action of the chlorine and the colouring matter. The chlorine combines with the hydrogen of the water, and is converted into muriatic acid; while the colouring matter combines with the oxygen of the water, and is converted into resin.

It would appear, that this change in the colouring matter renders it white; for linen will appear bleach-

* See his *Experiments on the Colouring Matter of Linen Yarn and its Solvents*, in the *Transactions of the Royal Irish Academy* for 1789.

Bleaching || Blockade.

ed if it be treated with a sufficient quantity of oxymuriate of lime. But this state of the colouring matter is not permanent. If it be allowed to remain in the cloth it speedily becomes yellow. Hence the reason why cloth, bleached with oxymuriatic acid alone, soon loses its white colour again. This happened to Berthollet, in his first trials to bleach in the large way, by means of oxymuriatic acid. It happened likewise, at first, to several bleachers in this country. It is requisite, that the colouring matter, now become soluble, should be removed by alkalies. Hence we conceive, contrary to the practice of bleachers, that the last process ought always to be boiling in an alkaline ley. In great towns, as in London, where linen cannot be exposed to the air and sun upon the grass, it would be a great advantage, if it were steeped, for some time before it is washed, in a solution of oxymuriate of lime. It might then be boiled in an alkaline ley. Linen or cotton, thus treated, would not become yellow by age, as is too often the case with linens in large towns.

The precise use of the steeping of the goods in sulphuric acid has not been ascertained; though it is known to be indispensable. It is supposed, that both linen and cotton contain a portion of iron, and that the acid removes this substance, which both renders the colour whiter and the cloth fitter for the subsequent processes of dyeing and calico-printing. This explanation is not improbable, though we are not aware of any accurate experiments, by means of which, the presence of iron in the sulphuric acid solution, employed as a souring, has been ascertained. But, probably, the great use of the acid is to remove or neutralize the alkali, which, if allowed to remain in the cloth, would gradually injure its texture.

We have taken no notice, in the preceding article, of a proposal, made a good many years ago in Ireland, and, in support of which, a pamphlet was published by Mr Higgins of Dublin; we mean the substitution of the hydroguretted sulphuret of lime for the alkali. The reason of this omission is, that we are not in possession of any facts on the subject. But we consider the circumstance of no British bleacher having introduced this substitute into his work, as sufficient to entitle us to infer, that the substitute would not answer the purposes for which it was recommended. Several objections to its use will readily present themselves to those who consider the subject. Among others, we may mention, that if any metallic substance, as iron, were to come in contact with the goods which are under the influence of hydroguretted sulphuret of lime, this last substance would act as a mordant, and fix the metal on the cloth; from which it could not be again removed without some expence, and without the risk of injuring the strength of the substance. (J.)

Definition.

BLOCKADE, in war, the shutting up of any place or port by a naval or military force, so as to cut off all communication with those who are without the hostile line.

There is, perhaps, no part of the law of nations which, in practice, presents so many perplexing questions, as that which concerns the respective rights of neutral and belligerent states. No definite line of distinction has yet been drawn between the privileges of war and peace; and the consequence has been, that, in all the wars which have been waged in Europe, the general tranquillity of the world has been endangered by the jarring of these two different interests. It has commonly happened, too, that all these important questions have been agitated during a season of war, when the passions of the contending parties were keenly engaged in the dispute,—when principles were already subverted,—and when the minds of men, exasperated by the glaring infraction of acknowledged rights, were not in a state to agree on any system of general equity, by which to regulate and reform the erring policy of states. In these circumstances, many points of international law, which appear to rest on the most obvious principles, and which are very clearly settled in the writings of civilians, have, nevertheless, been the occasion, in practice, of no small controversy, and have frequently involved nations in all the miseries of protracted war. This has been, in some measure, manifested in the case of the *Rights of Blockade*; respecting which, though no difference of opinion has ever prevailed among speculative writers, a controversy arose during the late contests in Europe, which, along with other points, ultimately involved Great Britain in a war with the neutral powers. We propose, in the course of the subsequent observations, to state, 1*st*, The general principles from which the most approved writers have deduced the rights of blockade; and, 2*d*, To give a short account of the recent differences which have taken place between the neutral and the belligerent states, respecting the extent of those rights.

Foundation of the rights of Blockade.

In regulating the respective privileges of the neutral and the belligerent, it has been generally held as a fundamental principle, by writers on the law of nations, that those rights, from the exercise of which less benefit would accrue to the one party than detriment to the other, should be abandoned; and in all cases where the rights of peace and the rights of war happen to come into collision, the application of this rule will decide which of the two parties must yield to the convenience of the other. Thus the neutral state is debarred from carrying on any trade with either of the belligerents in warlike stores. The general right to a free trade is modified, in this particular instance, by the paramount rights of the belligerent. To refrain, for a time, from trading with an individual state in warlike stores, can, at most, only impose a trifling inconvenience on the neutral power, while the continuance of such a trade might terminate in the destruction of the belligerent. The detriment occasioned to the one party, by the existence of such a trade, is,

in this manner, infinitely greater than the loss suffered by the other from its abandonment. Warlike stores, and whatever else bears a direct reference to war, are, accordingly, proscribed as unlawful articles of trade, and made liable to seizure by either of the belligerents. To this inconvenience the neutral is exposed, to avoid the greater inconvenience and damage which might fall on the belligerent, by the licensing of such a trade. On the other hand, the neutral state enjoys the most unlimited freedom of trade in all other articles, with either of the powers at war; and though, by means of this beneficial intercourse, they may be both furnished with the means of carrying on a protracted contest, this is a contingent and incidental consequence of the trade, which, in its character, is substantially pacific, and which is attended with such great and immediate advantages, that they could not, with any regard to equity, be sacrificed to the remote convenience of the belligerent.

Applying these principles to a siege or to a blockade, it is evident, that the belligerent who had an expensive scheme of hostile operations of either kind in dependence, would be far more seriously injured by its interruption, than the neutral would be benefited by a free intercourse with the blockaded place. On this ground, therefore, a belligerent who has formed a siege or a blockade, has an indisputable right to debar the neutral from all intercourse with those who are included within his lines; and any attempt to penetrate the blockade for the purposes of trade, subjects those who attempt it to destruction, and their properties to confiscation. The very existence, indeed, of a siege or a blockade, as a lawful act of hostility, implies the right of enforcing it by an indiscriminate exclusion of all who seek access to the besieged.

But though this view of the nature of a blockade, and of the rights attaching to it, is clearly laid down by all writers on the law of nations, and though it has been acknowledged, in practice, by all civilized states, a question has been agitated in the late wars of Europe, between the neutral and the belligerent powers, as to the *degree* of restraint necessary to constitute a blockade, and, of course, to entitle the blockading party to all the rights consequent upon this scheme of operations; and it is this dispute which was, in a great measure, the occasion of a general war with the neutral powers.

The unexampled success which attended the naval operations of Great Britain, during her late wars with France, naturally suggested to her rulers the possibility of extending this species of annoyance, and of converting the all-powerful navy which they possessed, into an instrument of active hostility. With this view, in place of confining its efforts to the mere watching of the enemy's already ruined trade, it was resolved to give greater scope to such an immense engine of maritime power, by placing under blockade the enemy's ports,—the mouths of navigable rivers,—and even extensive tracts of his coast. Proclamations to this effect were, accordingly, issued,—the neutral trader was duly warned off, and prohibited, under the peril of detention, from all intercourse with the interdicted coast. But the legality of these blockades by proclamation being disputed, both by the neutral powers and by the enemy, their execution was resisted by a counter-decree, which, on the plea of retaliation, placed under blockade the whole island of Great Britain, and subjected all neutral vessels to detention and capture, which should have been found touching at any of its ports. On the same plea of retaliation, several decrees, or Orders in Council, were issued by Britain, ordaining, that no neutral vessel should have any intercourse with France and her dependencies, except such vessel should first touch at a British port, where, in some cases, the cargo was to be landed, and was to pay certain duties to the British government. From this period the maxims of equity, and the rules of international law, were set aside, and the ocean became a scene of proscription and pillage. All this anarchy originating in a disagreement respecting the nature and extent of a blockade or siege, it becomes of importance to settle this important question.

Principles according to which these rights ought to be exercised.

The object of a blockade is to reduce the inhabitants of the blockaded town to such straits, that they shall be forced to surrender to the discretion of their enemies in order to preserve their lives; and the legality of every blockade, except with a view to capture, has been questioned. But without entering into this question, it seems obvious, that, in order to constitute the blockade of a town, either with a view to capture, or to temporary annoyance, the line by which it is surrounded should be so complete, as entirely to obstruct all access into the place. When a place is blockaded, with a view to capture, the task of maintaining a real blockade may be safely left to the blockading party. But when a port is blockaded, with a view to mere maritime annoyance, the case is widely different; because, in these circumstances, the belligerent will equally attain his end by maintaining the mere show of a blockade, while he is in possession of all its substantial rights. He may, to save himself expence and trouble, relax the blockade of his enemy's ports, while he enforces the exclusion of all neutrals, as rigorously as if he were maintaining an effectual blockade; and, in this case, his proclamations, while they are issued ostensibly for the blockade of the enemies' ports, would, in reality, amount to edicts for the suppression of the neutral trade. The urgent, immediate and obvious interests of the neutral would here be sacrificed to the remote, and in many cases, imaginary, convenience of the belligerent. The edict might be issued for the blockade of the enemies' ports, or for extensive tracts of his coast, round which no hostile line can ever be drawn so as to constitute a real blockade, and the whole trade of the neutral, with those interdicted parts of the enemies territory, must be immediately given up at the arbitrary mandate of one of the belligerents. The neutral trade,—in place of being carried on as a matter of right,—in place of being regarded as a common benefit to the civilized world, and on this account to be cherished and encouraged, would, under such a system be looked upon in the light of a tolerated evil,

existing only by the sufferance of those who imagined they had an interest in obstructing and in crushing it. The law of nations is not a partial system, modelled to suit the convenience of one party. It is a system of general equity, and its edicts are founded on a comprehensive view of what is for the common advantage of all. In this view, then, the consequences to the neutral of those extensive and nominal blockades are sufficient to constitute them illegal. The damage to the neutral is infinitely greater than the benefit to the belligerent. The rights of blockade, and the limitation of those rights, must stand upon the same principle of justice and of public law; and their extension beyond this equitable principle, must terminate in universal confusion and anarchy.

In opposition to those arguments in favour of the neutral powers, it has been urged, that the new system of naval annoyance, introduced by Great Britain in 1806, was legal according to the strictest construction of the law of blockade, because the proclamations for interrupting all intercourse between the different parts of the French coast, were not issued until it was ascertained, by the most particular inquiries, that Great Britain possessed an effectual naval force to blockade the enemy's coast from Brest harbour to the mouth of the Elbe. It is solely upon this principle that the ministers of this country maintained the legality of those blockades, and any breach in the line of blockade, they admitted, would be sufficient to constitute them illegal. Such, then, is the present state of this important controversy, which seems to resolve itself into a mere question of fact, namely, whether the blockading power has actually carried into effect the blockade, of which notice by proclamation has been given to the neutral powers.

At the conclusion of the last treaty between Great Britain and America, no settlement took place of those disputed questions. The main war between the European belligerents, out of which the American dispute had incidentally sprung, being at an end, the controversy respecting rights, which could only be exercised in a state of war, had lost all practical importance. It had become a mere question of abstract right, the decision of which was wisely adjourned by the powers at war, and not suffered to clog the great work of a general peace. It is likely, however, that on the breaking out of any new war, this and other questions of a like nature would recur; and on this account it might be of importance to the future peace of the world, if, in the present interval of universal peace, while men's passions are at rest, these questions could be settled according to some acknowledged rule of equity or policy, and not left, in the case of another war, to the rude arbitration of force. (o.)

BLOCH (Mark Eleazar), an Ichthyologist and Helminthologist, born at Anspach, about the year 1730. He was of the Jewish nation, and his parents being indigent, his early education was much neglected; but, having entered into the employment of a surgeon at Hamburgh, he supplied the deficiency by his own exertions, and made great progress in the study of anatomy, as well as in the other departments of the medical sciences. He established himself as a physician at Berlin, and found means to collect there a valuable museum of the subjects of all the three kingdoms of nature, as well as an extensive library; and these objects often attracted to his house an assemblage of the most accomplished naturalists of his age and country.

He applied himself, however, more particularly to those parts of natural history which are the most connected with the practice of physic: and, on occasion of a prize question of the Academy of Copenhagen, he entered into a very elaborate examination of the different species of worms, which are found in the bodies of other animals. In his Essay on this subject, to which the prize was adjudged, he maintains, that the parasitical species are only found within the animal body; and since they often occur in the fœtus, and in cavities which are completely inclosed, he infers that they must be generated in some unknown way, and not taken in with the food in the form of eggs. For the general remedy in cases of worms in the intestinal canal, he recommends large draughts of cold water, followed by cathartics. He has added to his Essay a complete classification and description of all the species of intestinal worms, accompanied by figures.

M. Bloch also published a variety of papers on different subjects of natural history, and of comparative anatomy and physiology, in the Collections of the various Academies of Germany, Holland, and Russia, particularly in that of the Friendly Society of Naturalists at Berlin. But his great work was his Ichthyology, which occupied the labour of a considerable portion of his life. His attention was first directed to the subject by receiving a present of a species of salmon, which he could not find described in the Linnæan System of Nature; and he discovered a number of similar omissions in Artedi, and in all former ichthyologists. He undertook to collect into one work every thing that was known respecting the natural history of fishes, and to give figures of all the species; and he passed several summers by the sea side, and among fishermen and their nets, comparing the descriptions of authors with nature, and taking bold sketches of the most interesting subjects, not uncommonly on board of the very boats which furnished them. His publication was encouraged by a large subscription, and it passed rapidly through five editions in German and in French. He made little or no alteration in the systematical arrangement of Artedi and Linné, although he was disposed to introduce some modifications into the classification, depending on the structure of the gills, especially on the presence or absence of a fifth gill, without a bony arch; a character which affords some useful subdivisions of several genera. To the number of genera before established, he found it necessary to add 19 new ones; and he described 176 new species, many of them inhabitants of the remotest parts of the ocean; and by the brilliancy of their colours, or the singularity of their forms, as much objects of popular admiration as of scientific curiosity.

In 1797, he paid a visit to Paris, where he was secure of finding a variety of collections of such subjects of natural history as had been inaccessible

to him on the shores of the Baltic; and he returned to Berlin by way of Holland. His health, which had hitherto been unimpaired, began now to decline. He went to Carlsbad for its recovery, but his constitution was exhausted, and he died there the 6th of August 1799. (*Coquebert* in *Rapport de la Société Philomathique*, Vol. IV. 8vo, Par. 1800.) E. X.

BLOCK, an instrument or machine of wood, chiefly employed in the rigging and other parts of a ship, by means of which a facility is given to the hoisting up or lowering down the masts, yards, and sails, or to the moving of any great weight, as guns, anchors, bales, casks, &c. It is, in fact, a modification of the pulley, and the names may almost be considered as synonymous.

There is nothing in the appearance of a block which, to an unpractised eye, would seem to require any stretch of mental ingenuity or of manual dexterity to manufacture. It is a machine apparently so rude in its structure, and so simple in its contrivance, that the name was probably given to it from its general resemblance to a log of wood, as is obviously the case with a butcher's *block*, a barber's *block*, the *block* of the executioner, &c. Of the two constituent parts of a ship's block, the external *shell* and the internal *sheave*, every carpenter might make the one, and every turner the other; and yet, when blocks were made by the hand, it seldom happened that the several parts were adjusted to each other with sufficient accuracy, or that a strict uniformity was observed in the various sorts and sizes, without which they cannot be expected to work with that degree of ease and truth, which is so desirable, and even necessary in the important office they are designed to fulfil, in the rigging and other parts of a ship.

BLOCK-MACHINERY. To acquire a greater degree of accuracy and uniformity, as well as celerity in the making of blocks, Mr Walter Taylor of Southampton took out a patent in the year 1781, to secure to himself the benefit of some improvement he had made in the construction of the sheaves; he also shaped the shells, cut the timber, &c. by machinery, which was put in motion by water on the river Itchin, near Southampton, where he carried on so extensive a manufactory of blocks, as to be able to contract with the Commissioners of the Navy for nearly the whole supply of blocks and blockmakers' wares required for the use of the royal navy.

Mr Dunsterville of Plymouth had also a set of machines for making the principal parts of blocks, which was wrought by horses; his manufacture, however, of this article was not carried to any great extent; but the blocks made by this machinery, as well as those by Mr Taylor's, were said to be of a superior quality to those constructed by hand, though still deficient in many respects.

No objection, however, would probably have been made to the quality of the blocks furnished by Mr Taylor, and used in the navy. It would rather appear that the enormous quantity consumed in the course of a long protracted war first called the attention of the Admiralty or Navy Board to the possibility of some reduction being made in the expence of so indispensable and important an article in the naval service; and that it was not prudent to depend entirely on a single contractor, whom accident or misfortune might disable from fulfilling his contract: A fire might destroy his wood-mills, in which case it would have been difficult to procure, in all England, an adequate supply of blocks for the navy.

On these considerations, it seems to have been the intention of government to introduce, among other improvements then carrying on in Portsmouth Dock-Yard, a set of machines for making blocks, at the new wood-mills erected in that yard in 1801. About this time, the improvements which had been introduced into private concerns were gradually finding their way into the great public establishments of the country. Still, however, an old maxim seemed to prevail, that government ought not to be its own manufacturer. This maxim, though perhaps generally just in political economy, is, we conceive, neither just nor wise when applied to those articles which are of the first necessity in the King's navy. Indeed, where the safety of so many thousand lives depends wholly, as is sometimes the case, on the strength of materials and goodness of workmanship, it is most desirable that the whole ship, and every part thereof, from the pin of a sheave to the sheet anchor, should be manufactured under the immediate superintendence of respectable officers in the King's service.

About this time, too, Mr Brunell, an ingenious mechanist from America, had completed a working model of certain machines for constructing, by an improved method, the shells and sheaves of blocks. This model was submitted to the inspection of the Lords Commissioners of the Admiralty, and by them referred to General Bentham, the Inspector-General of Naval Works, who represented that, as the making of blocks was one of the purposes for which a part of the force of the steam-engine, erecting at the wood-mills, was intended to be applied, he did not hesitate to recommend the new machine, as an invention which would enable the government to construct its own blocks with a greater degree of celerity and exactness than those which were then in use; and that it appeared to be well suited for manufacturing blocks of every description and size, with a degree of accuracy, uniformity, and cheapness, far beyond any of the methods hitherto practised. The adoption of Mr Brunell's machinery was the consequence of this opinion.

The advantages to be expected from blocks so made were stated by Mr Brunell to consist, first, in bringing the shape of the outside of the shell to certain determined dimensions, so that those of the same size should actually be so, and not differ from one another, either in the proportion of the mortices, or in the shape and dimensions of the outside. Secondly, in adding strength where it was wanted, by making the head and bottom more substantial, and less liable to split; and, thirdly, in leaving the wood between the two mortices thicker, so as to admit a sufficient bearing for the pins; all of which would be accomplished without requiring any dexterity on the part of the workman, but entirely by the operation of the machinery. The uniformity and exactness with which they were to be made, would be attended with another important advantage to the

public—the difficulty of counterfeiting them would act as a precaution against embezzlement. Another very considerable advantage would be derived from the employment of much waste wood in the dock-yard, usually sold for little or nothing, for firewood and other purposes.

The sheaves or shivers would, by this new machinery, be made so mathematically true, and so exact to each other in their thickness and diameters, that every sheave of any particular size would equally fit any shell of the size for which it was intended; and the inconvenience to which ordinary blocks are liable from the friction of the ropes against one or alternately both of the sides of the mortices, was intended to be removed, by placing a sheet of metal on the upper part of the mortice, bent to the proper shape by an engine adapted for the purpose. Brunell also proposed a new form for the *clue-line* and *clue-garnet* blocks so as to secure the sails from splitting, by preventing the points of the sails getting into the blocks, which has since been adopted and greatly approved of in the navy.

In the sheaves, instead of the double coak or cogue inserted in two halves, he substituted a mixed metal coak of a new and particular form, which will be described hereafter, of increased strength and durability. This coak was to be cast with a precision in moulds, and fitted by an engine with the greatest nicety; the pins or axes of the sheaves to be of wrought iron, case-hardened and coated with tin, which would preserve the iron from rust in the parts which are not kept free from it by friction; as it has been found by experience that, however tight the pin be forced into the shells, the water will insinuate itself and corrode the pin; when this is the case, the rust soon extends itself to the parts on which the sheave turns, and renders it unfit for use.

From the machines that were already completed for manufacturing blocks of certain dimensions, Mr Brunell was enabled to make a calculation of the saving as to the first cost compared with the contract prices, which would be effected by the adoption of his invention. It was as under:

Blocks of	8 *inch.*		12 *inch.*		16 *inch.*		21 *inch.*	
	s.	d.	s.	d.	s.	d.	s.	d.
Brunell's prices,	1	$8\frac{3}{4}$	4	5	8	$11\frac{1}{2}$	18	$1\frac{3}{4}$
Contract prices,	2	$3\frac{1}{2}$	6	$11\frac{1}{2}$	13	6	27	$0\frac{3}{4}$
Saving in first cost,	0	$6\frac{1}{4}$	2	$6\frac{1}{2}$	4	$6\frac{1}{2}$	8	$10\frac{3}{4}$

These savings, if realized to the full extent, were probably not more important than the increased strength, durability, and facility of working, which have been gained by the adoption of the block-machinery.

Those parts of the machinery which Brunell had completed in London, under his patent, were transferred to Portsmouth, and, in the course of the year 1804, were in operation; but the increased number of machines, the improvements that suggested themselves to the ingenious inventor, the application of other machines for making dead-eyes, trucks, and all manner of block-maker's wares, besides circular and upright saws, lathes, engines for turning pins, rivetting, polishing, &c. exercised his skill and ingenuity till the year 1808, when he considered the whole system to be complete in every part, and incapable, so far as he could judge, of further improvement. From that time to the present, the block-machinery has been in full and constant employment, without requiring the least alteration, and very little repair, beyond the unavoidable tear and wear of engines that are kept in almost constant motion; and, which is still more extraordinary, without requiring the aid of the inventor, though attended only by a few common workmen or labourers; but they are superintended by Mr Burr, the master of the wood-mills, who is considered as an able and ingenious machinist. The quantity of blocks of every description, manufactured by the machinery in Portsmouth wood-mills, is more than sufficient for the consumption of the whole navy and the Board of Ordnance, and if pushed to the utmost extent of the works, would also have been sufficient to supply a great part of the shipping employed in the transport service.

It may be a matter of some curiosity to know the results of this system of machinery. It is put in motion by a steam-engine of thirty-two horses' power, which, however, is applied to a great variety of other purposes at the same time, wholly independent of the block-machinery. It has been found by calculation, that four men with the machinery, as it now stands, can complete the shells of as many blocks as fifty men could do by the old method; and that six men will furnish as many sheaves as before required sixty; and that these ten men, in displacing the labour of one hundred and ten men, can with ease finish in one year from 130,000 to 140,000 blocks of different sorts and sizes, the total value of which cannot be less than L. 50,000; and this is stated to be the average number which has annually been made from the year 1808, to the conclusion of the war. This number is found to be fully sufficient for supplying the wear and tear of blocks, not only in the naval, but also in the ordnance department. The consumption, however, must depend on other circumstances besides the number of ships in commission, and will be greater or less according as ships have been employed on severe or easy service, in a good or bad climate, in fine or rough weather, &c. Nor will the number here stated appear to be enormous, when it is considered what a multitude of blocks are required for a thousand sail of ships, which, at one period of the war, were in commission at the same time. A ship of 74 guns, for instance, requires the following blocks for her equipment:

	No.
Single blocks from 5 to 26 inches, -	622
Double ditto from 7 to 26 ditto, -	130
Various other blocks, generally large, and several of them treble,	74
For each of the 74 guns, 6 blocks, -	444
Total,	1270
Besides dead-eyes, hearts, parrels, and puttock-plates, all manufactured at the mills,	160
Of all kinds in a 74 gun ship,	1430

The average number of ships of the line in commission, appears to have been about 100; these would require 143,000; and allowing the remaining 900 ships and vessels to require only twice this number, there would be wanted for the first equipment of the 1000 ships of war, 429,000 blocks, which, at the ordinary rate of making them at the mills, would require three years in completing.

The different sorts and sizes of blocks used in the navy exceed two hundred, and they vary from four to twenty-eight inches in length. Those above eighteen inches are more sparingly used, and the shells of the largest kinds are made in parts, and fitted together by hand.

To the completion of this ingenious machinery, Brunell gave his whole attention from the month of September 1802 to June 1808, during which time he received no other compensation beyond the daily allowance of one guinea; but as it was now in full operation, and ascertained to be capable of making a sufficient number of blocks for the whole naval and ordnance departments, it became a question in what manner the author of the invention should be rewarded. It was suggested by General Bentham, and agreed to by Brunell, that the savings of one year, as compared with the contract prices, would be a fair and not an unreasonable remuneration for the time, labour, and ingenuity, bestowed on these extraordinary machines. It was no easy matter, however, to ascertain with precision what the actual savings amounted to.

Mr Brunell, by estimate, made them amount to -	L. 21,174	0	0
Mr Rogers, clerk to General Bentham, by estimate -	12,742	0	0

General Bentham, after going into every possible details of expence with the utmost minuteness that could be expected in a private manufacturing concern, calculated them at -	L. 16,621	0	0
Add six years' allowance at a guinea a-day, about -	2,400	0	0
For the working-model -	1,000	0	0
Total amount received by Brunell, about - - -	L. 20,000	0	0

Supposing, therefore, the whole cost of the buildings, steam-engine, machinery, interest of money, &c. to amount (which we understand to be about the mark) to L. 53,000, and the net compensation for profits to about L. 18,000, the whole expence of the concern was completely cleared in four years. The savings of L. 18,000 on one year's manufactured articles of the value of L. 50,000, amounts to somewhat more than Brunell had originally made it by computation.

It would occupy too much space to enter into a minute description, and require more time than we can spare, to prepare engravings in detail of the various complicated systems of machinery that are employed for the completion of a block; and, after all, they would afford but little use or instruction, excepting perhaps to a professed machinist; and perspective views of the several systems would tend rather to mislead or confuse, than to inform the general reader. But as every body who happens to inspect Portsmouth dock-yard, makes a point of visiting the block-machinery, we think it may be of some use, in conveying a general idea of the most striking parts of the machinery, by following the process of making a block from the rough unsided tree, till the last finish is given to it.

We have stated, that the original intention of the building was that of a wood-mill, in which all manner of sawing, turning, boring, rabbetting, &c. was to be performed, and that the block-machinery was superadded to the first design, with which, however, it has interfered so little, that, in addition to the immense number of blocks manufactured at the mill, upwards of a hundred different articles of wood work are made by other machinery—put in motion by the same steam-engine, from the boring of a pump of forty feet in length, to the turning of a button for the knob or handle of a drawer. (See Dock-yard, Portsmouth.) Lest, however, the engine, with such a variety of work, might be overloaded, a second engine has been added, to assist, if found necessary, or to substitute in the event of accident happening to the other. Among the many ingenious machines belonging to the wood-mills, exclusive of those for making blocks, one of very great effect, and, at the same time, great simplicity, is a circular saw for cutting rabbets in the edges of deal planks, invented by Mr Burr, the superintending master of the wood-mills.

The whole of the machinery in these mills is put in motion by straps passing over drum-heads, by which the several movements, numerous as they are, are carried on without the least noise; and all the engine-work, and every part of the machinery, are so truly made, and so firmly put together, and work with such accuracy in all their motions, that, though the spectator is surrounded on all sides with movements in every possible direction, and some most rapid and violent, the only noise that disturbs him arises from the cutting, boring, turning, polishing, and other instruments which are actually in contact with the work that is under execution, and none of it from the working of the machinery. All the iron work, of which it is chiefly composed, was made by Mawdsley; and there is but another workman, perhaps, in the United Kingdom, who could have finished the engines in a manner so worthy of the invention.

The first wing of the building is chiefly occupied by upright and circular saws, used for a variety of purposes not immediately connected with the making of blocks. The only operation for this department is that of converting the rough timber, which is generally elm or ash, most commonly the former, into its proper scantling; that is to say, squaring it by the upright or straight-cutting saw, and then, by a circular saw, cross-cutting it into a certain number of parallelopipedons, whose lengths may bear the required proportion to the thickness of the log. Some of these pieces are again cut longitudinally, according to the thickness that may be required for the shell of the block, especially those for single and double blocks, which of course are thinner than three and four-

fold blocks. This operation is performed by what is called a ripping-saw. The logs thus cut out are then taken into the second wing of the wood-mills, where the machinery peculiar for the construction of blocks is erected; and here the first process may be said to commence in making the SHELL.

This operation is performed by the *Boring-Machine*, which, by means of a centre bit applied to the middle of the shell, bores a hole for the centre pin of the sheave, while another bores one, two, or three holes, at right angles to the direction of the first, to admit the first stroke of the chisel, and, at the same time, to serve for the head of the mortice or mortices, according as the intended block is to contain one, two, or three sheaves. When thus bored, the log is carried from hence to the

Morticing-Machine, which is an ingenious and striking piece of mechanism. The block being firmly fixed on a moveable carriage, the latter is so contrived as to be made to advance to the cutting chisels, which are set fast in a moveable frame. Every time the frame, with the chisels, ascends, the block in its carriage advances a little, so as to present to the chisels a fresh surface of wood to be acted upon at each stroke of their descent; and this up and down motion is continued with such rapidity, that the chisels make from one hundred to one hundred and thirty strokes in a minute, until the prescribed length has been morticed out; when, by raising a handle, which is done by a boy, the machine is stopped precisely when the chisels stand at their greatest elevation; and are thus left in the proper position, ready to commence a second operation. No harm, however, would happen either to the block or the machinery, should the attending boy neglect to stop the work at the proper time, or even to fall asleep, notwithstanding the force and rapidity of the stroke; for, by a particular contrivance, the farther advance of the block is stopped, and the chisels, therefore, act in full space, and cut only the air. It is, indeed, a general characteristic of Brunell's machinery, to be so constructed as to carry with it a defence or protection against its own operations, and to counteract all ill effects that might otherwise arise from any neglect or inattention of the workmen.

The chips cut by the chisels are thrust out of the mortice by small pieces of steel attached to, and projecting from, the back of each chisel. They are each of them, besides, armed with two cutters placed at right angles to the edge, called *scribers*, which mark out the width of the chip to be cut by the chisel at each stroke. These scribers answer another purpose; their cutting is so true as to leave the two sides of the mortice so perfectly smooth, as to require no further trimming or polishing.

The next process is to remove the block from the morticing machine to a circular saw, in order to have the four corners taken off, by which operation it is reduced to an octagonal shape. This saw being fixed into a table or bench, the workman has nothing more to do than to slide each log along the surface of the table, in the direction of the line marked out for the saw to cut it.

The next operation is to place the block upon the *Shaping Machine*. This is perhaps one of the most ingenious and most effective contrivances in the whole machinery of the wood-mills. It consists principally of two equal and parallel circular wheels moving on the same axis, to which one of them is firmly fixed, but on which the other is made to slide; so that these two wheels may be placed at any given distance from each other, and blocks of any size admitted between their two rims or peripheries. For this purpose, both rims are divided into ten equal parts, for the reception of ten blocks, which are firmly and immoveably fixed between the two wheels. When the double wheel with its ten attached blocks is put in motion, the outer surfaces of the blocks, or those which are farthest from the centre, strike with great violence against the edge of a chisel or gouge fixed in a moveable frame, which, being made to slide in a curved direction in the line of the axis, cuts those outward faces of the blocks to their proper curvature, which can be altered in any way the workman pleases, by a contrivance attached to the cutting tool. As soon as the tool has traversed the whole length of the block, or over the space contained between the two peripheries of the wheels, the machine is thrown out of the gear, and its prodigious velocity checked by a particular contrivance. The ten blocks are then, by a single operation, and without removing them, each turned one fourth part round, and another fourth part of their surface brought outwards, which, being exposed to the cutting instrument traversing in the same direction as before, have the same curvature given to these new surfaces. A third side is then turned outwards, and, after that, the fourth and last side, when the whole ten blocks are completely shaped, and ten other octagonal logs applied to the peripheries to undergo the same operation.

The immense velocity with which the wheels revolve, and the great weight with which their peripheries are loaded, would make it dangerous to the workmen or byestanders, if, by the violence of the centrifugal force, any of the blocks should happen to be thrown off from the rim of the wheels; to prevent the possibility of such an accident, an iron cage or guard is placed between the workman and the machine.

The shell of the block being now mortised and completely shapen, the last operation is performed by the *Scoring Machine*, which, by means of cutters, scoops out a groove round the longer diameter of the block, deepest at the ends and vanishing to the central hole for the pin on which the sheave turns. The intention of this groove or channel is to receive the hempen or iron strap which surrounds the block. The only thing that now remains for completing the shell, is the removal of the little roughnesses from the surface, and giving to it a kind of polish, which is done by the hand.

The SHEAVES. The wood generally used for making sheaves is lignum vitæ; but iron or bell-metal have occasionally been substituted for this wood. An attempt was made to introduce sheaves of a kind of porcelain, which answered well enough for some particular purposes, but were not to be trusted in situations where they were liable to sudden jerks and irregular motions. In the navy they are almost invariably of lignum vitæ, a few perhaps of ebony. The machinery employed for making this

Block-Machinery.

part of the block, consists of a *Circular Saw* by which the log is cut into plates of the thickness required for the sheaves, according to their several diameters. These plates are next carried to a *Crown Saw* which bores the central hole, and, at the same time, reduces them to a perfect circle of the assigned diameter. The sheave, thus shaped, is next brought to the *Coaking Machine*, a piece of mechanism, not inferior in ingenuity to the *Shaping Machine*, for the shells. It would be useless to attempt to describe, by words, the movements of this engine, but the effect of the operation is singularly curious. A small cutter, in traversing round the central hole of the sheave, forms a groove for the insertion of the coak or bush, the shape of which is that of three semicircles not concentric with each other, nor with the sheave, but each having a centre equally distant from that of the sheave. The manner in which the cutter traverses from the first to the second, and from this to the third semicircle, after finishing each of them, is exceedingly curious, and never fails to attract the particular notice of visitors. So very exact and accurate is this groove cut for the reception of the metal coak, and so uniform in their shape and size are the latter cast in moulds, that they are invariably found to fit each other so nicely and without preparation, that the tap of a hammer is sufficient to fix the coak in its place. The coaks are cast with small grooves or channels in the inside of their tubes, which serve to retain the oil or grease, without which it would soon ooze out, and the pin become dry.

The sheave, with its coak thus fitted in, is now taken to the *drilling-machine*, which is kept in constant motion. In casting the coaks a mark is left in the centre of each of the three semicircles. This mark is applied by a boy to the point of the moving drill, which speedily goes through the two coaks and the intermediate wood of the sheave. A copper pin, cut from wire, of the proper length and thickness, is inserted into the holes thus drilled. And the sheave is then taken to the *rivetting-hammer*, which is something like a small tilt-hammer, and can easily be made to strike on the pin with greater or less velocity, according as the workman presses with more or less force on the treadle. The rivetting being performed, the next operation is that of broaching the central hole on which the sheave turns, by means of a steel drill or cutter.

The last process is that of turning a groove for the rope to run in round the periphery of the sheave, and this operation is performed by a lathe, which is so constructed, that while this grove is cutting round the rim of the sheave, another part of the engine is turning smooth the two surfaces or faces of the sheave; and this lathe can be made to adapt itself to sheaves of different diameters.

The shell and the sheave being now completed, there remains only the iron pin, which, passing through the two sides of the former, serves as the axis on which the latter turns within the mortice. These pins are also made, turned, and polished by engines for the purpose, so that, with the exception of strapping by rope or iron, the whole block is completed at the wood-mills. It may here be remarked, that the French, in the dock-yard of Brest, have long been in the practice of making blocks by machinery; but they have not attempted anything like a *Shaping-Machine*, nor any substitute for it; the external shape of the shell being made entirely by hand; nor have they such a *Coaking Machine* as that invented by Brunell. The machinery at Brest is put in motion by horses. (See Dock-Yard.)

Block-Machinery || Blow-pipe.

BLOW-PIPE, an instrument for directing the flame of a lamp or candle horizontally, so as to communicate an intense heat to small bodies placed in the flame. This is effected by impelling through a small aperture, against the flame, a stream of air moved with velocity, by means of the muscles of respiration and the mouth, or by a bellows. The Blow-pipe is used in soldering, by the jeweller and goldsmith, and other artists, who fabricate small objects of metal; by the glass-blower, in making thermometers and barometers, and other instruments made from the tubes which are got from the glass-house; by the enameller; and in glass-pinching, which is the art of forming glass in a mould fixed on a pair of pincers, into the ornamental pendants for glass lustres. This is one of the many ingenious processes carried on at Birmingham. The glass-blower, the enameller, and the glass-pincher, work their blow-pipe with the blast from a pair of bellows. As the process of soldering requires a shorter continuance of the blast, the blow-pipe for this purpose is blown by the mouth. By the mineralogist and chemist, the blow-pipe is used as an instrument for extemporaneous analysis in the dry way.

Different Forms of Blow-pipe.

Fig. 1. Plate XXXIV. is the common blow-pipe used in soldering; it is of brass. Fig. 2. is Dr Wollaston's blow-pipe, which is composed of three tubes of brass, of an elongated conical form, which are made to fit stiff and air-tight into each other when in use, and the two smaller pack into the largest; so that the instrument, when not in use, occupies a very small space, and may be carried in the pencil-case of a common pocket-book. This, with a piece of platina-foil, two or three inches long, to hold the object of experiment to the flame, constitutes a commodious docimastic apparatus for the travelling mineralogist. The three parts of the tube are represented, packed the one within the other, at A, separate at B, and put together ready for use at C, fig. 2.

Bulbed Blow-pipes.

A second division of blow-pipes consists of those which have a cavity for the purpose of retaining the humidity of the breath, which, without this precaution, collects into drops when the blowing is continued long, and is at last driven upon the matter under operation so as to cool it. They are of various forms; see figures 3, 4, 5, 6, 7; and have been contrived for the purposes of the chemist and mineralogist. Fig. 3. is of glass or of metal. Fig. 4. is of brass or of silver, containing no alloy of copper, so that it may not be subject to green rust. This is the form recommended by Bergman in his treatise on the application of the blow-pipe to the purposes of the mineralogist, which is contained in the collection of his works. (See *Bergmani Opuscula*, Vol. II.) For the facility of cleaning, it is in three pieces, which fit in stiff at A and B. Fig. 5. is of tin, that is to say, tinned iron; the small pipe A is of brass, and has two or three caps that fit on stiff; each cap is pierced with a hole of a different diameter, and as the blast

Blow-pipe. Jointed Blow-pipes.

issues through this hole, the force of the blast may be varied by changing the cap: this is called Dr Black's Blow-pipe. Fig. 6. is of silver; the adjutage, which is of platina, turns on an axis at right angles to the main tube at A, so that it may be made to form different angles with the main tube; the prolongation B, serves to receive the condensed vapour of the breath. Fig. 7. is of brass; A is cylindrical, the axis of the cylinder being at right angles to the axis of the blow-pipe. A consists of two pieces, one of which fits air-tight into the other, and may be turned on its axis, so that the pipe of issue may be made to form different angles with the axis of the blow-pipe, as the position of the matter under experiment may require.

Flame.

Flame consists of vapour in a state of incandescence. Many substances, both of the vegetable, animal, and mineral kingdoms, have the quality of giving out this incandescent vapour. For domestic uses, and for the arts, organized bodies of the vegetable and animal kingdom alone are employed to produce it; such as oils, some of which are solid, others fluid, at the usual temperature of the air, alcohol, ether, wood, and pit-coal. This latter, though found amongst minerals, is composed of organized matter, changed and rendered bituminous by a particular process of decomposition. The blow-pipe, by directing the incandescent particles of which the flame consists, so as to strike against and surround a small body, produces the effect of heating the body considerably. The flame used with the blow-pipe, may either be the flame of an oil or spirit lamp, or of a candle; the flame of the carbonated hydrogen gas proceeding from the distillation of pit-coal, is also found advantageous for this purpose.

Mode of Blowing.

In order to use the blow-pipe, the breath impelled through it is to be directed across the flame of a lamp or candle, applying the orifice from which the air issues a little above the upper end of the wick; a jet of flame is thus formed, as represented at fig. 8. This jet is made to fall on the body to be heated. The operation may be continued for a considerable length of time; an uninterrupted blast is kept up by the muscular action of the cheeks, whilst the ordinary respiration goes on through the nose: a little practice is sufficient to enable the operator to succeed. The jet of flame is conoidal, internally blue, and externally yellow, by more or less immersion in this jet of flame. The subject of operation receives a greater or less degree of heat, and becomes oxidated in a greater or less degree. If a bead of borax, containing oxide of manganese, be kept fused for some time in the inner flame, the bead becomes colourless; when it is afterwards kept fused in the outer flame, the manganese acquires more oxygen, and the bead becomes of a violet colour. This violet colour may be made to appear more speedily, by adding a particle of nitre.

Its Use in Mineralogy.

The first who applied the blow-pipe to the analysis of minerals was Swab, Counsellor of the College of Mines in Sweden, in 1738. Its application to the science of Mineralogy was afterwards farther improved by Cronsted, Rinman, Gahn, Scheele, and Bergman, and by other men of science since their time.

Blow-pipe.

The blow-pipe is useful to the mineralogist and chemist, as affording a ready method of knowing what the component parts of bodies are. Trials with the blow-pipe are generally made by the chemist in order to know the nature of the constituent parts, before he proceeds to the other steps of dry or humid analysis, which are requisite for ascertaining the quantities of the constituent parts. Then recourse is had to other means than the blow-pipe; for, in order to come at a knowledge of the proportions of the constituent parts, it is necessary that the quantity of each constituent part be large enough to be weighed in a balance, and, for this purpose, the quantity of the substance employed must be larger than what can be managed with the blow-pipe.

Support Charcoal.

In experimental mineralogy, with the blow-pipe, the small fragment of the body, subjected to trial, should not exceed the size of half a peppercorn; if larger, it cannot be sufficiently heated. It is placed in a lenticular cavity, made with a knife, in a piece of well burnt charcoal of wood, free from cracks, and not too porous, and of the length of four or five inches, so as to be held conveniently in the left hand. Some blow-pipes have been made with a stand, to which they are connected by a ball and socket joint; the stand is fixed to the table by a clamp; this construction leaves the right hand at liberty. In reducing fragments of metallic ores by the blow-pipe, charcoal should be used as a support, as the charcoal attracts the oxygen from the metallic oxide, and reduces it to a metallic form; and when thus reduced, the metal may be kept fused on the charcoal, which prevents or retards its again attracting oxygen. The charcoal support has likewise the advantage of increasing the heat by its incandescence. For both these reasons, to prevent oxidation, and to increase and reverberate the heat proceeding from the jet of flame, the goldsmith who solders his small work by the blow-pipe, attaches his work to a piece of charcoal, by means of wires, in the process of soldering.

Support Platina.

When it is required that the fragment of a mineral should be heated, without the contact of charcoal, the fragment is exposed to the flame in a small spoon of platina, with a wooden handle; the cavity of the spoon is a hemisphere of three-tenths of an inch in diameter; or on a thin lamina of platina two or three inches long, and half an inch broad, and of the thickness of common writing paper; or it is held by a forceps, three inches long, made of thin platina. Bergman, who published his treatise on the blow-pipe in 1780, before the working of platina had come into use, employed a small gold spoon, as that metal has the quality of remaining pure and uncontaminated, whilst in contact with many of the chemical agents; but platina is preferable, for, besides possessing the quality of resisting the action of many chemical agents, it has likewise the advantage of difficult fusibility. It has now, for a good many years, been wrought into various instruments both in London and Paris; when wrought, it is sold at the price of about a guinea the ounce, which is one quarter the price of gold. Some platina workers, as Jeanetti of Paris, who was one of the first, form the

crude granular platina into masses, by melting it with arsenic, and subsequent heating and forging; others dissolve the crude platina in nitro-muriatic acid, and reduce the nitro-muriate of platina to a metallic state by heat. Platina, however, although infusible alone by the heat of the common blow-pipe, will be dissolved and melted, if heated along with some of the metals. Platina supports, therefore, should not be used where they are liable to be in contact with a fused metal. These effects are notable in the case of tin; when tin is melted in contact with a vessel of platina, the tin enters into a combination with the platina, corrodes and renders it brittle, so that pieces of the platina vessel come off on the application of a small force, and the vessel is thus rendered useless. Platina vessels also become unserviceable by frequent and continued exposure to great heat. Platina crucibles that are much used become brittle, and crack at the edges; and care should be taken to cool these vessels gradually, that they may last as long as possible. A platina vessel, in which sulphuric acid was boiled, for a long time, at last became perforated and unserviceable.

Borax (borate of soda) is used along with the fragment of mineral in many cases. When exposed to the flame, it becomes opaque, swells and ramifies much, in consequence of parting with its water of crystallization; afterwards it fuses into a colourless and transparent bead. It is convenient to use calcined borax, which is borax deprived of its water of crystallization by heat in a crucible; this melts into a bead on the charcoal at once. The solubility of a mineral in borax, with effervescence, or without effervescence, and the colour that the mineral communicates to the borax, are the chief distinctive characters obtained by treating a mineral with that substance. Phosphate of ammonia is also sometimes used as a flux in the same manner as borax, and carbonate of soda; but both these, especially the latter, have the inconvenience of sinking into the charcoal, which borax is free from.

Mention may be made here of a few of the most prominent phenomena, characteristic of different mineral substances when treated by the blow-pipe. Some minerals are fusible alone, such as garnet and felspar; this last is rather difficult to fuse. Some are infusible and change colour; bituminous shale loses its black colour, and becomes white, green, and dark; coloured steatite become white. Some dissolve in borax without effervescence, as agate, quartz, felspar, amiantus, garnet. Some dissolve in borax with effervescence; this is the case with carbonate of lime; it forms with borax a globule transparent whilst in fusion, but in cooling it, the globule becomes opaque, the lime being no longer held in solution by the borax; in like manner, as the watery solutions of certain salts, saturated when hot, deposit a part of the salt on cooling. Some of the metals communicate peculiar colours to borax. Copper, in certain proportions, and at a certain degree of oxidation, gives a brown colour to borax when heated by the blow-pipe. Cobalt gives a deep blue tinge. Manganese a violent colour. Iron tinges borax brown, and if in greater quantity black. These colours are produced by the metals in a state of oxide. The smell emitted by some minerals, when heated by the blow-pipe, is another character serving to distinguish them. That of minerals containing sulphur, is the peculiar suffocating smell of sulphureous gas; minerals that contain arsenic, emit, when heated, a smell like that of garlic. The nature of some minerals is recognised by the particular form of crystallization which they assume in cooling; this is the case with phosphate of lead, which, after being fused, cools on the charcoal into an opaque white spheroidal polyhedron. Some ores are reduced to a metallic globule, with great ease, on the charcoal; thus the native sulphuret of lead, called Galæna, being heated by the blow-pipe, the sulphur is driven off, and the lead remains in its metallic state. A small particle of silver may be melted by the blow-pipe, likewise gold, copper, and, Bergman says, cast-iron. Metallic zinc, when exposed to the flame of the blow-pipe on the charcoal, melts and burns with a bluish green flame, and becomes covered with oxide, which flies off and floats in the air in light white flocks. Metallic antimony becomes red hot, and melts on the charcoal; and if the operator ceases to blow, a white fume rises, and oxide of antimony forms upon the globule, in whitish crystalline spiculæ: if the globule, in a state of fusion, be thrown upon a brick floor, it runs along for a considerable way, rebounding several times, and leaving a trace of white oxide of antimony.

Some substances communicate colour to the flame of the blow-pipe. Muriate of copper, whose crystals are green, communicate a vivid green to the flame; sulphate and nitrate of copper, whose crystals are blue, likewise impart a green colour to the flame when they are exposed to its action. Some of the salts of strontian give a purple tinge to the flame.

What precedes relates to the blow-pipe worked by the breath. When it is required to continue the use of the blow-pipe, so long as would be fatiguing if the breath merely were employed, the glass-blowers' table, fig. 9. Plate XXXIV. is used. It consists of a double bellows, so fixed as to be worked by the foot, and to impel a current of air through a tin blow-pipe, against the flame of a lamp fixed on the table. For the sake of durability, the blow-pipe is sometimes of brass, on which is screwed a nozle of platina. The blow-pipe may have a stop-cock, as in fig. 9. serving to regulate the blast. The lamp has a cotton wick of nearly an inch in thickness; the wick is kept together by a tin wick-holder, which is soldered to the lamp; melted tallow fills the lamp, and feeds the wick with fuel. In order to get rid of the smoke, which is in considerable quantity, there may be placed, at a convenient distance above the flame, a tin funnel ending in a tube, which conveys the smoke out of the room. A convenient method of carrying away the smoke from the glass-blowers' lamp, is represented in fig. 13. It consists of a cover of thin sheet copper, which is placed on the table, covering the lamp and nozle. The fore-part of this cover is open, so as to allow the jet of flame to pass freely. From the upper part of the cover two tubes go upwards for the exit of the smoke; between

these two tubes the glass-blower has a view of the object he is at work upon, whilst his eyes are screened from the light of the flame. The two tubes join above in one short tube. Over the open end of this short tube, at a small distance above, is a tube suspended from the ceiling by wires, which conveys the smoke into the chimney of the room. By a handle attached to the cover, the cover with its tubes is removed when it is necessary to trim the wick. The flame of gas from pit-coal may be used instead of a lamp, with a bellows of this kind.

Water-pressure Apparatus.

The regularity of the blast in the double bellows, is effected by means of a weight pressing on the air contained in the second copartment of the bellows; just in the same way as a stream of air is made to issue regularly from a tube fixed in the mouth of an inflated bladder, when a weight is placed on the bladder. A regular stream of air may also be obtained, by subjecting inclosed air to the pressure of a column of water, mercury, or some other liquid. If a vessel containing air, and open at the mouth, be plunged into water with the mouth downwards, and if the water on the outside of the vessel rise higher than the surface of the water within the vessel, then the column of water, whose height is the difference of level, exercising its pressure, as all liquids do, in every direction, acts upwards on the inclosed air; and the inclosed air will be pressed and more condensed than the external air, and will escape in a current, by a stop-cock opened on the top of the vessel for its issue; this issue will continue till the surface of the exterior and interior water come to a level; for then the air in the vessel is come to have the same density as the external air. The force with which the inclosed air is pressed, is equal to the weight of a volume of water whose height is the difference of levels, and its base the surface of water exposed to the inclosed air. The gasometers used by Lavoisier, to afford a stream of oxygen gas and a stream of hydrogen gas, for accomplishing the composition of water, are constructed upon this principle. An apparatus of the same nature has, for many years, been employed in the great way, in different parts of Britain, to regulate the most powerful blast used in the arts,—that for reducing ironstone to the state of cast-iron. In blast-furnaces upon this construction, the blast is raised by means of a large cast-iron cylinder which acts as a bellows, having a valve in the bottom that opens inwards, and that admits the air during the ascent of the piston; when the piston descends, the valve shuts, and the air is driven into a large parallelopipedal vessel, less in height than in the other dimensions, immersed in water, and having its under surface closed only by the water. In this vessel the air is pressed by the column of water, whose height is the distance between the surfaces of the exterior and interior water; a pipe of issue terminating in a nose-pipe, conducts the blast to the furnace.

Melograni's Blow-pipe.

The blow-pipe of the Abbé Melograni of Naples, for the use of the mineralogist, operates by the pressure of water. It is composed of two hollow globes, the upper filled with water, which, by running into the lower, forces the air contained in the lower to issue through a nozle. This apparatus is described by Mr Greenough, in *Nicholson's Journal*, Vol. IX. p. 25 and 143. It has some inconveniencies, and does not appear ever to have come into much use.

Water-pressure Blow-pipe, for Glass-blowers.

The water-pressure apparatus, applied to the blow-pipe, of which a section is given at fig. 10. was contrived by Mr Tilley, an ingenious fancy glass-blower. It consists of a tin box with a partition in it, reaching within half an inch of the bottom; water is poured in equal in bulk to three-fourths of the capacity of the box. The water in the cavity DE is open, and subject to no other pressure but that of the atmosphere, being only covered by the lid of the vessel; the apartment F is closed at top, so as to be air-tight, and the water in it is pressed by the elasticity of the air confined in its upper part. The tube C has its lower extremity always plunged in water, so that, when air is blown in through it, the return of the air by that tube is prevented. Before the apparatus is set to work, the surface of the water in both copartments is at the same height, both being pressed by air of the density of the surrounding air; but, when air is blown in through C, the air rises through the water to the top of the copartment F; and as the only issue for the air is through the small aperture of the blow-pipe, by which it cannot escape nearly so fast as it is blown in, the air consequently becomes condensed in the upper part of the copartment F; and this condensed air pressing on the water in F more strongly than the atmosphere does on the water in DE, depresses the surface of the water in F, and causes it to rise in DE, which is effected by a portion of the water passing under the partition into the open copartment DE. Thus the pressure exerted by the column of water whose height is the difference of level of the water in DE, and of the water in F, forces the air from the copartment F through the blow-pipe *a*, which is directed against the flame of a lamp; and this pressure keeps up a constant blast till the water in the two copartments comes nearly to the same height. The degree of condensation of the inclosed air, and the height of the column of water pressing on the condensed air, are measures of each other, when much air is blown in, so as to occasion a considerable degree of condensation. The difference of level resulting is considerable; and the column of water, which is always reacting with an equal and contrary pressure on the condensed air, causes it to issue with greater velocity from the blow-pipe: when the condensation diminishes, so does the column of water, and the velocity of the issuing stream of air. More air is to be blown in with the mouth through the tube C, from time to time, so as to keep the blast regular. Mr Tilley is of opinion that this apparatus produces a more regular stream of air than a double bellows, and it has likewise the advantage that the operator is free from the trouble of moving a pedal. The dimensions of the vessel AA, which is either of tinned iron or of tinned copper, are 17 inches in height, 5 inches in width, and 9 in breadth; the lid of the vessel opens and shuts on hinges, and supports the tallow lamp B. The bent glass tube *a*, which terminates in a

small hole, is fitted air-tight into a tin tube, which is made conical, and which forms the issue from the top of the copartment F; for this purpose, paper is wrapped round the glass tube, and then cotton wick yarn, in a conical form, so that the glass tube thus clothed may fit tight into the socket, and may nevertheless be moved round, that the blast may act properly on the flame. The bent metal tube C is also fixed into its socket in the same manner; its junction with the socket is seen in fig. 10. There is a screen formed of a tin plate sliding vertically in grooves between two upright pieces of tin; the edge of this is seen at S, in fig. 10. It is intended to protect the eyes of the operator from the light of the lamp, whilst, at the same time, he can see the subject of his operation over the top of the screen. This screen is not soldered to the vessel, but is held fast by its foot being placed between the lid of the vessel and the top of the close chamber F. Two rests for supporting the operator's arms project one from each side of the vessel; upon these the arms are placed when any substance is held to the flame. These rests are wrapped round with woollen list or leather, so as to be more convenient for leaning upon. The whole of the apparatus, including the lamp and case, weighs only three pounds and a half. When it is to be used, the vessel is fixed to a table or bench, by means of a leather strap buckled to two loops, which are on the sides of the vessel opposite to each other; the strap is passed under the table or bench. The long flat cotton wick is preferred by some glass-blowers to the usual round cotton wick. The lamp is filled with tallow, which melts after the lamp has been lighted for some time, and then it burns as freely as oil, and with a less offensive smell. When not in use, the tallow becomes solid, and is more conveniently carried about than oil: hogs' lard also does well for burning in this lamp. Some glass-blowers mix cocoa-nut oil, which is solid, at the temperature of the climate of Britain, with hogs' lard, and find it to answer well in the lamp. The lamp is placed within another vessel, marked K, which supports it at a proper height, leaving a space between all round, to receive any tallow that may run over the edge of the lamp. A wire bent at the end is convenient for trimming the wick, and forming it into a channel through which the stream of air is to be directed. It is convenient to have several lamps with wicks of different thicknesses, namely, one to hold two flat cottons of about one inch and a quarter broad, another to hold four, a third to hold six, or as much common wick-yarn as is equal to those wicks in bulk, and glass adjutages of different sized apertures to suit the different sized wicks. See *Transactions of the Society for Encouraging Arts*, Vol. XXXI.

[Eo]lipile.

The Eolipile, fig. 11., Plate XXXIV. has been applied to act as a blow-pipe. It is a hollow vessel of brass, sometimes made in form of a small kettle, sometimes in form of a ball of two inches in diameter, with a tube of brass that screws into it. The tube is to be screwed off in order to pour in alcohol by a small funnel; and then the tube being replaced, and heat applied to the bulb, the vapour of the alcohol issues from the small aperture of the tube, and being directed against the flame of a lamp, the flame is driven in a horizontal stream, such as the blow-pipe produces. The instrument has a safety-valve (S) to prevent the danger of explosion, which might happen if the nozle were stopped. The same wick that heats the bulb may serve to furnish the jet of flame, as is the case in the eolipile represented in fig. 11. This instrument has been proposed to be applied to the purposes of the mineralogist; but it does not appear to be either so readily put in action, or so efficacious as the common blow-pipe, which is also simpler in its construction, less bulky, and more easily carried about.

Newman's Blow-pipe;

Mr Newman, philosophical instrument maker of Lisle Street, London, having observed that air, condensed in a cavity, required a considerable time to escape through a small aperture made to give it issue, contrived the apparatus represented at fig. 12., which acts as a blow-pipe. This apparatus consists of a strong plate copper box perfectly air-tight, three inches in width and height, and four in length, a condensing syringe to force air into the box, and an adjutage with a stop-cock at one end of the box, by which the issue of the air is regulated. The piston rod of the condensing syringe works through collars of leather in the cap, which has an aperture in the side, and a screw (N) connected with a stop-cock, which may be made to communicate with a jar, bladder, or gazometer, containing oxygen, hydrogen, or other gases. When this communication is made, and the condenser worked, the gas contained in the jar or bladder is thrown into the box, and issues through the adjutage upon the flame of a lamp placed near it. When the apparatus is worked with common air, a few strokes of the piston fills the chamber with compressed air. When the cock of the adjutage is opened, the air issues with great velocity in a small stream, and when directed on the flame of a lamp, produces a jet of flame as the common blow-pipe does, but with more precision and regularity. The force of the stream of air is easily adjusted by opening more or less the stop-cock of the adjutage; and, when the box has been moderately charged, the stream will continue to issue uniformly for twenty minutes; when the strength of the blast begins to decline, it will be restored by working the syringe. The apparatus is very portable, and not liable to injury. It is made by Mr Newman, the inventor, with a lamp adapted to it, so as to pack up in a box not more than six inches in length, and four inches in width and height, enough of space being left for other small articles: others he makes in boxes somewhat larger, so as to contain also a selection of chemical tests. See *Journal of Science*, edited at the Royal Institution, No. 1.

with a mixture of Oxygen and Hydrogen.

Sir Humphrey Davy having discovered that the explosion from oxygen and hydrogen gases would not communicate through very small apertures, Mr Children proposed to him to employ Newman's blow-pipe for effecting a combustion of a mixture of oxygen and hydrogen gas, issuing from a small aperture. This Sir Humphrey did, and found that the flame produced the most intense heat, which instantly fused bo-

dies of a very refractory nature. Dr Clarke, Professor of Mineralogy at Cambridge, having consulted Sir Humphrey on the subject, proceeded to expose a great variety of mineral substances to the flame, for the purpose of observing its effects upon each of them. The tube of glass through which the mixture of the two gases is to issue, is cemented on the pipe of issue of Newman's blow-pipe. The tube at first used by Dr Clarke was 3 inches in length, and the diameter of its cavity $\frac{1}{70}$th of an inch. The end of the tube was constantly breaking during the experiments, owing to the sudden changes of temperature, until at last he usually worked with a tube only one inch and three-eighths in length. When the current of gas is feeble, from the gas in the reservoir having come nearly to the same degree of density as the surrounding air, or from the current being suppressed in the beginning of an experiment, then the flame has a retrograde movement, passing up the capillary cavity of the tube about half an inch, and, after splitting the end of the glass tube, the flame goes out of itself; so that, even in this case, there is no danger of explosion. In order to try the effects of an explosion, four pints of a mixture of the two gases were condensed into the chest, which was all that the syringe could force into it. The glass tube was taken off, so that the diameter of the nose-pipe, by which the gas was to issue, was about one-eighth of an inch. A burning spirit-lamp was placed at this aperture, and the stop-cock being opened by means of a long string attached to it, the whole gas exploded with a report like that of a cannon; the chest was burst, the stop-cock driven out, and one end of the chest was torn off and thrown against the wall of the room. This shows the danger of using the apparatus with too large an aperture, and the necessity of employing a capillary tube.

Dr Clarke's Experiments.

When the mixture of the two gases is to be employed in Newman's blow-pipe, the chest is first exhausted of air, and then the gaseous mixture in a bladder, screwed on at N, is to be forced into the chest by the condensing syringe. The proportions of the two gases, which Dr Clarke found to produce the greatest heat, are, two volumes of hydrogen and one of oxygen gas. The intensity of the heat is much greater when the gases are pure; the oxygen procured from manganese does not produce nearly so great a heat as that got from the hyper-oxymuriate of potass. The intensity of the heat may be regulated, by allowing the gas to issue in a more or less copious stream, which is done by turning the stop-cock. The heat, Dr Clarke thinks, is greater than that produced by the largest galvanic batteries. Most substances hitherto tried are fused by it, so that it is difficult to find supports for holding the subject of experiment to the flame. The supports employed by Dr Clarke were, charcoal, platina, a piece of tobacco-pipe, black lead. Lime, strontian, and alumine, were fused. The metal of strontian was got, and retained its lustre for some hours. The alkalies were fused and volatilized almost the instant they came in contact with the flame. Rock-crystal fused into a transparent glass full of bubbles. Quartz gave the same result. Opal fused into a pearly white enamel. Flint fused rapidly into a white frothy enamel. Blue sapphire melted into greenish glass balloons, ramified singularly. Foliated talc fused into a greenish glass. Peruvian emerald melted into a transparent and colourless glass, without bubbles. Lapis lazuli fused into a transparent glass with a slight tinge of green. Pure foliated native magnesia, from America, is the substance the most difficult of fusion; it is, however, at last reduced to a white opaque enamel. Agalmatolite of China fuses into a limpid colourless glass. Iceland spar is next in difficulty of fusion to the native magnesia; it does at last melt into a limpid glass, and, during the process, gives an amethyst-coloured flame as strontian does; the fusion of pure lime and of all its compounds, is attended with a flame of the same colour. Diamond first became opaque, and then was gradually volatilized. Gold fused along with borax, on a piece of tobacco-pipe, was nearly all volatilized. Platina wire, $\frac{1}{20}$th of an inch diameter, melted the instant it was brought into contact with the flame of the gas; the melted platina ran down in drops, and the wire burnt as iron wire does in oxygen gas. Brass wire burnt with a green flame, differing from the green flame that salts of copper give. Copper wire melted rapidly without burning. Iron wire burnt with brilliant scintillation. Plumbago melted into a bead which was attractable by the magnet. Blend or native sulfuret of zinc melted, and metallic zinc appeared in the centre of the melted mass. Metalloid oxide of manganese, crystallized in prisms, was reduced to a metallic state.—See Dr Clarke's *Account of his Experiments, in the Journal of Science*, edited at the Royal Institution, October 1816. (Y.)

BLOW-PIPE, IN ANATOMY, a straight hollow tube of brass, of an elongated conical form, six inches in length, and open at both ends. The aperture of the large end is three-tenths of an inch in diameter, that of the smaller end is of the size of a needle's point. It is used for blowing air into the collapsed vessels of the dead subject, in order to know the course of these vessels. (Y.)

BLOWING *of a Fire-Arm*, is when the vent or touch-hole is run or gullied, and becomes wide, so that the powder will flame out.

BLOWING-MACHINES, in the arts and manufactures, and in domestic economy, are instruments for producing a continued current of air, principally for the purpose of facilitating the combustion of fuel. The first idea of such a machine was doubtless derived from the lungs, which we are constantly in the habit of using for the purpose of blowing, but more especially in the simple and useful application of the blow-pipe.

Common Bellows.

Of these different machines, the common bellows bears the greatest resemblance to the lungs, and was, in all probability, the first contrivance for artificial blowing. In the first instance, this instrument might be a simple bag, capable of distension by a mechanical force, the air being drawn in and pressed out of the same aperture in the manner of breathing. The first improvement upon this simple form would be, to admit the air by a valve opening inwards when the bellows were distended, the blast outwards being

lowing-
achines.

from another aperture. This improvement consists in the air being admitted at a wider aperture, which fills the bellows in less time than would be performed through the small pipe through which the air should escape. The blast, in this state of the machine, is not continuous, but in puffs, at intervals of time required for the air to enter the bellows through the valve; the blowing interval being to the filling interval as the areas of the apertures. This irregular blast was for some time remedied by employing two bellows which blew alternately, the blowing on one taking place while the other was filling. This inconvenience was but partially remedied by this contrivance. The invention of what are called double bellows must have been considered a valuable acquisition in the art of blowing. Previous to describing these, it will be necessary to give a description of single bellows above mentioned.

ngle Bel-
ws.

It will be needless, however, to say more than refer the reader to common domestic bellows, which are in every respect the same as the single bellows first used. The leather nailed to the upper and lower boards is prevented from collapsing, when the boards are separated by a hoop of wood contained within, performing the office of the ribs in the sternum of animals, without which the breathing would not be performed. The lower board contains the valve which admits the air. When the two boards are separated, the air lifts the valve in entering the cavity. When full of air, the closing of the boards causes the air within to close the valve to prevent its return in that direction, and compels it to escape at the pipe, the mouth of which is called the nozle or nose-pipe.

uble
ellows.

In order to conceive the construction of the double bellows, we have only to take a third board exactly of the shape of the other two, and connect it with the lower board by a piece of leather similar to that of the single bellows, making two cavities exactly similar, and separated by the lower board of the single bellows, which now becomes the middle board of the double bellows. The third board we shall now call the lower board. This latter has a valve in it exactly similar to the first, which still retains its place in the new construction.

The middle board is now fixed in a horizontal position, the pipe being placed to the fire to be blown. The lower board is held down by a weight, which keeps the lower cavity constantly full of air. The top board has a weight laid upon it which presses all the air out of the upper cavity through the pipe.

The machinal action by which the blowing is performed, is, first, to lift up the lower board. This forces the air from the lower into the upper cavity, the valve in the middle board preventing its return. The weight on the upper board now presses the air with a uniform blast through the pipe. During this time the lower board descends, which fills the lower cavity with air from the atmosphere. This again rises, and gives its contents to the upper cavity, and thence through the nose-pipe. Hence we see that irregular puffing blast which belongs to the single bellows is here confined to the lower board only, which supplies air to the upper cavity, while the upper board is constantly pressing uniformly upon the air in it. Although this is a considerable improvement upon the single bellows, it does not completely obviate the irregularity of the blast. So long as the lower board is not in action, the pressure on the upper board being uniform, the blast is the same. Every time, however, the bottom board rises to force the air into the upper cavity, an extra pressure is given to the air in the upper cavity, and a temporary puff is produced. In the application of bellows to the smith's forge, the continued blast was of less importance than in the blast-furnaces applied to the smelting or refining of ores. The single bellows are at present almost exclusively employed by anchor-smiths and cutlers, while the blacksmith and most others use double bellows, which are doubtless better for all purposes.

Blowing-
Machines.

Wooden
Bellows.

In France and other parts of the Continent, bellows have been formed entirely of wood, instead of the flexible sides of leather, which serves to increase and diminish the capacity. The wooden bellows consist of two boxes, each open on one side, the one being just capable of containing the other; the outer box being placed with the mouth upwards, the other is made to descend into it, with the mouth downwards; the latter being capable of moving up and down, while the other remained fixed. In the bottom of the fixed box is a valve like the common bellows, and a pipe on the same level, to let out the blast. The change of capacity, by the motion of this box, causes the blast, and with less waste of power than that occasioned by the bending of the leather in the common bellows. This advantage is, however, probably more than compensated by the loss of air, from the box not fitting on the sides. See a description of this and some other blowing-machines, under PNEUMATICS, in the *Encyclopædia Britannica.*

Circular
Bellows.

The common smith's bellows have lately been constructed of a circular form. The boards of these bellows are round, and the moveable boards parallel to the horizon and to each other. We have given a view of this construction in Plate XXXV. figures 4. and 5. A is the blast-pipe, B the moveable lower board, C the fixed board, into which the pipe is inserted, and D the upper moveable board, on which is placed a weight, to regulate the strength of the blast. Motion is given to the lower board by the lever L, and the chain H working on the roller R.

The form of these bellows being cylindrical, the weight required to give a given pressure and strength of blast will be easily determined. If the diameter be 1 foot, the area will be 113.19 inches. The most convenient and proper blast for smith's bellows is about $\frac{3}{4}$ lb. upon the inch, or from that to $\frac{1}{2}$ lb. The upper board, in this case, would require a weight of 56.5 to give a blast equal to half a pound upon an inch. This pressure would give a velocity equal to about 207 feet a second. If the diameter of the nose-pipe be changed, the number or length of the strokes, or both, must be changed, in order that the pressure and the corresponding density of the blast

may remain the same. If the number and length of the strokes were kept up, and the aperture diminished, at the same time that the capacity of the bellows will not admit of enlargement, the pressure and density of blast will be increased, although no additional weight is laid on. This frequently happens in the smith's bellows when he makes an increased effort to blow after the upper cavity is full. It is much better, however, not to exert the bellows in this way when a stronger blast is required, but to produce the effect by an additional weight. A very strong blast is found to be very injurious to the iron when welding heats are required, and still more so in working steel. It is much better that an increase of air, which is frequently wanted, should be furnished by increasing the aperture, supposing the power to be at the time adequate to keep up the increased supply. Bellows should therefore be so constructed that the pressure may be uniform, and not immediately under the control of the workman. When he wishes to quicken his heat, he should have the means of increasing the aperture by a circular plate turning on an axis at right angles, to the length of the pipe, as seen in fig. 9. When in the position *ab*, the whole area is filled; when in that of *cd*, the air passes in its full quantity. The index being placed at any intermediate points, *ef*, will let in any proportionate quantity required.

The aperture might be made to change, by the increase of power upon the machine, and thus made to regulate itself. Several simple contrivances of this kind may be applied by any one skilled in machinery.

New Blowing-Machines.

These improvements would render the common leather bellows, of the form above given, very useful for smiths. The irregular blast occasioned by their present construction is found to be very injurious to the iron, both as to its quality and economy. This is abundantly shown in the use of some blowing-machines lately invented, which have the advantage of a uniform blast, and at the same time much softer, being produced by a small pressure.

These blowing-machines are also found to answer very well for melting cast-iron, the soft blast having less tendency to destroy the carbon the quantity of air being compensated by increasing the aperture.

One of these machines is the invention of Mr Street, for which he has taken out a patent. It consists of a barrel-shaped vessel, from 4 to 5 feet in diameter, and of a length more or less proportionate to the work it has to perform.

This cylinder is supported on two bearers by the two ends of its axis like a barrel churn. The cylinder is divided into two equal parts by a plane in the direction of its length, fitting the two ends and the upper side, water-tight, and extending downward to a small distance from the opposite side. This septum is in a perpendicular position when the cylinder is at rest. When this vessel is partly filled with water, and is made to pass through a certain space on its axis, the air which occupies the upper part of the vessel will be compressed on one side by the water, which flows from one side of the septum to the other, and will become in the same degree rarified on the other, from a contrary cause. If, however, in this situation, a valve be made to open inwards from the atmosphere on the rarified side, and another to open outwards on the condensed side, two equal and contrary currents will be established, one inwards, and the other outwards. On the returning stroke both these valves will shut, and the other two sides will be put in the same situation with the first cavities. If, now, two similar valves to the last be introduced, two similar currents will be produced. If the two valves at which the air escapes from the machine, one on each side the septum, be made to communicate with one cavity from which a nose-pipe proceeds, while the other two valves communicate with the asmosphere, every stroke will discharge a quantity of air through the nose-pipe from one cavity, and introduce the same volume of air from the atmosphere into the other cavity. These strokes are produced by the oscillating motion of the machine, the limit of its vibrations being about a quarter of the circle or 90°.

These alternate puffs of air are first propelled into a vessel containing water to regulate the blast. This vessel is divided into two portions by a septum, which passes from the close cover at the top nearly to the bottom. When the air is forced into the cavity, which is close at the top, it expels the water under the septum at the bottom into the open cavity, so as to keep a constant head in the latter, compressing the air in the former. From this air-chest, a nose-pipe proceeds to the fire, and the air escapes from it with a uniform velocity so long as the same column of water in the chest is preserved. This description answers to the first machine of the inventor; he has since taken out a second patent; the specification of which is given in the *Repository of Arts*, Vol. XXVIII. p. 193. We shall here give a description of this machine, with the patentee's improvements. See Plate XXXV. figs. 1, 2, and 3.

Fig. 1. is a longitudinal section of this machine, AB is the cylinder resting upon the axis *ab* and *cd*, which are supported on the uprights *gg*. The oscillating motion is given to it by a rod working upon the pivot *p*, the other end of which is connected with a crank of such a length as to cause the cylinder to move through an arch of 90 degrees. The vessel is filled with water to the height *ws*.

The part CBD (fig. 2.) is cut off from the rest of the cylinder by two planes meeting at *c*, and continuing down to the axis *x*, so as to work upon its convex surface. These planes extend the whole length of the cylinder, and are then divided transversely into three cavities GHI, as seen in fig. 1. The cavity G is for the reception of the external air, and is called by the patentee a receiving box. The cavity H is open to the atmosphere, the periphery of the cylinder being removed in that part. The cavity I is appropriated to the air which is driven out of the machine, through the valves *tt* and *qq* (fig. 3.), which open alternately on each side. The cavity G is divided longitudinally in the middle, forming two cavities, *m* and *n*, fig. 2., two valves, *e* and *f*, fig. 1.,

open into each, one from the end of the cylinder, and the other from the cavity H. Each of the cavities *m* and *n* communicate with the body of the cylinder by the holes *hh* in the dividing planes. The cavity I has no division, as it receives the air from both sets of exit valves, which escapes at the pipe P.

The axis *av* works within the axis *ab* and *cd*, and is rendered air-tight by a stuffing-box within the latter. This axis will have the effect of remaining at rest, while the cylinder is in motion, there being no other force exerted to turn it than the friction of the stuffing-box. The use of this axis is to support and turn a swing valve MV, which is made of rolled iron, strengthened by ribs connected with the axis. This valve is a plane, which would exactly sweep the interior surface of the cylinder without touching it. If the axis *vx* be held fast, the valve will retain its perpendicular position, while the cylinder performs its vibrating motion. The water would also remain at rest, with the exception of the motion which its friction and the compression of the air occasions. When the machine moves from D (fig. 3.), till the plane DC comes very near to the surface of the water *ws*, the valves *qq* open, and a volume of air equal to the space DCS will be expelled through the cavity I (fig. 1.), along the pipe P, during the time the valves in the cavity *m* (fig. 2.) have opened to admit the same volume of atmospheric air on the returning stroke. The point B is carried the contrary way, by which another portion of air opens the valves *tt* to pass through the pipe P, while the same volume of air from the atmosphere enters the cavity *n*, which in its turn is forced through the exit valves *tt*.

The use of the swing valve MV will now be obvious. If it did not exist, every time the air was compressed on one side, the water would be depressed on that side, and the compression of the air would be limited by the increased column of water on the other side. This valve, however, prevents the water from immediately changing its situation, no more escaping from one side of the valve to the other than what can pass between the edges of the valve and the cylinder, which, in the short space of one stroke, can be only a very small quantity. This may be considered as a great improvement upon the first machine, which we have before described. The patentee further intends occasionally to give to this swing valve a contrary motion to that of the cylinder, and thus still more increase the blast. Or, in the use of a very small blast, the valve may be left at liberty, and merely prevent the too great agitation of the water, which, in the original machine, was considered as an objection. Two of these machines are frequently used together, and worked by cranks, which make an angle of 45° with each other, to make the strong part of the blast of the one to occur with the weak part of the other.

The part I of the exit pipe PL, must be precisely in the centre of motion. The part L works in a stuffing part, or a ground socket connected with the pipe LN. The latter should communicate with a regulator which the patentee does not describe, but recommends one of water. This may be a vessel at least of the capacity of the cylinder, inverted in a reservoir of water, and stand near to the bottom. The pipe N is inserted into the bottom, which is now uppermost; the height of the water in the reservoir must be equal to giving the required pressure to the air.

When the air is forced into the inverted vessel by the machiner, the water descends in this, and rises in the reservoir, which now gives a pressure to the continued air equal to the difference of the height of the water in the inverted vessel and the reservoir. The surface of the reservoir should be the greatest possible, in order that it may be raised in the least degree by the water which comes from the inverted vessel, which will have the effect of keeping the blast more uniform.

The water regulator is certainly the best for smiths' bellows, for refinaries, forges, and perhaps the common melting furnace, but they have been found very objectionable in the blowing of large blast-furnaces. The air in the common blowing-engine, which has been already described under PNEUMATICS in the *Encyclopædia*, undergoes a great increase of temperature, during its passage through the machine, often as much as 40 or 50 degrees. The heated air has the effect of carrying a greater quantity of water along with it into the furnace, which destroys a larger quantity of carbon than the same bulk of common air, without producing an adequate portion of heat. A great part of the heat of the air is doubtless produced by the friction of the piston of the blowing cylinder, which, in this construction, has a very tight wadding. In the blowing-machine above described, the water would doubtless be an objection in blast-furnaces, but, as its little friction would not heat the air like the common blowing cylinder used in blast-furnaces, the objection would be less formidable. Air must doubtless give out some heat by its decrease of volume, just as it will absorb the heat by rarification, as is experienced in exhausting the receiver of an air-pump. The converse of this is equally shown in the little instrument employed to kindle tinder by condensing the air within it.

The heat by the friction of this piston, is probably much more than by the condensation of the air; the latter is obviated in the machine above described, and in another blowing-machine lately introduced, of which we shall give a description.

This machine, in its general appearance, does not seem to have any advantage over the common blowing cylinder, but in practice it is found superior.

It resembles in some degree the common smith's bellows of the Chinese, which consists of a square wooden trunk, in the form of a parallopipedon. A board is made to fit its cross section, pretty nearly, to which is attached a long rod by which the board is pushed backwards and forwards like a piston. At one end of the trunk is a valve opening inwards to admit air, and at the same end is a pipe with a valve opening outwards.

The machine above alluded to having some resemblance to this, is the invention of a Mr Vaughan, who has fitted up several of them for founderies, and which are much approved. The writer of this ar-

Blowing-Machines.

ticle has taken a drawing from one of these machines employed to melt cast-iron at the Phœnix Foundry in Sheffield.

Figs. 6. and 7. are two views of the machine. ABCD is a square box formed of pieces of cast metal, screwed together by hinges. Two of these are placed side by side, as may be seen in the end view, fig. 7. MQ is a piston fitting the square box, which is drawn backward and forward by the rod EF, which works horizontally on the wheels *wx* by the spear G, which communicates with the crank of a wheel at a distance.

The piston MQ, which is the most ingenious part of this machine, is enlarged in fig. 8. to render it clearer. The body of the piston is a cast-iron plate about one-half inch thick, with a socket in the middle to receive the rod. The diameter of this plate is about one-fourth of an inch less than that of the box. Two pieces of wood, *v n*, are cut diagonally, in order to place the pieces of leather, *l l*, between them. These leathers, with the wood, are firmly fastened to the plate by bolts, such as *g h*.

This leather extends about two inches beyond the wood: their slight elasticity keeps them in contact with the metallic surface, which is not required to be very smooth. When the piston moves towards the end of the box, towards which the leather projects, the leather claps close to the surface, rendering it air-tight, while the leather on the other side of the piston becomes loose, and has no friction. These leathers will be contrarily acted upon, when the piston acts the contrary way. The projecting curved pipes, HI, form a communication between the box where the piston works, and the air-chest N. When the piston moves from B to D, the valves F and V open, while L and S are shut. The air contained in the box is now forced through the valve R into the chest N, and from thence along the blast-pipe P.

In the returning stroke, which is the whole length of the box, the valves R, V, and K, are shut, while L and S open. The air is forced through H to N, and then through P.

Two of these work at the same time by two cranks, which cause one to be in full blast at the time the other is returning the stroke; so that, with due management, the four puffs produced by two double strokes may be made to succeed each other at equal intervals, which almost amounts to a steady blast. The inventor recommends four of these boxes all to work together, which would produce eight puffs in the time of one double stroke, which, if divided into equal intervals, would produce a sufficiently uniform blast for any purpose.

When the leathers of the piston are rubbed with black lead, the friction almost amounts to nothing. The leather acts so easy to the surface, and is so flexible, that it may be very easily raised with the fingers. This could not be the case, if it were applied in the same way in a cylinder; and this is a sufficient reason for using the square box instead of the cylinder.

This machine makes 70 strokes in one minute; the nose-pipe, where the blast enters the furnace, is $2\frac{1}{2}$ inches in diameter. When the length of stroke is the greatest, at the above speed, it furnishes about 1200 cubic feet *per* minute.

This machine steers clear of the objection of the water, and, from its small friction, will have less tendency to heat the air. Its original cost is also less than any other machine yet constructed. In the situations where it has been adopted, it gives the highest satisfaction. The first construction of Street's bellows, above described, was only fitted for some smiths' fires, where a very soft blast was required. In their improved state they may be employed for most purposes.

Blowing-Machines ‖ Bogalcund.

All the calculations relative to bellows will be easily made, by the following rules and formula:

First, get the space or capacity formed by one stroke of the machine, call this c, cubic feet.

Then get the number of strokes *per* minute, which call n.

The area of the nose-pipe, in feet, call (a).

The pressure on the air to be discharged, whether by a column of water or by a weight, call p.

$v =$ the velocity which the air escapes with.

$r =$ the resistance, in pounds, which the blast will give.

Then $cn = q$ the quantity discharged in one minute; and $v = \frac{cn}{a}$ in one minute, or $= \frac{cn}{60\ a}$ for one second.

Then since the resistance is equal to a column of the fluid of the area a, and twice the height to give the velocity, $\frac{v^2 a}{32 \times 14} = p$. The weight of 14 cubic feet of air being equal to 1 lb.

The energy of air in blowing fires, is as the quantity, and inversely as the space it occupies. For if the same quantity of air be consumed in half the space, the intensity of the heat, or the temperature of that particular place, will be double. Hence it is found, that the same quantity of air, by weight, in winter, will produce a greater effect on a blast-furnace than in summer, merely from the difference of density. The great difference in produce of iron in the cold and hot seasons of the year, is a fact notorious with iron masters. (T.)

BOGALCUND, a district of the province of Gundwana in Hindostan, in the 25th degree of north latitude, and 82d of east longitude; bounded on the west by the British possessions in Bundelcund; on the east by the small territory of Manwas; and watered by the rivers Soane, Bichanuddy, and Behennuddy.

General description.

The exact dimensions of this country, so far as we know, are not ascertained, but they appear to be considerable. Part of it is fertile and well cultivated; the chief crops are wheat, barley, and different kinds of pease, all in tolerable quantity: nevertheless, very little grain, exceeding their own necessities, is raised by the natives. They have also numerous herds of black-cattle, and large flocks of sheep. The whole surface is traversed by good roads. Its access from Allahabad, to which it was annexed by Aurengzebe, is by a pass called Sohagee Ghaut, long, steep, and difficult, having at its extremity a redoubt in a strong position. From hence Bogalcund appears

Bogalcund. like a great table and, without any descent, and the traveller is conducted by a good road to the capital.

Inhabitants. Gundwana is inhabited by various tribes, who seem to receive the generic name of Goands. Their manners and civilization are different, and in various stages of advancement; some, particularly the mountaineers, are rude and savage. They go almost naked, if not entirely so; practise gross superstitions; and dwell in villages consisting of a few huts in places almost inaccessible. But those in the lower and fertile parts of the country are more cultivated, and sufficiently courteous to strangers. The inhabitants of Bogalcund are called Bogals, Bogheleis, or Boghels, synonymes used indifferently; but it is not evident whether they should be considered a distinct race from the Goands of Gundwana. They are reported to have migrated hither from Guzerat many centuries ago, and gradually enlarging their confines by an encroachment on those of their neighbours, expelled a tribe of mountaineers from Shewah, which their chief was induced, by the excellence of its situation, to select for his own residence. It is not unlikely they are of Tartar origin. As this is one of the northern countries of India, whose history and statistics are extremely obscure, very little can be said of the manners, customs, and conditions of its inhabitants. They consist of five different tribes, acknowledging the same government, but without admitting an equal control, or paying the like obedience to it. Part, or the whole, profess the Mahometan religion, and many temples are to be seen in the territory. Three of the tribes follow a practice, too general in the east, of destroying their infant daughters, which must inevitably restrict the population.

The Bogals are skilful in agriculture; and they have many fine tanks, or artificial ponds, conveniences of greater importance in India, and of infinitely greater size than Europeans are wont to conceive. These are generally situate on a declivity, three sides being built up with much art and labour, and the fourth serving as a natural embankment. The agricultural skill of the inhabitants results, in a great measure, from the nature of the government. Here the feudal system prevails, and many of the lands are held by military tenure. The forces have no pay, but, in lieu of it, certain lands are assigned for their subsistence. Their influence is thence very great, and there is not an officer among them without one or two villages for his support. The country is thus partitioned among innumerable feudatories, who find it their interest to promote agriculture in order to provide more amply for their own subsistence. It is common with the peasantry to change their abode at intervals of three or four years, for the purpose of tilling the ground whereon their cottages stood. The traces of villages recently abandoned are, therefore, frequently to be seen, and would indicate declining prosperity, did not their renewal in other places, as often presented to view, prove the reverse.

The chief town of Bogalcund is Rewah, which is large and populous. It is situate on the small river Bichanuddy, rising twenty miles to the east, and joined by the Behanuddy just above the town. The united stream runs immediately under a large fort in the capital, which includes the houses of the most wealthy and respectable inhabitants, and where the Rajah resides. In the neighbourhood are some memorials of the slain, who lately fell in a great battle, wherein the Bogals were victorious against an invading enemy. Rewah stands in lat. 24° 37′ north, and 81° 25′ east longitude; distant 126 miles north-east of Benares.

Government. This district is under the government of an independent Rajah, who is said to be the Maher-Rajah, or sovereign of several neighbouring territories; and although the Rajah of Bundelcund is himself quite independent, and infinitely the more powerful of the two, it is necessary for him to be invested by the Rajah of Bogalcund, wherein we find another analogy to feudal principles. His revenues are very small, principally owing to the subdivisions of the district; for it has sometimes excited astonishment that the sovereign of so fertile a territory should be so poor. He receives an inconsiderable tribute from the Rajahs acknowledging his superiority, land-rents, and customs on merchandise passing through the capital.

Ali Bahauder, a Mahratta chief who holds a powerful command in the army of the Peshwa, or Head of the nation, threatened Bogalcund with invasion about the year 1794 or 1795, to levy contributions from the Rajah, which he was little enabled to afford. But he was beloved by his subjects, and Ali Bahauder having put his menaces in execution, he raised an army of about 3000 men to oppose him. The enemy advanced with 6000 men, carrying every thing in his course, until arriving within two miles of the capital. There he was encountered, and totally defeated by the Rajah, with the loss of his General and his cannon. The invader vowed to revenge the destruction of this army, and the death of his General. He again collected a powerful force, and invaded Bogalcund a second time, in the year 1795; but the Rajah, then aged and incapable of the exertion necessary to resist so active an enemy, purchased peace by concessions. Either at this time or previously, he engaged to pay Ali Bahauder L. 14,500 Sterling,—a stipulation which he proved totally unable to perform, and a neighbouring Rajah, who had become security for the payment, and required hostages for his indemnification, afterwards obtained the cession of a valuable district in Bogalcund, probably from having been obliged to fulfil his part of the engagement. But this was not the only calamity; for a supervening scarcity in the succeeding season followed the depredations of Ali Bahauder's troops. The natural fertility of the soil, however, and importation of various commodities from Misapour, contributed to relieve the inhabitants, and the country began to recover speedily from the disasters it had been exposed to. Nevertheless, its dismemberment, at no distant period, was anticipated, from the growing poverty and declining power of the Rajah, though the nature of the soil, and the state of agriculture, were both suf-

ficient to support a numerous population. Formerly, the influence of the Rajahs of Bogalcund was very considerable in Indian affairs, and they have been known to afford an asylum to powerful Princes, whom temporary adversity exiled from their own dominions. Here the illustrious Emperor of the Moguls, Ackber, was born in the year 1542. On occasion of a usurpation of the empire, his father, Humayoon, retired from Delhi; and his mother, when pregnant, was, for greater security, sent to a strong fortress, where, tradition reports, she was almost immediately taken in labour. But the Astrologers of the day having previously determined that future felicity would attend the child who should be born at a certain moment, she was suspended, during two hours, by the legs, in order to retard the period of delivery, and then being taken down, the great Ackber saw the light. More recently, when his descendant, Shah Aulum, was dispossessed of the throne of Delhi, in the course of last century, by the invasion of another potentate, he sought refuge with Ajet Sing, the Rajah, of whom we have already spoke; and here, also, between the years 1750 and 1760, one of his wives was delivered of a prince, whom she called Ackber, in commemoration of his ancestor, and who lately survived at the capital, Delhi, which was restored to him. But the future greatness of the latter Prince being of less importance, his mother probably escaped the cruel experiment to which the parent of Ackber was subjected. (s.)

BOHADDIN, or, more properly, BOH-A-EDDYN, an eminent Arabian Writer and Statesman; is better known in the East under the appellation of Ibn-Sjeddad, *the son of Sjeddad*. He was born at Mossul, in the year 539 of the Hegira. (1145 A. D.) He early became eminent in the study of the Koran, and of the traditions and controversies founded on it, as well as that of Jurisprudence. At twenty-seven, he obtained the place of Repeater or Lecturer at Bagdad; and, soon after, a Professor's chair, in a College, founded at Mossul. In 1187, he made the pilgrimage to Mecca, and then proceeded to visit Jerusalem and Hebron. In passing through Damascus, he was sent for by Saladin, who was then employed in the siege of Kancab. The Sultan seems to have been pleased with the interview; and, his Secretary Omad-Eddyn-Isfahamy, a man of great learning and eloquence, advised him, after completing his pilgrimage, to present himself again before Saladin. Our author had observed, as he himself mentions (*Vita Saladini*, ch. v.), that the whole soul of the Monarch was engrossed by the war which he was then waging against the enemies of the faith; and, that the only mode of acquiring his favour was, by urging him to its vigorous prosecution. He, therefore, composed a treatise on *the Laws and Discipline of Sacred War;* and made a collection of all the passages in the Koran and the books of traditions, in which, the extermination of infidels was recommended and enforced. This work, on his return, he presented to Saladin, who received both it and the author with peculiar favour. Bohaddin, from this time, remained constantly attached to the person of the Sultan, and was employed in various important embassies and departments of civil government. That Prince seems also to have sought, by the friendship of so eminent a doctor, to exalt the reputation for sanctity, of which he was extremely ambitious. Often while riding through the ranks, Bohaddin rode by his side, and read to him passages out of the Koran or its interpreters, to which Saladin lent more apparent attention than to the arrangements of the army. Our author was now appointed to two important posts; those of Judge of the Army, and Judge of Jerusalem. In this latter capacity, an incident occurred, which he adduces to prove the impartial justice exercised by the Sultan. A merchant presented himself at the tribunal of Bohaddin, and complained, that he had been unjustly deprived of a large sum of money. On being asked the author of the injury, he replied, "the Sultan himself." Here the Judge deemed it expedient to suspend proceedings, until the case was laid before the royal defendant. Saladin, on learning the circumstances, denied the truth of the charge; but said, that the man should have justice. Accordingly, he was introduced into his presence; the Sultan descending from his throne, placed himself in the posture of a defendant; and each pleaded his own cause before Bohaddin. The latter decided (on just grounds as he alleges) in favour of Saladin; and even hinted, that the temerity of the plaintiff merited some portion of chastisement. The Sultan, however, dismissed the person not only unpunished, but with the present of a handsome robe, and a large sum of money.

Bohaddin continued in favour with Saladin during the whole of that Monarch's life, and boasts, that he often obtained ready admission, while the principal officers and generals were waiting in vain for an audience. After the Sultan's death, he was active in securing the throne to his son, Melik-al-Dhaker. That prince created him Cadhi of his capital, Aleppo, which gave Bohaddin an opportunity of founding in that city a College, of which he himself was the principal Professor. Under his auspices, the sciences, which had greatly declined in Aleppo, soon rose to more than their former lustre. Melik-al-Dhaker dying, left his son, Melik-al-Aziz, a minor, and Bohaddin obtained the principal sway in the Regency. This gave him an opportunity of introducing learned men at court, and loading them with honours. As the prince, however, approached to manhood, he attached himself to more youthful counsellors; Bohaddin, then, though he still retained his offices, found it expedient to retire from court, and devote himself entirely to the pursuits of learning. Even after he was unable to go to college, he continued to give lectures in his own house; and he persevered in these learned labours till the age of ninety, when he died, on the 29th October 1235. (Hegira 633.)

Bohaddin wrote several works on Jurisprudence and Moslem Divinity; but, the only one that can be interesting to us is his *Life and Actions of Saladin;* which, with several other pieces connected with the

Bohaddin ‖ Bombay.

same subject, was published by Albert Schultens, at Leyden, in 1732, accompanied by a somewhat inelegant Latin translation; also by notes, and a Geographical Index. This work affords a favourable specimen of the historical compositions of the Arabs. Neither Bohaddin, however, nor any of his contemporaries, can enter into competition with those great historians, who have adorned the better ages of European literature. They display no philosophical views nor accurate discrimination of character; but confine themselves chiefly to a mere chronological record of events. The work of Bohaddin is written with some spirit; and, at the same time, is free from that verbose and empty inflation which deforms the composition of some of his contemporaries. Whatever relates to Saladin, breathes, of course, the highest tone of panegyric; yet, the enthusiasm with which every thing about him is narrated, and the anecdotes which the author, from his own personal knowledge, is able to communicate respecting that extraordinary character, give his work a great degree of interest. (B.)

BOMBAY. The account of Bombay in the *Encyclopædia*, contains several interesting particulars relative to its soil, climate, and the manners of its inhabitants, and we propose, in the present article, to add such farther information as we have collected from the works of recent observers.

Island.

The Island of Bombay, which is the seat of Government for the western part of India, is situate in lat. 18° 56′ N. and lon. 72° 56′ E. Its length, from north to south, is 6½ miles, and its breadth, near the fort, is about a mile. It is separated from the mainland by an arm of the sea, and it forms, in conjunction with the adjacent islands of Colabah, Salsette, Butcher's Island, Elephanta, and Caranjah, a large, commodious, and well sheltered harbour. The north side of the harbour is partly formed by the Island of Colabah, which is separated from Bombay by a small creek, fordable at low water, and is about 2½ miles long. Near its southern extremity stands the light-house,—a building of a circular form, rising from the sea to the height of 150 feet, and shewing its light at the distance of 21 miles. The Island of Salsette, which is about 20 miles long and 15 broad, is separated from Bombay by a narrow arm of the sea. Over this strait a causeway was constructed in 1805, which, by improving the communication with the mainland, is of infinite service to the surrounding country, with the produce of which Bombay is supplied; but it is said to have had a prejudicial effect on the harbour. Butcher's Island is nearly opposite to Bombay Castle, at the distance of three miles; and about two miles from this, and still fronting the fort, is the inconsiderable, but celebrated, Island of Elephanta. The two small Islands of Henery and Kenery, lie at the entrance of the harbour.

Town of Bombay.

The town of Bombay is nearly a mile in length, from the Apollo Gate to that of the Bazar, and about a quarter of a mile broad in the widest part, from the Custom-house across the green to Church Gate, which is nearly in the centre, between the Apollo and the Bazar Gates. There are likewise two gates towards the sea, having commodious wharfs, and cranes built out from each, with a landing-place for passengers. Between these gates is Bombay Castle,—a regular quadrangle, built of hard and durable stone, and having the advantage, in one of the bastions, of a large reservoir of water. The fortifications are numerous, and they have been improved in proportion as the place has risen into greater importance from its increasing trade. They have lately received a considerable accession of strength from Dunganee Hill, which commanded the town, having been included within the fort; and towards the sea they are extremely strong, the harbour being completely commanded by ranges of batteries placed one above another. But on the land side, its means of resistance are not so formidable; nor is this of much moment, as an enemy once landed, would find no difficulty in possessing himself of the place. A bombardment would, in a few hours, lay the town in ashes; and were the houses, which are lofty and made of combustible materials, once on fire, the troops could no longer preserve their station on the ramparts. Indeed, it is probable, that the destruction of the magazines would be the consequence of the conflagration of the adjacent buildings.

In the centre of the town is a large open space, called the Green, around which are many large and well-built handsome houses. Here is also the church, which has an extremely neat and light appearance; and, on the left of the church-gate is the Government-house, which is a showy edifice, but liable to the inconvenience of having the largest apartments in both floors a passage-room to the others. On the right of the church-gate is the Bazar, which is crowded and populous. Here the native merchants reside, and at the entrance to the street stands the Theatre, which is a handsome building. In the year 1803, this part of the town was greatly injured by a destructive fire, which destroyed nearly three-fourths of the Bazar, together with the barracks, custom-house, and many other public buildings, besides property of immense value belonging to native merchants. The flames spread with such rapidity, that the magazine was endangered; and, in order to preserve the town from total destruction, many houses in the neighbourhood of the castle were battered down with artillery. Since this period, the town has been rebuilt on an improved plan, at the expence of the Company.

Docks and Ship-building.

Bombay is the only principal settlement in India where the rise of the tides is sufficient to admit the construction of docks on a great scale. The highest spring tides rise to the height of 17 feet, and the height of the ordinary tides is 14 feet. In consequence of these natural advantages, the dry-dock of Bombay has scarce its equal for size and convenience; having three divisions, with a pair of strong gates to each, so that it is capable of receiving three ships of the line at the same time. Near this dock is a convenient place to heave down several ships at once, and this operation is well executed, and with great expedition, by the Persees, who are generally accounted excellent ship-carpenters. Here is an excellent rope-walk, equal to any in England, with the exception of the King's yard at Portsmouth,

Bombay.

where cables and all sorts of lesser cordage are manufactured. It has also a covering, to protect the workmen from the heat or inclemency of the weather. The dock-yard is large and well contrived, having ample supplies of naval stores deposited in the warehouses, together with large quantities of timber, for repairing and building ships, and forges for all kinds of smith's work. With all these advantages, Bombay claims a distinguished rank as a naval arsenal, and within these few years many merchant ships of from 600 to 1300 tons, partly for the country trade and partly for the service of the Company, have been built in its docks, which, in beauty of construction, good workmanship, and durability, are superior to any other class of merchant ships in the world. Bombay is the only port in any of the British possessions out of Europe at which a ship of the line was ever built; and it deserves to be recorded that the Minden, a 74 gunship, was launched from its dock-yards in 1810. It has also added several frigates to the British navy. All these vessels are built of Malabar teak, which is esteemed superior to any in India. The Teak forests, from which supplies of wood are derived, lie along the western side of the Ghaut mountains, and other contiguous ridges on the north and east of Basseen; the numerous streams which descend from them affording water-carriage for the timber. The docks belong to the Company, and the King's ships pay a monthly rent for repairs. They are entirely occupied by Persees, who are esteemed remarkably skilful and assiduous. Bombay, thus possessing, in the skill of its workmen, the excellence of its timber, and the superiority of its docks, all that is necessary for a naval arsenal, may be considered as a station of the first importance to the British power in India.

Commerce.

From its position, Bombay commands an extensive commerce with the countries situate in the Persian and Arabian gulfs, and with the western coast of India. It carries on, also, a valuable trade with the eastern parts of India, the Islands in the eastern ocean, and with China. Of the trade with China, the staple commodity is cotton-wool. The other articles consist of sandal-wood and pepper, the produce of Malabar and other adjacent countries; gums, drugs, and pearls, from Arabia, Abyssinia, and Persia; elephants' teeth, cornelians, and other produce of Cambay; sharks' fins, birds' nests, and other articles from the Maldive and Lackadive Islands. The ships generally arrive at Canton in June or July, and lie there until December or January. In 1808, the quantity of cotton brought to Bombay for re-exportation amounted to 85,000 bales, of 375 pounds each, which is partly procured from the country on the Nerbuddah, and from Gujrat and Cutch. The quantity, however, is not usually so large; and in this trade, Bombay has been lately rivalled by the competition of the merchants of Bengal and Madras, who, having adopted a different method of cleaning their cotton, have sold it to greater advantage in the market of Canton than the merchants of Bombay; and unless the latter adopt the same method of preparing their commodity, it is probable that this lucrative branch of trade will decline. It is about thirty-five or forty years since the cotton-trade from Bombay to China was first established. At that period, a great scarcity of provisions having occurred in China, the cultivation of cotton was restricted by an edict of the government, and grain was ordered to be raised in its stead. Hence a great demand arose in the Chinese market for cotton, which has continued ever since to increase. But the general inattention of the Bombay merchants to the quality of the commodity, and the many frauds which have been practised upon the Chinese, have induced them to resume the cultivation of cotton, for the purpose of having within themselves the necessary supply of this useful article. On this account the demand from China may be rather considered as precarious. In stowing and packing the cotton, great dexterity is displayed. It is pressed down by means of a screw, worked by a capstan, to each bar of which there are 30 men, amounting on the whole to 240 to each screw. Hemp is packed in the same manner, but it requires to be carefully laid in the press; its fibres being liable to be broken if they are bent.

Bombay carries on a considerable trade with Europe, and with different parts of America. The imports from Europe are principally articles for the use of the natives and Europeans; consisting mostly of the finer articles of European manufacture; the produce of other countries for re-exportation, piece goods, and treasure. The value of goods imported from London, from May 1811 to April 1812, was 20,58,942 rupees, equal to L. 231,630. The value of the following exports to London, during the same period, was 15,37,800 rupees, equal to L. 173,000, viz.

Bombay.

* A Lack is 100,000, which, at 2s. 3d. *per* rupee, is L.50,000 Sterling. When any sum amounts to more than 100,000 rupees, the usual mode of numeration is to divide the lacks from the remaining part of the sum, thus, 15,37,800, which is 15 lacks, thirty-seven thousand eight hundred rupees.

Bombay. The following is a TABLE of the estimated Value in Rupees of the Exports and Imports to and from other places.

Imports.	Sicca Rupees.	Exports.	Sicca Rupees.
From Madeira	70,360		
From Brasils (of which there was treasure to the amount of 13,57,650)	15,18,400	To Brasils	43,334
From the Isle of France, of which cloves composed two-thirds	5,34,183	To the Isle of France	2,63,403
From China, consisting of articles for the use of the natives and Europeans, manufactures, piece-goods, treasure	40,64,654	To China	37,17,522
From Manilla, half of which consisted of sugar	2,29,350	To Manilla	78,837
From Pegu		To Pegu	6,458
From Prince of Wales Island, and the Islands to the Eastward	4,99,886	To Prince of Wales Island	7,54,560
From Bengal, consisting of raw silk, piece-goods, sugar, groceries, grain	27,70,051	To Bengal	4,25,615
From the Coast of Coromandel	80,771	To Coast of Coromandel	1,87,464
From Ceylon	1,14,331	To Ceylon	67,048
From Malabar and Canara, grain, manufactures, piece-goods	30,01,139	To Malabar	17,66,193
From Goa and the Concan, grain, manufactures, piece-goods	20,40,364	To Goa and Concan, consisting generally of the produce imported from other countries	51,29,222
From Bassein and adjacent villages	3,63,682	To Bassein, &c.	2,96,179
From Cutch and Sinde	3,26,668	To Cutch and Sinde, consisting chiefly of Chinese goods	11,11,227
From Persian Gulf, grain, manufactures, piece-goods, treasure, horses	21,40,740	To the Persian Gulf, merchandise imported from other countries	19,48,205
From Arabian Gulf, merchandise, treasure, horses	9,44,292	To the Arabian Gulf, merchandise and European goods	3,64,731
From East coast of Africa	1,37,386	To the East coast of Africa	46,449
From Surat, grain, manufactures, piece-goods, treasure	10,30,336	To Surat, manufactures of other countries, treasure	19,07,032
From Gujrat, &c. piece-goods, treasure,	51,11,636	To Gujrat	39,53,572
The whole value of the imports for 1811-12, amounted to	16,970,626	The whole value of exports, for 1811-12, Merchandise	14,550,642
Treasure	3,737,084	Treasure	3,027,963
Horses	239,875	Horses	229,473
	20,947,585	Rupees	17,808,100
In pounds Sterling, these imports amount to	L.2,356,603	In pounds Sterling, these exports amount to	L.2,003,411

Inhabitants. Bombay is estimated to contain 220,000 inhabitants, of whom nearly three-fourths are Hindoos. The other fourth is composed of persons from almost every Asiatic nation. The number of Persees is estimated at 8000, there is nearly the same number of Mahometans, and there are 4000 Jews. The Portuguese are also to be found in considerable numbers. The Persees rank next to the Europeans, and carry on, many of them, extensive commercial transactions. They are the brokers and factors of Europeans, and have a concern in most of the foreign speculations of European mercantile houses. They are a rich, industrious, and active body of men, and contribute greatly to the prosperity of the settlement, and are treated by the government with great favour and indulgence. For the protection which they enjoy, they are exceedingly grateful, and openly express their conviction that they could not obtain the same advantages in any other part of the East. They are the descendants of the ancient Persians, who fled from the persecution of Shah Abbas in the sixteenth century, when he expelled the worshippers of fire from his dominions, and compelled them to seek an asylum in other countries. The Persees at Bombay appear to be quite domesticated in their new residence, in which they have purchased valuable properties. Besides the Persees, many considerable Portuguese, American, and Hindoo merchants reside at Bombay, who have acquired valuable property, and have the reputation of great integrity. There are likewise some Bonah merchants, or Mahometan Jews, who carry on a great trade with Guzzerat, and other places to the northward. All those different classes of inhabitants live happily together, and enjoy great prosperity under the mild and equitable rule of the British government.

Bombay.

Company's Naval Force.

The Company's naval force at Bombay consists of fifteen fighting vessels, besides armed boats, advice-boats, and other craft; and to man this navy, a regular establishment of officers and seamen is maintained. The western coast of India, from the shores of the Persian Gulf to Goa, is infested by swarms of pirates, who are distinguished, particularly those in the northerly tracks, by courage, address, and by habits of extreme ferocity. It is to protect the country trade against the depredations of these banditti, who have haunted those seas since the time of Alexander the Great, that the Company finds it necessary to maintain this naval force. Out of 104 marine covenanted servants of the Company, Bombay employs 93.

Army.

In 1811, the regular army of the Company at Bombay, including all descriptions of force, amounted to 20,988 men. The officers amounted in number to 549, and their pay and allowances to L. 171,450. In the same year, the civil servants of the Company on the Bombay establishment, amounted to 74, and their pay and allowances to L. 174,238.

Productions of the Island.

The Island of Bombay scarcely produces any articles of food, which have to be imported from various parts of India, and which are consequently much dearer here than in the other presidencies. Considerable quantities of rice and other grain are annually imported. The prices are continually fluctuating, from the state of the market, which is under the superintendence of the police. Potatoes, which, though recently introduced, are now produced in the greatest abundance in this quarter of India, are brought to the Bombay market from Gujrat, from which also is procured cheese, which is hard and ill flavoured. The only vegetable for which Bombay is celebrated is the onion, which is esteemed excellent. All other vegetables are scarce and dear.

The Bazar mutton is, when well fed, thought to be as good as the English. Kid is always good, and there is abundance of poultry, which is not good, however, unless it is fed on purpose. The fish are excellent, but those of a larger size are not plentiful. The prawns are uncommonly fine; and though the Island is too small to furnish great abundance of game, the red-legged partridge is not uncommon, and snipes are sometimes seen. The frogs here are large, and are sometimes eaten by the Chinese and Portuguese.

Court of Justice.

A court of justice is held at Bombay by a single Judge, with the title of Recorder. Its cognizance extends to all British subjects, and generally to all the inhabitants of Bombay. But it is allowed no cognizance over the land revenue. The Judge is directed, in all suits to which the natives are parties, to respect the usuages of the country, and in matters of inheritance or contract, the law acknowledged by the respective litigants is to be the rule of decision. Criminal offences are tried by a jury, consisting exclusively of British subjects. The law practitioners of this court are three barristers, and eight attornies.

Buildings.

The same passion for country-houses prevails at Bombay as at Madras. These houses are generally comfortable and elegant; and if they have not the splendid Grecian porticos of Calcutta and Madras, they seem to be better adapted to the climate, and have the advantage of the most beautiful and picturesque views; the Island of Bombay being broken by several beautiful hills, either covered with cocoanut tree groves, or villas of the inhabitants. The only English church in Bombay is in the fort. There are numbers of Portuguese and Armenian churches both within and without the walls, and there are three or four synagogues, with many temples and mosques.

Climate.

Bombay, from its situation, might be supposed to be healthy, but this is said not to be the case; the liver complaint being more fatal and frequent here than in any part of India. A land breeze sets in every evening, which is described as being peculiarly noxious, and is frequently followed by a fever, and by a loss of the use of the limbs. This breeze is mentioned by Lord Valentia, to have been chillingly cold at the time he visited Bombay. But he attributes its deleterious effects not merely to this cause, but to the noxious vapours with which it is tainted in its passage over the rank vegetation which springs up in the marshy parts of the bay immediately after the rains. Moderate living affords the best security for health; the extremes of intemperance and over abstemiousness being equally injurious.

Distance from other chief Cities.

The travelling distance from Bombay to Calcutta is 1300 miles; to Delhi 965; to Hyderabad 480; to Madras 770; to Poonah 98; to Seringapatam 620; and to Surat 177 miles.

History and Settlement.

Bombay was first settled by the Portuguese, to whom it was ceded in 1530; having been before dependent on one of the native chiefs. In 1661, it was ceded by the Crown of Portugal in full sovereignty to Charles II. by the treaty of marriage concluded with that power, when he espoused the Infanta. In order to take advantage of this acquisition, and to make it a profitable dependence on the Crown, a fleet was dispatched under the command of the Earl of Marlborough in 1662, to receive formal possession of the Island and its dependencies. Some doubts arising, however, as to the construction of the treaty, the Viceroy refused to surrender the Island, on which the Earl of Marlborough returned to Europe, after having left the troops, amounting to 500 men, in the Island, where most of them died. In 1664 a treaty was concluded by this nobleman's successor with the Viceroy of Goa, in which the former renounced all pretensions to the dependencies of Bombay, and accepted of the cession of the Island alone, which the English accordingly received in 1665; the troops who had survived the ravages of disease, only mustering 119 rank and file.

It was soon discovered that the revenues of the Island were not equal to the expence of retaining it, and that the East India Company were much injured by a contraband trade carried on by persons in the King's service. In consequence of these and other reasons, the sovereignty of the Island was, in 1668, transferred to the East India Company. The Company's servants made every exertion to place this new acquisition in a respectable state of defence, and to encourage settlers; and, in 1673, the Island of Bombay, from being almost a desert, had become the centre of the Company's trade, protected by fortifications with 100 pieces of cannon mounted, and a suit-

able garrison. In 1676 letters-patent were obtained from the King to establish a mint at Bombay, at which they were empowered to coin rupees, and other smaller pieces. At this period Bombay continued to be of very little importance, which partly proceeded from the vigorous government of Aurengzebe, and the rising power of the Mahrattas. These two powers contended for the possession of the Island of Kenery, which was seized on by the troops of both, the Bombay government not daring to oppose either party, but trembling for its own safety amid these formidable contentions. Bombay was soon afterwards, in consequence of the capture of Bantam by the Dutch, constituted an independent English settlement, and the seat of the English power in the East Indies.

In 1678, the Company, finding it necessary to retrench the expences of the establishment, proceeded to reduce the salaries and to lower the rank of their military officers, which produced general discontent, and, finally, a serious revolt, which threatened the most alarming consequences to the Company's affairs. This insurrection was headed by Captain Richard Reigwin, Commander of the Garrison, who seized the Governor and such members of the council as still adhered to him, and having assembled the troops and militia, annulled the authority of the Company by proclamation, requiring the inhabitants to renounce obedience to their authority, and to take the oaths of allegiance to the King. The whole inhabitants and all the troops immediately complied with the terms of this proclamation; and all the exertions of the Governor of Surat to persuade the revolters to return to their duty were in vain. The mutiny was at length quelled by the prudence of Sir Thomas Grantham, who arrived from Surat with a commission from the King, and had a conference with Reigwin, in the course of which the latter agreed to deliver up the fort, on condition of receiving a free pardon for himself and his associates.

Since this period, the settlement of the English East India Company at Bombay, has been frequently in a very precarious condition, sometimes from the unhealthiness of the climate, and, at other times, from the jealousy of the native powers. But, after the power of the Company became more firmly rooted in India, it has continued gradually increasing in wealth and consequence, and may now be accounted one of the most important and durable possessions of the British in India.

The Government of Bombay and its dependencies, is by law vested in a Governor and three Counsellors, who are placed under the control of the supreme government of Bengal, and are in all cases to obey such orders as they may receive, provided they have no different instructions in their possession from the Court of Directors, of which they are bound to send immediate notice to the Bengal Government. The Court of Directors appoint the Governor and members of the Council, and likewise the Commander in Chief of the forces, who is not officially a member of the Council, but may receive such an appointment from the Directors, and, in that case, he takes precedence of all the other members.

It is difficult to fix with precision the extent of the territories included within the Presidency of Bombay, as some districts belonging to the native powers are intermingled with them. On a general estimate, however, they may be calculated to comprehend 10,000 square miles, and to contain a population exceeding altogether two millions and a half, which may be supposed to consist of one Mahometan to fifteen Hindoos. Of the Persees no exact estimate has ever been made.—See Milburn's *Oriental Commerce. Voyages and Travels of* Lord Valentia. Hamilton's *East India Gazetteer.* (o.)

BORDA (JOHN CHARLES), a Mathematician and Nautical Astronomer, celebrated for his improvements in the theory of Hydraulics and Pneumatics, and in the construction of instruments for observation. He was born at Drax, the 4th of May 1733, and was originally destined for the bar, but abandoned the pursuit of the law in favour of a military life, which he considered as better calculated to afford him opportunities for the cultivation of his mathematical talents, and, for the application of the results of his studies to practice. His acquirements in science had very early attracted the attention of D'Alembert, who predicted his future eminence, and warmly recommended his turning his thoughts to the occupation of a place in the Academy. He obtained a commission in the Light Cavalry, and was appointed Teacher of Mathematics to the corps; and, in 1756, he presented to the Academy of Sciences (A.) *A Memoir on the Paths of Bombs,* which was ordered to be printed in the collection of the *Savans Etrangers,* but which has not excited much attention. He was elected in the same year a member of the Academy; and in the next he was present at the battle of Hastinbeck, in the capacity of Aide-de-Camp to the celebrated General Maillebois, to whom he looked up as a great master in the art of War.

He was afterwards admitted into the corps of Engineers, without the usual form of examination into his qualifications; and, being stationed at a seaport, the occurrences of the place naturally directed his attention anew to the phenomena of the resistance of fluids. He published, in 1763, a detailed memoir on this subject (B. *Mém. Ac. Par.* 1763, p. 358), in which he relates a variety of experiments, showing, that the resistance of the air is actually proportional to the square of the velocity, as had commonly been supposed from theoretical considerations. He also determines, by other experiments, the magnitude of the resistance to the motion of a sphere, and proves, that nothing can be more erroneous than the supposition, that the resistance to an oblique surface decreases as the square of the sine of the angle of incidence. He also finds, that the resistance to the motion of a cube, in the directions of the diagonal of its base and of one of the sides, are as 21 to 16, while the calculations of former theorists had made the resistance greatest in the direction of the side.

In 1766, he published an Essay on the discharge of fluids through the orifices of vessels (C. *Mém. Ac. Par.* 1766, p. 579), in which he first states the objections to considering the different strata of a fluid as descending in all cases very nearly in parallel directions; he examines the contraction of the jet after its escape from the orifice, and determines some

Borda.

of the effects of abrupt changes in the velocity of the fluid passing through pipes or apertures of different forms.

He contributed, in 1767, to the publications of the Academy, an important *Memoir on Water Wheels* (D. p. 270), which has escaped the notice of his able Biographer M. Lacroix. He observes, in this paper, that the simple hypothesis of a resistance varying as the square of the velocity, which is so near the truth in common cases, where a number of particles, proportional to the velocity, strikes, in a given time, upon a small exposed surface with a force also protional to the velocity, is totally inapplicable to the action of a confined stream upon the floatboards of a wheel, since, in this instance, the number of particles concerned cannot vary materially with the velocity, the whole stream being supposed to operate in all cases upon the successive floatboards; so that the analogy would require us to suppose the force in this case nearly proportional to the simple relative velocity; a conclusion which agrees remarkably well with the experiments of some practical authors.

The same volume contains a continuation of M. Borda's researches relating to the resistance of oblique surfaces (E. *Mém. Ac. Par.* 1767, p. 495), with a statement of experiments still more conclusively confuting the received hypothesis, respecting oblique impulse, than his former investigations had done. We also find in it an Essay on isoperimetrical problems (F. p. 551), in which it is shown, that Euler's method of treating them, which had been in great measure abandoned by its equally profound and candid author, in favour of the more general and more elegant calculations of Lagrange, was still capable of affording all the results that had been derived from the method of variations; and he even pointed out some deficiencies in the first Memoir of Lagrange, which contained the detail of his ingenious invention. These investigations of M. Borda afford collateral evidence of the strict truth of the demonstrations of both his great predecessors; and though they have been little employed by later Mathematicians, yet it must be admitted to be of some importance, in enabling us to appreciate the value of a new mode of calculation, to determine whether its results are or are not such, as might be obtained, with almost equal convenience, by methods before in use.

His memoir, inserted in the collection of the Academy for 1768 (G. *Mém. Ac. Par.* 1738, p. 418), is devoted exclusively to the theory of pumps; and he considers especially the effect of the passage of the fluid through valves and other contracted parts, in diminishing the quantity of the discharge. His results are derived from the principle of the preservation of the living force or energy of a system of bodies, throughout all the vicissitudes of its motions, which had before been employed with success by Daniel Bernoulli in problems of a similar nature; but it was not until the experiments of Buat had afforded sufficient grounds for the determination of the friction of fluids, that cases of this kind could be submitted to exact calculation.

In his Essay on the curve described by cannonballs, published among the Memoirs for 1769 (H. *Mém. Ac. Par.* 1769, p. 247), he has greatly simplified the practical theory of projectiles, which had been treated in a satisfactory, though very general manner by John Bernoulli, and had been reduced into a much more convenient form by Euler. M. Borda has substituted some approximate expressions for the true value of the density of the air, and has thus been enabled to integrate equations which, in their more strictly correct form, had resisted the powers of Euler himself; and he has justified the adoption of the formulas thus obtained by a comparison with experiment.

Borda.

In the meantime his talents were very actively employed in the naval service of his country, which he entered in 1767, by the nomination of M. Praslin. The time-keepers of Le Roy and Berthoud were beginning to rival those of the English artists, and the French Government ordered several vessels to be fitted out for cruises, in order to examine the accuracy of these time-keepers. M. Borda was appointed a Lieutenant on board of the *Flore*, and acted jointly with M. Pingré as a delegate of the Academy of Sciences for the purposes of the expedition. The voyage occupied about a year, and extended to the Canaries, the West Indies, Newfoundland, Iceland, and Denmark. M. Borda had a considerable share in the account which was published of the observations; and the formula, which he has here given, for the correction of the effects of refraction and parallax, is considered as equally elegant and convenient. He also presented to the Academy a separate Memoir on the results of the expedition. (I. *Voyage pour éprouver les montres de Leroy*. 4. *Paris*. (K. *Mém. Ac. Par.* 1773, p. 258.) After an interval of six weeks, these watches were found capable of determining the longitude within about fifteen minutes of the truth.

In order to supply some deficiencies in the observations made at the Canaries, Borda was sent out a second time, with the *Boussole* and the *Espiegle*, and he published, after his return, (L.) a very correct and highly finished map of these islands. He was soon afterwards promoted to the rank of Captain, and served under the Count d'Estaing as a Major-General, an appointment nearly similar to that of our Captains of the fleet. In this capacity, he observed the inconvenience of too great a variety in the sizes of the vessels constituting a fleet, and proposed to abolish the class of 50 and of 64 gun ships, as too small for the line of battle, and to build ships of three rates only, the lowest carrying 74 guns, so that a smaller quantity of stores should require to be kept ready for use in the dock-yards, than when ships of more various dimensions were to be refitted. In 1780, he had the command of the *Guerrier*, and in 1781 of the *Solitaire*, which was taken, after a gallant resistance, by an English squadron. He was thus compelled to pay a visit to Great Britain, but was immediately set at liberty upon his parole.

He proposed to the Academy in this year (M. *Mém. Ac. Par.* 1781), a mode of regulating elections, which was adopted by that body. Its peculiarity consisted in having the names of the candidates arranged by each voter in a certain order, and collecting the numbers expressing the degrees of preference into separate results, so that the simple majority of voters did not necessarily establish the

claim of any individual, if he was placed very low in the list by any considerable number of those who voted against him. But, it must be allowed, that this mode of election is by no means wholly unobjectionable.

M. Borda appears to have rendered an essential service to the cultivators of Practical Astronomy, by the introduction and improvement of the repeating circle, although this instrument has probably been less employed in Great Britain than elsewhere, on account of the greater perfection of those which were previously in common use. It had been suggested by Mayer, in 1767, that a circle with two moveable sights, would enable us to observe a given angle a great number of times in succession, and to add together the results, without any error in reading them off, and thus to obtain a degree of precision equal to that of much larger and better instruments of a different construction; but the proposal had been little noticed until ten years afterwards, when Borda pursued the path pointed out by Mayer, and trained Lenoir, then a young and unlicensed artist, to the execution of the improved instrument, notwithstanding the opposition of the rival opticians, and the want of encouragement from the opulent public. He published, in 1787 (N.) his *Description and Use of the Reflecting Circle, with different Methods for Calculating the Principal Observations of Nautical Astronomy*; but the officers of the French navy, for whom this work was intended, appear to have profited but little by his instructions. His instrument was, however, much employed in the operations for determining the length of the terrestrial meridian, and he himself took charge of the experiments required for ascertaining the length of the pendulum, and for the comparison of the different standards with each other. He invented some very ingenious methods of overcoming the difficulties which present themselves in the pursuit of these objects; but he was interrupted in his researches by the horrors of the Revolution, nor did he live to see the whole of the operations completed. He endeavoured, also, to promote the introduction of the new mode of subdividing the circle, by the laborious computation of *Tables of Logarithms* (O. 4to, *Par.* 1801), adapted to decimal parts of the quadrant,—a work in which he was assisted by M. Delambre. From the increasing indisposition of M. Callet, who had undertaken to correct the proofs of these tables, some very material errors had been committed in the first half of the tables, and M. Borda thought it necessary to cancel a great number of the pages; and in order to meet the expence thus entailed on him, he was obliged to dispose of an estate which he had lately acquired in his native place. He was also engaged, towards the close of his life, in the measurement of the force of magnetism, and in the calculation of astronomical refraction. His health had been threatened for several successive winters, and he died the 10th of March 1799.

In his manners he was animated and unaffected: he avoided those who sought his acquaintance merely from the vanity of being intimate with a man of talents, whatever pretensions to importance they might derive from their casual relations to general society. He never married; and he was too much absorbed in the pursuit of science, to associate with a very extensive circle even of private friends. Though not a man of learning, he was not deficient in literary taste, and he was, in particular, a passionate admirer of Homer. He seems to have possessed a considerable share of that natural tact and sagacity, which was so remarkable in Newton, and which we also discover in the works of Daniel Bernoulli; enabling them, like a sort of instinct, to elude the insurmountable difficulties with which direct investigations are often encumbered; while Euler, on the contrary, as M. Lacroix most truly observes, seems to have taken pleasure in searching for matter which would give scope to his analytical ingenuity, although wholly foreign to the physical investigations which had first led him to the difficulties in question. It would have been fortunate for the progress of science, if some of the most celebrated of M. Borda's countrymen had profited by his example, in studying to attain that unostentatious simplicity which is the last result of the highest cultivation. (Lacroix in *Rapport des Travaux de la Société Philomathique.* Vol. IV. 8. Par. 1800.) (AL.)

BORING, generally speaking, is the Art of perforating a solid body. In the present article, we propose to give some account of the Boring of CANNON, of CYLINDERS, of MUSKETS, of PORTLAND STONE, of ROCKS, and of WOODEN PIPES.

Cannon.

1. Boring of CANNON is performed by placing the cannon on an axis which is turned by a very strong power, whilst a steel cutter, in form of a drill, is pressed against the metal, and excavates the cylindrical cavity which is required. Boring may be considered as a branch of the art of turning, which, in general, is the formation of cones, cylinders, and other figures that have an axis, by making a straight line or curve revolve round the axis on which the material is fixed, or by making the material revolve whilst the generating line remains at rest. In turning bodies of no great degree of hardness, and where it is required to take off only a small portion of the surface at once, a small power is sufficient to put the turning machine in motion; and the longer the edge of the cutter which is applied to the metal is, and the harder the metal, the greater force is required to turn the machine.

Cannon, at first, were frequently made of bars of malleable iron, placed longitudinally, and these bars covered with iron hoops, the whole welded or brazed together. Ordnance of this construction was not sufficiently strong to resist the explosion of the powder, and did not admit of the cylindrical cavity being formed with much accuracy. Its use was, therefore, gradually laid aside, and guns of cast metal were employed. And before the casting of cannon became general, guns of cast metal were reserved for the most important situations; thus the ships of the Admiral and Vice-Admiral alone had cast-metal cannon, the other ships of war being armed with wrought-iron guns only.

Copper, without mixture, has been employed to cast guns, as appears from two large cannon made in the time of Henry VIII. and bearing his name, in

Cannon.

the armoury of the Tower of London. But the only two materials now used for cannon are bronze, which is a mixture of copper and tin, and cast-iron. In modern times, the use of cast-iron cannon has become more general, as that metal has the advantage of not being softened by the heat of the inflammation of the powder; whereas brass guns, when fired many times in rapid succession, become heated so nearly to the melting temperature of the metal, that the muzzle of the gun droops.

The first cannon made of cast-metal were cast hollow, with a cavity as nearly cylindrical as could be executed by casting. The surface of this cavity was then smoothed on a boring machine by steel cutters set in a copper head, and disposed so as to describe a cylinder terminated by a half spheroid. These cutters (in French *alézoirs*, and the operation *alézer*) are represented in the French *Encyclopédie*—Planches—*Fonte*. This method of making guns has been long laid aside on account of the holes and inequalities in the cavity thus formed, and the difficulty of casting the cavity so as that its axis shall coincide with the axis of the piece. Cannon are now always cast solid, and the cylindrical cavity is formed by boring in this solid mass.

The power employed for boring cannon ought to be in proportion to the hardness of the metal of which they are composed, and to the size of the pieces. For the boring of guns of brass, as it is called, that is, a metal composed of ten parts of copper, one of tin, and two of brass, or of these metals in other proportions, a metal softer and more easily bored than cast-iron, horses are frequently employed as a moving power; but the strong moving powers of water or steam must be had recourse to for boring large guns of cast iron, which is the material used for making the largest guns now in use, and is also the hardest substance used in their manufacture. Indeed, some kinds of cast-iron are too hard to admit the action of the borer; and for the making of guns it is necessary to melt pig-iron of different qualities together, in order to have a metal that shall possess no more than the required degree of hardness.

The quality of pig-iron is known by the appearance of its surface, but more decisively by the appearance which its fracture presents. To obtain this fracture, a man takes one end of a pig in each hand, and lifting it as high above his head as he can, throws it with force, so that the middle of the pig shall fall across another pig placed on the ground; in this way the pig thrown down is broken. Soft or grey pig-iron, which is the most valuable, breaks with difficulty, and the surface of its fracture is of a grey colour, composed of pretty large crystalline grains. Hard or white pig-iron breaks easily; the surface of the fracture is white, and not sensibly granulated, the grains that compose it being small. The pig iron here spoken of is that smelted by the coak of pit-coal. Pig-iron smelted with charcoal of wood has a fracture of a different appearance, sometimes lamellar, like the fracture of a metallic bismuth. Formerly guns used to be cast from the blast-furnace; that is to say, immediately from the ironstone. This was attended with uncertainty in respect to the nature of the metal; for the nature of the metal given by the blast-furnace varies frequently and suddenly, from causes either unknown, or not under the command of the iron-master. For this reason guns are no longer cast from the blast-furnace, but pig-iron already formed is taken, of such qualities, and in such proportions, as to form a metal neither too soft nor too brittle and hard for guns. The different kinds of pig-iron thus selected are melted together in a furnace called, in iron manufactories, an *air-furnace*, and by some writers a *reverberatory furnace*, by the flame of pit-coal; the flame being impelled by a strong current of air produced by the rarefaction of the air in a chimney of thirty or forty feet in height, the column of the atmosphere of which the air in the chimney makes a part, being lighter than the unrarified columns of the atmosphere next it, its equilibrium with these columns is destroyed; the neighbouring columns therefore rush through the grate of the furnace, which is the only aperture by which they can attain the bottom of the rarified column, and they carry the flame of the coal against the pig-iron, which is thereby brought into fusion. From the iron thus fused only one large gun is cast at one time, the furnace not being capable of melting more metal than is requisite for that purpose.

The gun is cast with two appendages, which are to come off before it is finished and ready for use: The one is a square piece beyond the cascabel, for fixing the gun so as to revolve with the axis of the boring-mill; the other is the head.

The head in cast-iron cannon is a mass of cast-iron two or three feet long, somewhat bell-shaped. It is a prolongation of the mass of metal beyond the muzzle ring, and in the position in which the gun is cast, the head is the top of the whole mass, the square beyond the cascabel being the lowest part. After the metal has cooled, the upper surface of the head is cavernous, as is the case with the surface that is uppermost during the casting and cooling of any large body of cast iron: the sides of the cavities in the head are frequently formed of cast iron crystallized in a fern-leaf form. The intention of the head is to prevent these cavities, which are formed most abundantly at the upper surface of the cooling cast iron, from forming in the gun itself. But, notwithstanding the precaution of casting the gun with a large head, and of mixing proper kinds of cast iron in the air-furnace, it frequently happens that small cavities occur in the guns.

Vertical boring.

The gun with its head being cast and allowed to cool, is taken to the boring-mill, where the head is to be taken off, the cylindrical cavity or bore is to be formed, and the outside of the gun is to be turned. Formerly the boring of guns was done in an upright position; the gun being placed above the boring-bar was fixed in a frame sliding vertically in grooves; this frame was suspended on each side by a block and tackle, and the end of each of the two ropes was wound round a windlass. By turning these windlasses, the gun might be raised or lowered, and by this means might be allowed either to press with its whole weight on the boring-bit, or

Cannon.

with any part of its whole weight. A figure of this apparatus may be seen in the French *Encyclopédie*—Planches—*Fonte*. Another vertical apparatus for boring cannon is represented in Rinman, *Bergwerks Lexicon*, Stockholm, 1789, Tab. IV.

Horizontal boring.

The practice which has long been followed in this country, is to place the gun horizontally in the boring-mill; and it is fixed on the axis of the mill by means of the square piece at the cascabel.

In a boring-mill constructed by Smeaton, one gun is placed on the horizontal axis of the water-wheel itself, and, consequently, revolves with the same velocity. On this same axis is a toothed wheel with 78 teeth, which works two wheels, one placed on each side of it, and each having 29 teeth; on the axis of each of these a gun is placed; their power is $\frac{10}{27}$th of the power of the centre wheel. (See Smeaton's *Reports*, Vol. I.) On the axis where the power is least, smaller sized guns are bored; on the axis of the greatest power, the large guns are bored. A crane moveable on a vertical axis, with a sweep that extends over all the carriages, with a tackle hanging from its beam, and wrought by a windlass, serves to place the gun on the carriage where it is to be bored, or to remove it from one carriage to another if required; and afterwards, when the gun is bored and turned, the crane serves to remove the gun from the boring-mill.

The gun, when placed on the machine, has the square at the cascabel fixed in a square iron box (G, Plate XXXVI. fig. 5.), on the axis. This box has a screw passing through each of its sides, and by the operation of these screws, the square of the gun is adjusted, centered, and fixed; the chace of the gun is also fixed in a collar N, in which it is to revolve. (The collar in the figure is represented too near the muzzle ring.)

The axis on which each gun is fixed, may be set in gear or put in connection with the revolving axis of the machine, so as to move round with it, or taken out of gear, so as to remain at rest, although the other parts of the machine continue in movement. There are various methods of doing this; one is given by Smeaton in the work above cited. After the gun is fixed on the axis, and before beginning the operation of boring, the head, which has been described above, is cut off near the muzzle ring: for this purpose, the gun is set in gear so as to revolve on its axis with the moving power; and a bar of steel, in shape and size like the coulter of a plough, is applied at right angles to the axis of the gun; the narrow side of this bar is sharpened to a cutting edge, so that it has the form of one tooth of a very large saw; and this cutting edge is opposed to the direction of the revolving motion of the gun, and held strongly on to the gun by a screw pressing on the bar; the cutter takes off an angular portion at right angles to the axis, till the cylindrical part connecting the head with the gun is so much diminished, that the head is made to fall off by the blow of a hammer applied on it. In brass guns, cast with a core, the head was sawed off by hand with a blade of steel, whose edge was toothed as a saw, and the sides toothed as files. See the French *Encyclopédie*—Planches—*Fonte*.

A great degree of heat is generated by the violent friction of the steel-cutter on the cast-iron, during the operation of cutting off the heads of guns. The quantity of this heat has been estimated by Rumford in one of his *Essays on Heat*.

After the head is taken off, the workmen proceed to bore the gun. This is done by exposing the revolving gun to the action of a steel-cutter, fixed on the end of a bar, which bar is placed on a carriage, and impelled continually towards the gun. The operation of boring is done on the same axis on which the head was cut off, if the power be sufficient; if not, the gun is removed, by means of the crane, to an axis, where it is made to revolve by a stronger power.

The boring-bar is fixed on a carriage, sliding in iron grooves, which are truest when made triangular. The carriage, which, in the apparatus represented at fig. 5. consists merely of the bar on which the rack is, is pressed forward by a pinion P, whose gudgeons are on a fixed frame BB: this pinion works into a rack R. The axis of the pinion has mortise holes in it, through which one end of a lever L is passed; the other end of this lever is loaded with a weight W, which causes the pinion to propel the carriage and boring-bar towards the gun. In many boring-machines there are two pinions on the same axis, acting on two racks; in others, the carriage is propelled by two upright levers, on the end of one of which acts a weight, hanging from a rope, that passes over a pulley; the lower end of the upper lever acts on the upper end of the lower, whilst the lower extremity of the lower lever presses forward the carriage. This method, which is free from any inequalities that may arise from the teeth of the rack, is figured by Smeaton in his *Reports*, Vol. I. p. 396. Another method of propelling the carriage of the boring-bar, is by a screw acting on the end of the carriage. See Meyer in the *Transactions of the Acad. of Stockholm*, 1782, Tab. IX.

The boring-bar is a strong piece of wrought iron, of less diameter than the intended calibre of the piece, in order that the boring dust or shavings, detached by the cutter, may be got out. The boring-bar is increased in diameter near the end, for some inches; see fig. 6. B; in this part there is a superficial groove for receiving the sides of the steel-cutter or bit, which is to be firmly fixed in the bar. The bit T, fig. 6. is made from a rectangular piece of a steel bar, in which the two diagonally opposite upper angles are cut off obliquely, so as to form two cutting edges like an obtuse angled drill; the side of the rectangle, opposite to the point of the drill, is hollowed out in the form of a pigeon hole; this hollow fits into, and embraces, the solid part of the boring-bar, whilst the sides of the pigeon hole fit into the grooves of the bar. The point of this obtuse angled bit is pressed against the revolving metal of the gun, by the force which propels the boring-bar; and the edges coming in contact with the revolving metal, a conical cavity is produced; and by taking off successively a multitude of similar shells or shavings, the cylindrical bore, with a coni-

cal termination, is formed. The diameter of the pointed bit first used, must be less than the intended calibre of the piece, as the boring is to be repeated again at least once, in order to make the internal cylindrical surface as smooth as possible, by taking off any inequalities that have been left by the first cutter. In finishing the bore, a cross bit may be employed. It is a rectangular piece of steel, ground to a cutting edge at each end, and put through a hole in the boring-bar, in which it is fixed. The edges of this cutter, in revolving, describe a cylindrical surface. After the cylindrical surface of the bore is made sufficiently true, and of the required calibre, a bit without a point, and rounded off to the desired curve, is used to form the bottom of the chamber.

Some recommend, that the boring bit for cast-iron should have its cutting edges brought to an acute angle, by being filed hollow; but in this case the two edges cannot be brought into one point; but the obtuse angled edge formed by the thickness of the metal of the bit, joins the two cutting edges crossways; and forces itself forwards by being near the centre, requiring, however, a considerable pressure. These hollow edged bits are not so well adapted to continuance of grinding, as the plain ones, but they make amends by their much less frequently wanting sharpening. It does not appear, however, that these hollow edged bits have been found advantageous in gun boring.

The howitzer appears to have had its origin in Germany. This piece of ordnance, the mortar, and the carronade, in all of which the diameter of the chamber for the powder, is smaller than the diameter of the rest of the bore, are first bored all through, nearly to the intended calibre of the chamber, and then that part of the bore that requires it is enlarged.

The cutters, in gun boring, become magnetic, in consequence of being continually rubbed in the same direction, so that the boring dust is seen adhering and hanging from their edges, when they are withdrawn from the gun.

It is required, that the bore shall be a cylindrical cavity, whose axis coincides with the axis of the gun; for this purpose, care must be taken to place the axis of the boring-bar, and that of the gun, both in one horizontal line, and it is requisite that these two lines continue in this position during the whole operation of boring. The centering of the boring-bar for this purpose, requires to be done by an experienced workman, and an accurately constructed boring-machine is necessary for the continuance of the right position.

Whilst on the axis of the mill, the gun has a smooth outer surface given it by turning tools, which are applied in the way usual in turning metals; a wooden guage, or cut-out profile, of the gun, with its intended mouldings, being applied to know when the turning has been continued to a proper depth. When this is done, the gun is taken out of the boring-mill,—the square, at the cascabel, is cut off by the chisel,—and the trunions, and other parts which are not susceptible of being turned, are dressed by the chisel. The cyphers and arms which had been cast on the gun, are finished by the chisel.

A cannon is said to be the *ultima ratio regum*,—the last argument that governments have recourse to; and even this severe kind of argument has sometimes been embellished. Amongst ornamented cannon, the brass three-pounder in the Tower, brought from Malta, is a masterpiece: it is covered with carving in a good taste, by a sculptor of Rome.

The touch-hole is drilled by stock and bit, or by drill and bow; the drill being propelled by a lever placed on a carriage, moveable on wheels. A figure of this apparatus is given in the *Encyclopédie*—Planches—*Fonte*. Another apparatus for this purpose is figured in Rinman, *Bergwerks Lexicon*, Tab. XIV. fig. 9, 10. See also Monge, *Description de l'Art de Fabriquer les Canons*, in 4to, Paris, 1794. This work was published by order of the revolutionary government, and distributed to the Iron-masters and Founders, in different parts of France, for their instruction. It contains, amongst others, figures and descriptions of two kinds of vertical boring machines,—of three kinds of horizontal boring machines,—of a machine for turning the trunions,—of two different machines for boring the touch-hole,—of a machine for putting copper boshes in brass guns,—and of various instruments for examining and proving guns.

Before the gun is sent off, it is examined and proved in various ways. And first to ascertain whether the bore is free from holes, an instrument is employed, consisting of several elastic steel prongs disposed in a circle, and with their sharp points turned outwards; this being fixed on a hole, is introduced into the bore of the gun, and drawn to and fro; the points of the prongs press against the sides of the bore, and the presence of a hole is known by one of the prongs getting into the hole, and preventing the instrument from being drawn out directly, unless by the use of a ring that is pushed over the prongs to unbend them.

There is another instrument, composed of a board twice as long as the bore of the piece; along the middle is a groove proceeding in a straight line. In this groove a button is moveable, and on the button as a centre are fixed two radii or arms; the two ends of these arms within the gun describe a line on the inside of the bore when the button is pushed inwards, whilst the extremities of the arms on the outside describe two lines similar on the part of the board that is situate without the bore: in this way the outline of a longitudinal section of the bore is described, and its sinuosities or deviation from the axis are rendered sensible. This instrument is seldom used: it requires to be made by a workman skilled in the construction of mathematical instruments, or in watchmaking.

A lighted wax-candle is introduced into the gun for the purpose of seeing any defects there may be in the box, or the light of the sun is reflected into the box by a mirror. The strength of the gun is proved by firing it with a large charge of powder; and by forcing water into the bore by a powerful forcing pump, the touch-hole being stopped, and the

inders. mouth of the piece, so that water forced in by the mouth cannot return that way.

2. Boring of cylinders for steam-engines, and for blowing machines, and the boring of the working barrels of large pumps, and other hollow cylinders in which pistons are to work, is performed by making the steel-cutters describe a cylindrical surface on the inside of the cylinder, whilst the cylinder remains fixed. The first steam-engine cylinders in this country were of brass, or of a mixture of copper and tin; this was the case with the cylinder of the steam-engine, erected in the early part of the eighteenth century, for lifting water from the colliery of Elphinston in Stirlingshire. But, since that time, the construction of steam-engines, and the manufactory of cast-iron, have been greatly improved; the uses of both have been much extended; and cast-iron has now for a long time been the only material employed in making cylinders for steam-engines, and other large cylinders in which pistons are to move.

In the boring of cylinders, the steel-cutters are fixed in a cutter-head, which revolves with the boring bar at the same time that it is impelled along the interior surface of the cylinder by a rack, with a pinion moved by a lever and weight as already described. The axis or boring-bar, employed for cylinders, is a hollow tube of cast-iron, and has a groove passing through it: the length of this groove is proportioned to the length of the cylinder to be bored. The cutter-head consists of two cast-iron rings, the first of which is accurately fitted on the boring-bar, which is turned truly cylindrical, so that this ring may slide along the boring-bar; the second ring is fixed round the first by wedges; its diameter is proportioned to the diameter of the cylinder to be bored; on its circumference are eight notches to receive the steel-cutters, which are fixed in by wedges. The first ring is fixed on the boring-bar, so as to make the whole cutter-head move round with the boring-bar, by means of two small iron bars, which go through notches in the first ring, and pass through the groove of the boring-bar. These small bars have each a round hole in the part which passes through the geometrical axis of the boring-bar; through these round holes there passes a bolt, which forms the end of the rack; a key is put through the end of the bolt, which prevents the rack from being drawn back by the lever and weight; and by this means, the rack impelled by the lever and weight pushes forward the cutter-head, which is at the same time revolving with the boring-bar: the connection of the rack and cutter-head being round, and in the axis of motion, the rack is thereby free from the circular motion of the cutter-head. This mode of constructing the boring-bar was invented in the works of Mr Wilkinson, at the time when accurately bored cylinders came to be required in consequence of Mr Watt's improvements in the steam-engine. In the machines about to be mentioned, the cutters are made to advance by a train of wheels deriving their motion from the power that turns the boring-bar.

lingsley's chine. An apparatus of great merit was contrived and described in 1802 by Mr Billingsley, Engineer of the Bowling Iron-works, near Bradford. (See *Repertory of Arts*, second series, Vol. II. p. 322.) In this method, the cylinder is placed with its axis perpendicular to the horizon. The object of which is, first, that the boring-dust may fall out, and not remain on one side of the cylinder, wearing the cutters; so that in this way the cylinder may be bored through without changing the cutters, by which means a more regular bore is obtained. Secondly, That the cylinder may not deviate from its cylindrical form by its own weight, a deviation which is found to take place in large and slender cylinders when laid on their side; the vertical diameter being then less than the horizontal diameter. A similar loss of shape may happen to cylinders that are improperly wedged and strapped down for the purpose of being bored. In this method, the cylinder is fixed with screws by the flanges, where it is most capable of resistance, and the screws are disposed so as to press the cylinder equally all round. Thirdly, That the operation may be sooner completed, which is effected in consequence of less time being employed to fix the cylinders in this method. In the usual mode of propelling the cutters described above, the attendance of a man is necessary to change the position of the bar on the axis of the pinion, and to raise the weight. This attendance is dispensed with in the machine under consideration, the mechanism for propelling the cutters being as follows. A leather strap passing over the boring-bar, communicates the revolving motion of the boring-bar to a wheel, which communicates a slow motion by a train of wheels and pinions to an axis, bearing two pinions which work into two racks; these racks push the boring-head and cutters slowly forward on the boring-bar, at the same time that the boring-head is revolving with the boring-bar. The velocity with which it is required that the cutters shall advance, varies as the diameter of the cylinder varies, the moving power remaining the same. And by altering the train of wheel-work, the cutters may be made to advance with any velocity required.

Murray's. Figs. 1, 2, 3, and 4, Plate XXXVI., are different views of the machine for boring cylinders, invented by Mr Murray of Leeds. Fig. 1. is an elevation, and fig. 2. a plan of the machine. W fig. 1. and 2. is the spur wheel, deriving its motion from water or steam, and communicating a revolving motion to the boring-bar. The toothed wheel A fig. 1. moves round with the boring-bar B on which it is fixed; it gives motion through the wheels D and E, and to the screw S, whose threads act on the two racks, which racks are fixed to the cutter-head H, and revolve with it. The velocity with which the cutter-head is impelled along the cylinder, depends upon the number of threads of the screw in a given length, and on the proportions of the wheels A, C, D, and E to each other. By varying the velocity of the screw, the cutter-head may be made to move in either direction, up or down the cylinder. F is a pinion, whose axis ends in a square, which may be wrought by a key, so as to bring the cutter-head out of the cylinder, or push it home by the hand when that is required.

The cylinder is fixed in its bed by screws passing through two iron rings, as represented at fig. 4.; in

Cylinders ‖ Muskets.

this way the cylinder is equally pressed in the different parts of its circumference.

Fig. 3. is a transverse elevation of the collar in which the end of the bar at A, fig. 1. turns; X is the gudgeon in which the spindle X, fig. 1. turns. In fig. 3. are also seen the two apertures through which the two racks pass.

By this machine also, the flanges are turned truly plane, so that the lid of the cylinder may fit on exactly.

Murdoch's Patent.

The patent granted in 1799 to Mr Murdoch, Engineer, Redruth, for new methods of constructing steam-engines (See *Repertory of Arts*, Vol. XIII.), contains some articles relative to boring. He employs an endless screw, turned by the moving power; this screw works into a toothed wheel, whose axis carries the cutter-head; and this method, he says, produces a more smooth and steady motion than the usual mode of fixing the boring-bar immediately on the axis turned by the moving power.

Another article in Mr Murdoch's patent that relates to boring, is his method of forming the cylinder and steam case. He casts them of one solid piece, and then bores a cylindrical interstice, by means of a boring tool, made of a hollow cylinder of iron, with steel-cutters fixed to its edge, and acting like a trepan.

The chambers of brass pumps, whose diameter does not exceed a few inches, are fixed within iron rings, by means of screws, in the manner described above when speaking of Mr Murray's apparatus. The rings are made accurately cylindrical by turning, as is also the boring-bar. The boring-bar has four cross arms on its outer extremity, to one of which a handle is fixed, whereby a workman makes the boring-bar revolve. The cutter-head is made to advance along the boring-bar by a screw.

Muskets.

3. Boring the barrels of muskets and other small arms. Rectangular pieces of iron are forged of a proper length and breadth; these are heated in the fire, and the two long edges, which had been previously thinned off, are welded together on a mandril. The barrel thus formed, is fixed by a screw on a carriage that moves in iron grooves; this carriage is propelled towards the boring-bar by a rope which passes over pullies, and has a weight hanging from its end. The boring-bar is turned by the power of the same mill that turns the grinding-stones for polishing the outside of the barrels. (See *Encyclopédie—*Planches*—Arquebusier;* and Rozier, *Introduction aux Observations sur la Physique*, Tom. I. p. 157.) Water is thrown on the barrels whilst boring from a trough placed underneath. After the barrel is bored, the interior surface of the bore is polished by the action of the boring-bar. The barrel is tried during the operation, by an iron gauge of an inch and a half in length, and of a diameter equal to the intended diameter of the musket. When the barrel is bored, it is held to the light and looked through, and if it contains any flaw, the place of that flaw is marked on the outside with chalk, and the barrel is put on the mandril again, and the defective place heated and hammered; the workman also examines with a gauge, whether the barrel is crooked. When the bore has no flaws, the barrel then undergoes the operation of the grinding-mill, to the effect of polishing its exterior surface.

Muskets ‖ Portland Stone.

Rifled-barrels are put on a bench twelve feet long. The boring-bar is guided by a matrix or female-screw, whose spiral curve is similar to the spiral of the rifles intended to be made; the boring-bar being fixed to a male-screw, which passes through the female-screw, and fits it exactly. The female-screw is fixed to the bench, and has four threads and as many furrows; these threads, in general, return to the point of the circumference from which they set out, or make a revolution in the length of two feet. The male-screw, which fits into the female-screw, has at one end an iron bar attached to it, by which it is put in motion; at the other extremity is fixed the boring-bar, which passes through the barrel to be rifled; the boring-bar has a cutter fixed in it, which forms a spiral furrow in the barrel when the screw is turned by the handle. The number of spiral threads in rifle-barrels is from three to twelve. Sometimes the threads and furrows of the rifle-barrel are required to be in straight lines; in this case a straight lined matrix is used. In order that the threads may be placed at an equal number of degrees of the circumference from each other, the bench is furnished with a brass plate, divided in the same way as the plate of the machine for cutting the teeth of clock-wheels.

Portland Stone.

4. Boring of Portland stone, so as to form pipes. That kind of calcareous stone, called by Geologists oolite, which is quarried for building at Portland, Bath, in the neighbourhood of the city of Paris and other places, admits of being cut with an iron blade, with sand and water, acting as a saw. The more compact limestones and marbles are also cut in this way, but not so easily. The other kinds of stone that can be squared for building, namely sandstone and granite, do not yield to the saw, but are formed into the desired shape by the chisel and hammer. A modification of this mode of working Portland Stone, consists in forming it into pipes. The method of Sir George Wright, proposed in 1805, is as follows: A hole is drilled through the block of stone, in which a long iron bolt is inserted for the saw to work round as a centre; this bolt forms the axis of the cylinder which is to be taken out, and projects considerably beyond the block at both ends. Another hole is drilled in the intended circumference; into this the blade of the saw is introduced. The frame of the saw is so disposed, that when it is wrought to and fro, the blade is guided by means of the centre bolt so as to describe the intended cylindrical circumference. In this way a solid cylindrical core of stone is detached, and a cylindrical cavity or pipe left in the block. Or the saw may be made to describe a circle without drilling a hole in the centre, by drilling a hole in the circumference, and fixing on the surface of the stone two metallic concentric rings, so that the hole shall be included in the interstice between the rings. The saw is then introduced into the hole, and being worked, it cuts in the circular path formed by the interstice of the rings. See *Repertory of Arts*, second series, Vol. VIII.

Mr Murdoch's method, for which he obtained a

Portland Stone ‖ Rocks.

patent in 1810, is preferable in practice to the above mentioned method. He employs a cylindrical saw to form the pipe. A plug of wood is inserted in the centre of the intended pipe; this plug receives the lower end of a vertical spindle, longer than the intended pipe; this spindle is square, and has sockets sliding on it. On the upper part of the spindle is a pulley or toothed-wheel, by which the spindle is made to revolve. Near the lower end of the spindle is a wheel, having a circumference like a hoop, three inches broad. The diameter of this wheel is somewhat less than that of the pipe to be bored. It regulates the motion, and fits in the inside of a tube of metal attached to the spindle. The diameter of the tube is nearly equal to that of the intended pipe; its length is greater by two feet. On the lower edge of the tube is a rim of metal, so much thicker than the tube, that the groove cut in the stone by the rim, may admit the tube to move freely in it. This rim has an edge like that of a stone-cutter's saw, and performs here the office of a saw. The tube is caused to make a reciprocating circular motion round the spindle. There is a cistern placed above the tube, for the purpose of conveying a mixture of sand and water into the cylindrical groove formed in the stone, whilst the machine is working.

Stone pipes, made in the above described way, have been tried for conveying water in London. They were joined by means of Parker's cement, which consists of clay ironstone, burnt, and ground to a fine powder. This was the best material that could be got for forming the joints; but these joints cracked, and allowed the water to escape in consequence of the motion of the carriages on the streets under which the pipes were laid; and the adventurers found that they "had hewed out unto themselves broken cisterns, that could hold no water."

Rocks. 5. Boring of rocks, for the purpose of splitting them by means of gunpowder. We have already treated this subject under Blasting, and shall only add here the mode of boring for this purpose practised in the mines of Germany.

A boring bar of steel is applied to the stone by its lower end, whilst its upper extremity is struck with a hammer of two pounds in weight. The form of the lower end of the boring-bar is various; some were formed like a swallow's tail, ending in two points; this form is no longer in use. Another kind has the end formed by the intersection of two wedge-shaped edges, with a point at each corner, and one in the middle. A third kind has the end composed of four pyramidal points, with cavities between them. A fourth kind, and which is that most frequently used, has the end in form of a wedge. See Rinman, *Bergwerks Lexicon*. Stockholm, 1789, Tab. II. Three sizes of boring bars are employed to make one hole; the first is the shortest and thickest, the second is longer and less in diameter, the third is the longest, and the least in diameter. When a hole is to be made, a small opening is first formed with a pick in the place where the boring-iron is to be applied; and all pieces of the rock are removed that might impede the action of the powder. Then the workman uses the first boring-iron, which he drives with blows of the hammer till this boring-iron can reach no farther; he then employs the second and third boring-bars in like manner; after each stroke of the hammer, the boring-bar is turned round a portion of the circumference. The stone, pulverized by the action of the boring-bar, as it hinders the progress of the operation, must be removed from time to time by means of an iron rod, terminated at right angles by a small round plate. From the different diameter of the boring-bars, it follows that the end of the hole is of a smaller diameter than the beginning. The depth to which the hole is bored is proportioned to the nature of the rock. It varies from 10 to 15 and 20 inches. When the rock is solid a great way round, a deep hole is not used, because the resistance at a considerable depth, in such a situation, is too great; so that the explosion does not split the rock round the powder chamber, but acts upwards against the ramming, where it meets with less resistance. But if the rock be laid bare on one side, a deep hole is advantageous. Water is poured into the hole during the operation, to facilitate the action of the boring-iron. When the hole is perpendicularly downwards, it is kept full of water; when the hole is driven from below upwards, no water can be used. The water must be taken out, and the hole dried, before the cartridge is introduced. The most frequent case is, that one man performs the work, holding the boring-iron in his left hand, and striking on it with the two pound hammer in his right. Sometimes two men are set to do the work, one holding the boring-iron, whilst the second strikes it with a hammer of 4 or 5 pounds; this is done where it is required to make the hole 30 or 36 inches deep. When a still deeper hole is wanted, two men strike alternately with heavier hammers.

Rocks ‖ Wooden Pipes.

6. Boring of wooden pipes, is done by means of a long auger, beginning with one of small diameter, and proceeding to employ successively spoon-formed augers of larger diameter. Notwithstanding the frequent employment of cast-iron pipes, some wooden pipes are still used for conveying water in London; they are of elm, which is the kind of tree most frequent in the neighbouring country. A pipe is bored out of one trunk of elm, and the bark is left on. When a tree is to be bored, it is fixed on a carriage, with a rack on the under part. This rack fits into a pinion, whose axis passes through gudgeons on a fixed frame. On the axis of the pinion is a ratchet wheel, moved by two catches, which derive their motion from the wind or water power that turns the auger; and the pinion is moved in a direction that brings the tree towards the auger. See a figure in the *Encyclopædia Britannica*, Plate CCCXIX; and in Belidor, *Architecture Hydraulique*, I. 1, 341. This apparatus is the same as the one employed in saw-mills. In the boring of pipes for the water-works in London, the tree is made to advance by ropes, which pass over a windlass wrought by men, whilst the auger is turned by a horse-mill. Wooden pipes are frequently bored by an auger having at its outer end a wooden drift or handle, which is put in motion by the workman. The trees are placed on tressels, and there are also tressels of a convenient height that support the auger; there is also a lathe

Wooden Pipes.

to turn one end of the tree conical, so as to fit into a conical cavity in the end of the adjoining tree, and thus form a joint water-tight. The end of the tree, which receives the adjoining pipe within it, has a surface at right angles to the axis of the pipe. Into this surface is driven an iron hoop, whose diameter is some inches greater than the diameter of the aperture of the pipe. This precaution prevents the tree from splitting when the conical end of the next tree is driven home. When the tree is crooked, a bore is driven in from each end, and the two bores meet, forming an angle. An auger, whose stalk is formed spirally for some way up, is figured in Bailey's *Machines of the Society of Arts*. The object of this is that the chips may be delivered without taking the auger out of the hole.

There is a patent granted in 1796 to Mr Howell, Coalmaster, of Oswestry, for boring wooden pipes by a hollow cylinder, made of thin plates of iron, about an inch less in diameter than the hole to be bored. To one end of this cylinder is fixed a flange about a quarter of an inch in breadth, and one part of this flange is to be divided, so that, being of steel, a cutter is formed thereby. The object of this method is to bore out a solid cylinder of wood, capable of being converted into a smaller pipe, or of being applied to some other use in carpentry. (*Repertory of Arts*, Vol. IX.) This kind of borer is like the trepan, which is a hollow cylinder of steel, saw-toothed on the edge, and, when made to revolve rapidly on its axis, in the hand of the surgeon, it saws or bores out circular pieces of the flat bones of the head. (Y.)

BORN (Ignatius) Baron Von, Counsellor in the Aulic Chamber of the Mint and Mines at Vienna; of considerable eminence in the scientific world as a Mineralogist and Metallurgist, and a promoter of science; was born of a family that had the rank of nobility, at Karlsburgh in Transylvania, in 1742; and died in 1791. He was educated in a College of the Jesuits at Vienna, and afterwards entered into that order, but continued a member only during sixteen months. He then went through a course of study in law at Prague, and afterwards travelled into Germany, Holland, and France. On his return to Prague, he engaged in the study of Mineralogy.

The mines in the dominions of the house of Austria are very important, and give livelihood to a numerous population, more particularly in Hungary, Transylvania, and the Bannat, and in Styria and Carinthia. Idria produces mercury; Bohemia, tin and cobalt; and the other metals are got in sufficient abundance, not only to supply the internal trade of the nation, but also for export, either in the form of raw metal, or manufactured into various instruments. A revenue accrues to the public Treasury from the mines in various ways. Some, as those of Schemnitz, Cremnitz, and Idria, are wrought on account of government. A tenth part of the produce of all mines wrought by private adventurers goes to Government as a royalty. Government has a right of pre-emption of all metals, and an exclusive right of buying all gold and silver, the produce of the country, at a stated price. The annual quantity of gold and silver got from the mines of Hungary and Transylvania, and coined into money at the Mint, during the reign of Maria Theresa, amounted in value to about L. 300,000 Sterling. The mines in other parts of the dominions produced likewise a considerable quantity. Maria Theresa, seeing their importance, did much for the regulation of the mines; and, with a view of diffusing the knowledge of Mineralogy amongst the nobles, many of whom were proprietors of mines, she had lectures on that science delivered in the Universities. The administration of the revenue arising to Government from this source, is conducted by a Board composed of Managers, Overseers, Assayers, and other Officers, who are brought up in the knowledge of Metallurgy and Mineralogy, and reside at the mines. The operations of these functionaries are under the control of the Aulic Chamber of the Mint and Mines at Vienna, which keeps a set of books where all the transactions relative to the mines, and their situation and state, are digested and registered. An administration thus constituted offers a field of some preferment. Von Born chose to devote himself to this line of life, and was received into the department of the Mines and Mint at Prague in 1770.

About this time he met with an accident which nearly proved fatal. In the course of a mineralogical journey through Transylvania, he came to Felso-Banya, where, the gang is rendered brittle and detached from the rock, by exposing it to the flames of wood heaped up in the mine and set on fire. Having gone into the mine soon after the combustion had ceased, and whilst the air was hot, and charged with arsenical vapour, and returning through a shaft which was occupied by a current of this vapour, he was deprived of sensation for fifteen hours, and, after recovery, continued long to suffer from a cough and general pain. Some time after this accident, he was affected with violent colics, which a large dose of opium removed, but left him with a numbness of the lower extremities, and lame in the right leg. In the latter part of his life he was deprived of the use of his legs. All these calamities, which, however distressing, did not repress the activity of his mind, were considered as the consequences of the arsenical fumes he had inhaled at Felso-Banya.

One of the chief objects of his exertion was to introduce amalgamation in Hungary, in place of smelting and cupellation heretofore used in that country, for extracting silver from the ores. Pliny and Vitruvius speak of the use of mercury in collecting small disseminated particles of gold. On the arrival of the Spaniards in America, the Peruvians extracted the silver from the ore by smelting-furnaces, exposed to the wind on the tops of hills. The quicksilver mines of Guancabellica in Peru were discovered in 1563, and three years thereafter the Spaniards began to employ amalgamation. Alonzo Barba, an Andalusian, farther improved the process by the addition of heat. Amalgamation had been practised in Europe for collecting silver and gold when they existed in visible metallic particles, but not in the case of ores where the gold and silver are invisible, even with the aid of a microscope. Soon after its application to ores in America, an attempt was made by a Spaniard to introduce this operation

Fig. 1.

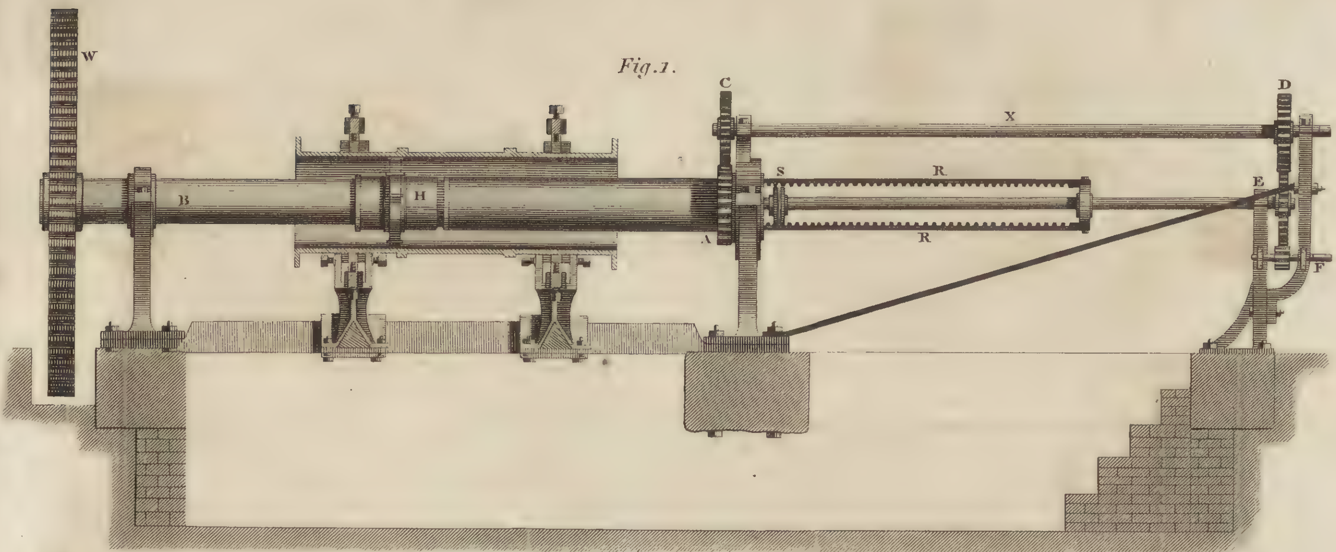

Fig. 2.

J. Farey Delin. Engraved by W. Archibald Edinr. Published by A. Constable & Co. Edinr. 1817.

for extracting silver from the ores in Bohemia, but without success. Gellert, Walerius, and Cramer, had written against the use of Amalgamation when applied to ores. But Von Born, seeing its advantages, particularly in the saving of fire-wood, which had become scarce in many parts of Hungary, set about examining the accounts given by authors of the different processes used in Mexico and Peru; repeated these processes experimentally, first in the small way, leaving out the ingredients that a knowledge of the chemical action of bodies showed to be unnecessary; afterwards he had the process carried on in the great way for several months near Schemnitz, under the inspection of Ruprecht. At this time he published his book *On Amalgamation*. It contains a history of Amalgamation, and extracts from different authors describing the South American methods. This occupies nearly one half of the volume. He then gives the chemical theory of operation in its different steps, describes the method he had adopted at Schemnitz, and gives figures of the machinery employed.

Von Born met with much opposition in his attempts to introduce Amalgamation. He says that some book-learned Chemists, who never had handled a retort, and some Mine-Overseers, when he first set about his experiments, declared that it was impossible to obtain silver by that method. After he had succeeded in getting silver from the ore publicly at Vienna, his detractors came forward with doubts and long calculations, showing that the process was inferior to that already in use. At last his process was tried successfully in the great way by orders of Joseph II. at Schemnitz; and then the calculators and doubters shrugged up their shoulders, saying, "It is only the old Spanish process of Amalgamation."

He obtained from the Emperor an order that his method should be employed in some of the mines belonging to Government, and that he should receive a third part of the savings arising from the improvement during the first ten years, and four *per cent.* of this third part of the savings for the next twenty years.

He was a Satirist, without possessing the qualities of style that are necessary to attain a high rank in that class of writers. The *Staats Peruche*, a tale, published without his knowledge in 1772, and an attack on Father Hell, the Jesuit, and King's Astronomer at Vienna, are two of his satirical works. The satirical description of the *Monastic Orders*, written in form of an academic inaugural dissertation, entitled *Monachologia*, is generally ascribed to Von Born. In this piece the Monks are described in the technical language of natural history. Von Born, however, was not deeply versed in the phraseology of Linnæus; and it is the opinion of some good judges of the subject, that the language at least was furnished by Hermann, Professor of Medicine in the University of Strasburg, and author of the very ingenious work on the mutual affinities of animated beings, entitled, *Tabula Affinitatum Animalium Commentario illustrata*. But although the technical language may not be Von Born's, the sentiments are such as he was known to profess; for the topic was so great a favourite with him, that he found room for invectives against the monks even in his book *On Amalgamation*. The Monks in the Austrian dominions were not then in a situation to obtain redress against this lampoon; for it was published in 1783, when Joseph II. had suppressed many of the Monasteries in different parts of his dominions, and transferred their property into his treasury, allowing but a scanty sum for the subsistence of the members of these communities.

Von Born was well acquainted with Latin, and the principal modern languages of Europe. He also possessed information in many branches of science not immediately connected with Metallurgy and Mineralogy, which were his professed pursuits. He had a good taste in the graphic arts, and his printed works are ornamented in a neat manner with vignettes illustrative of the subject.

His inclination led him to engage in politics; and, in particular, he took an active part in the political changes in Hungary. After the death of Joseph, the Diet of the States of Hungary passed a great many acts, rescinding the innovations of that scheming Ruler, which tended to force upon them German Governors and laws, and even the German language. This Diet conferred the rights of denizen on several persons of distinction who had been favourable to the cause of the Hungarians, and, amongst others, on Von Born. At the time of his death, he was employed in writing a historical work in Latin, entitled, *Fasti Leopoldini*, probably relating to the prudent conduct of Leopold II., the successor of Joseph, towards the Hungarians.

He was of a middle size, slender made, and dark complexion; his eye was penetrating and his countenance agreeable. His constitution was delicate even before his accident. He was a pleasant companion and fond of society. He lived in splendour, and his house at Vienna was resorted to by scientific men of all nations. It is likely, that his profits from the process of amalgamation were not considerable; at least, they were not sufficient to put his fortune to rights, as his affairs, at his death, were in a state of insolvency. His family consisted of a wife and two daughters, who survived him. See Townson's *Travels in Hungary*, and Pezzil, *Ostreich Biographien*, 1792.

The following is a list of his published writings, and of the works of others which he edited:

Lythophylacium Borneanum, 1775, 8vo. This is a Catalogue of his collection of minerals, which collection he afterwards sold to Mr Greville, and it forms a part of the magnificent Greville Collection of Minerals, purchased from the heirs of that gentleman by Parliament, and deposited in the British Museum. This Catalogue is arranged according to the system of Cronstedt, with the nomenclature of Linnæus.

Index rerum naturalium Musæi Cæsarei Vindobonensis. Pars. I. *Testacea. Vindob.* 1778, fol. maj. This splendid volume, which contains the description and figures of the shells in the Museum at Vienna, was composed by order of the Empress Maria Theresa. The shells are arranged according to the

Born.

method of Linnæus. Von Born's knowledge in this department of Natural History was not profound, so that, he needed some assistance in composing the work. The shells only are described; of the animals to which they belong little is said. Joseph II. coming to the throne, and being fully occupied with a multitude of innovations and vast schemes for the aggrandizement of the House of Austria, the project of continuing the work, so as to form a description of the whole Museum, was laid aside.

On the Amalgamation of Ores containing Gold and Silver, in the German language, published in 4to, in 1786. Of this work something has been already said above. There is a translation of the work into English, by Raspe, a Hanoverian, once Professor at Hesse Cassel, and who afterwards resided in Britain, where he was sometimes employed as a viewer of mines.

Catalogue methodique et raisonné de la Collection des Fossiles de Mademoiselle Eleonore de Raab, à Vienne, 8vo, 1790. This catalogue is drawn up so as to form a system of mineralogy, each species of mineral being carefully described, and arranged systematically. It was well esteemed, and cited by mineralogical writers in its time, but has been superseded, like other treatises, by more recent works, on account of the great additions that have been continually making to the science.

He edited the Jesuit Poda's description of the machines used in the mines of Schemnitz.

Ferber's Letters from Italy; were written to and edited by Von Born. Ferber and he were in habits of great intimacy; and, Ferber in return, published the letters that Von Born addressed to him, during his excursion in Transylvania, &c. in 1770; entitled *Briefe uber mineralogische gegenstande auf seiner reise durch das Temeswarer Bannat, Siebenburgen, Ober und Nieder Hungarn.* Frankf. 1774. To this work is prefixed a well engraved portrait of Von Born. There is an English version by Raspe, and a French one, with notes, by Monnet.

He lent his assistance to the first three volumes of a work published in German, entitled *Portraits of Learned Men and Artists, natives of Bohemia and Moravia.*

There are some papers of his in the *Abhandlungen der Böhmischer gesellschaft den Wissenschaften.*

The Transactions of a Private Society at Prague, in Bohemia, for the improvement of Mathematics, Natural History, and the Civil History of the country, contains several papers written by him. He was the founder of this society.

He published an annual periodical work in German, entitled *The Philosophical Transactions of the Masons' Lodge of Concord at Vienna.* This masons' lodge, of which Von Born was the founder and patron, employed a part of its meetings in scientific pursuits. This, as well as other societies of a similar nature, was tolerated by Joseph II. for some time; but he afterwards imposed restraints that caused its dissolution. Von Born was also a zealous member of the Society of Illuminati; and when the Elector Palatine of Bavaria suppressed the masonic societies in his dominions, Von Born being a member of the Academy of Sciences of Munich, was required to declare, within eight days, whether he would withdraw from the masonic societies. He returned an answer, in which he praised the principles of the free-masons, and resigned his place in the Academy, by sending back his diploma.

Born
||
Borneo.

He wrote some articles in the German work published by Trebra, mine-director at Zellerfeld in the Hartz, entitled, a *System of Instruction in the Art of Working Mines*, 4to. Also, *Observations in support of the Metallization of the Alkalis*, in Crell's *Annals*, 1790, 1791. Ruprecht and Tondi thought at that time that they had reduced the alkalis and barytes to a metallic state, by the strong heat of a furnace urged by bellows; but it was afterwards found that the metallic substance thus obtained was phosphate of iron, proceeding from their crucibles and fluxes. Sir Humphry Davy was the first who obtained any of the alkaline class of bodies in a metallic state; and this he accomplished by the intense heat excited by a galvanic battery, mamy years after the time here spoken of.

Relatio de Aurilegio Daciæ Transalpinæ, 1789, in the *Nova Acta Academiæ Naturæ Curiosorum*, Tom. VIII. p. 97. This is an account of the method employed in Transilvania in collecting gold from the sand of the rivers. The auriferous sand generally contains iron, attractable by the magnet. It is washed on a sloping board seven feet long and three feet broad, covered with a woollen cloth, having a dish-shaped cavity at the upper end, and inclined to the horizontal plane at an angle of 20 or 25 degrees. Only a very scanty livelihood can be gained by this employment. It is carried on by the poorer classes of the country people, and in some districts by bands of the people called Gipsies. The King's Collectors buy the gold from the gold washers at a stated price, to the amount of more than 800 pounds weight annually. (Y.)

General Description.

BORNEO, an Island forming part of the Great East Indian Archipelago. Next to New Holland, which may be considered as a species of continent, it seems indisputably the largest in the known world. It reaches from about 7° north to 4° south latitude, and from 109° to 118° east longitude. Its length may be estimated at 750 miles, its greatest breadth at 600, and its average breadth at 350. It exhibits the usual insular structure, a mass of lofty mountains in the centre, sloping gradually down to level and alluvial tracts along the sea shore. It is watered by many fine rivers, of which those of Borneo Proper, Banjar Massin, and Passir, are navigable for more than fifty miles above their junction with the sea. All these rivers are understood by Dr Leyden to be derived from an immense lake in the interior, called the Sea of Manilla. It is more probable that they all rise from the mountainous district of greatest elevation. The interior of Borneo is covered with immense forests, filled with wild animals, particularly oran-outangs. A great part of the coast is marshy, so that it is in portions only that it displays the exuberance of tropical fertility. Of all the East Indian Islands, Borneo ranks lowest as to civilization and improvement. Nothing, perhaps, has tended so powerfully to check its progress, as the

rneo. solid and unbroken form of its coasts, destitute of those large bays or inland seas, which have always proved the nursery of commerce.

The Portuguese discovered Borneo in 1526, though the superior wealth promised by the Spice Islands made it attract comparatively little attention. Yet they, as well as the Spaniards, the Dutch, and the English, formed establishments on different parts of the coast; but the small force defending them, and the fierce animosity of the natives, made their tenure generally of very short duration. The physical structure of Borneo, the vast forests, mountains, and jungles of the interior, obstruct communication between the different parts of its coast, as completely as if an extent of sea had intervened. It is thus split into a number of petty districts, entirely detached from each other, and which cannot be satisfactorily described, unless in detail. We shall consider, therefore, in this manner, the principal states, beginning with Borneo Proper, and thence making the circuit of the Island; after which, we shall attempt some general views of its population and commerce.

thern t. Borneo Proper occupies the northern coast, and is reckoned a state of great antiquity. The soil is comparatively fertile, supplying rice sufficient for the consumption of the inhabitants, as well as most of the camphire for which the Island is celebrated. The city, called also Borneo, is built upon alluvial ground, about ten miles above the mouth of the river of the same name. It is compared to Venice: canals are conducted through every street, and all business is conducted in boats, usually rowed by women. The houses are built upon posts, and ascended to by ladders. The river is navigable for large vessels considerably above the town; but there is a bar at its entrance, over which there is scarcely a depth of seventeen feet at high water. The Sultan is treated with those marks of peculiar respect which in this part of the world usually indicate an ancient dynasty; but the chief power rests in the council of the nobles. This state has little communication with Europeans; the English, who were accustomed to deal to a small extent in piece-goods, have in a great measure discontinued this traffic. The commerce of this city and district is almost entirely engrossed by the Chinese, who bring annually from Amou four or five junks, of about 500 tons burden. As the neighbourhood abounds in excellent timber, they frequently build their junks here, and carry them away loaded with the commodities of the country.

ern t. On the eastern coast of Borneo, Mangedava and Pappal are populous, fertile, and well watered districts. Malloodoo possesses these advantages in a still superior degree, and grows also a large quantity of rattans. Tiroon produces sago in abundance, and *birds' nests* more copiously than any other part of the eastern Archipelago. None of these states, however, are much frequented by, or known to, Europeans.

The chief state on the eastern coast is Passir, situate about fifty miles up a river of the same name. This district is very low and flat; and, were it not cooled by the sea breezes, would be intensely hot. Being marshy and filled with woods, it is extremely unhealthy. The town is said not to contain above 300 wooden houses, which are built along the river. The Sultan has a palace and wooden fort, along the northern bank. The people of Passir have an extremely bad reputation as to their conduct in mercantile transactions. They use false weights and measures,—manufacture counterfeit articles,—and embrace, in short, every opportunity of cheating that offers. The English East India Company made an attempt, in 1772, to establish a factory here, but it did not succeed. Borneo.

Banjar Massin is the principal state on the southern coast of Borneo; like the others, it owes its prosperity to a large river, on the banks of which it is situate. This river is five or six fathoms deep; but, unfortunately, the bar does not allow above 12 or 13 feet of water, and requires the aid of the tide to produce even that depth. Ships, however, may anchor in the port of Tombangou or Tombornio, near the mouth of the river, where they are well supplied with water and provisions. Banjar Massin, in 1780, was estimated to contain a population of 8500 Mahommedans, chiefly Javanese, with a considerable proportion of Bugis, Macassars, and Malays. The Chinese are also pretty numerous. The Sultan resides at Martapura, about three days' journey up the river, to which he is attached, by the circumstance of its being an uncommonly fine hunting station. Southern Coast.

The district of Banjar produces gold and diamonds, both of superior quality to those found in other parts of the Island. Pepper is so abundant, that, in a commercial view, it may be considered as the staple commodity. The iron is very excellent, and peculiarly fit for steel; though Dr Leyden asserts, that the inhabitants do not, themselves, understand the art of manufacturing it.

In 1700, the English East India Company formed a settlement at Banjar Massin. A rage then prevailed for multiplying establishments, and the present one was soon so far extended, as to equal that of Calcutta. But the expectations of extensive trade, which prompted to such an enlargement, were, in a great measure, illusory; a thousand tons of pepper being the most valuable article drawn from the settlement. Before, however, the Company could be fully aware of its unproductive nature, this settlement was brought to a premature end. An attack was made by the natives on so great a scale, and with such fury, that, though repulsed, it seemed to leave no choice, but the immediate evacuation of the factory, without even removing the stores. The damage sustained on the occasion is estimated at 50,000 dollars.

Succadana, or, as Dr Leyden calls it, Sacadina, was anciently the most powerful state on the western coast of Borneo. The Dutch began to trade there in 1604, but they soon after attached themselves, in preference, to Sambas. In 1623, they abandoned their factory at Succadana. In 1786, they united with the Sultan of Pontiana in an expedition against this place, which they took and entirely destroyed. It appears to have been since rebuilt, but is entirely in the hands of the Malays, and scarcely ever visited by Europeans. Western Coast.

Pontiana is a state of very recent origin, but it now exceeds, in wealth and power, all others upon

Borneo.

the western coast of Borneo. This distinction it owes to the wisdom of the Arab Prince by whom it was founded. He renounced, from the first, the pernicious policy, almost universal in these petty states, of embarking in trade, and monopolizing its principal articles. He confined himself to his proper functions, of dispensing justice, and securing protection to all, of whatever country or religion, who resorted to his dominions. Under this salutary policy, Pontiana soon rose to be the greatest emporium in those seas. It is situate on a large river, called, formerly, Laua, and the country behind produces diamonds the most abundantly of any district in Borneo. The Dutch established a factory here in 1776, and maintained ever after a good understanding with the Sultan. In 1813, after the British force had taken possession of Batavia, that Prince, dreading an attack from Sambas, solicited the protection of a British garrison, which was immediately sent; and he afterwards assisted our troops in the reduction of Sambas.

Momparwa, situate a little to the north of Pontiana, is the best market for opium upon this coast. The city lies 19 miles up the river; the entrance of which is obstructed by a bar, and by several small Islands. This is probably the same district called Mattan by Dr Leyden, who says, that the King possesses the finest diamond in the world, for which a high price was offered by the Dutch, which he refused to accept.

Sambas is situate about 30 miles up the river of the same name. Like most other towns in Borneo, it is built of timber and bamboos, and raised by stakes above the swampy foundation. Sambas has been always a powerful state, but for sometime past, has devoted itself so entirely to piracy, as to render its existence scarcely compatible with that of its civilized neighbours. Upon this principle, the British, in 1812, undertook an expedition against it; but they were repulsed with great loss in the attack, and suffered still more from the malignant influence of the climate. In the following year, however, a new expedition was undertaken under Colonel Watson, who, on the 3d of July, carried the fort by storm, and obliged the Rajah to retire into the interior of his dominions. We presume, however, that both Sambas and Pontiana have been evacuated by the British troops, in consequence of the recent treaty with Holland.

Population and Manners.

On a general view of the state of culture and civilization in Borneo, Mr Hamilton estimates the population at 3,000,000, which we should suppose to be rather above than under the truth. The interior is entirely occupied by a native race, called variously, according to the parts of the Island which they inhabit, Dayak, Idaan, and Tiroon. Those which subsist by fishing, are commonly called Biajoos. The appellations of Horaforas and Maroots, have also been applied to these races. The whole may be considered as one, almost savage, and nearly similar to that which occupies the interior of Sumatra. Some, indeed, cultivate the ground,—some display considerable industry in fishing,—and a few employ themselves in collecting gold; but their institutions, in general, indicate the very rudest state of human society. It has been strongly reported, that they devour the flesh of their enemies; an assertion not noticed by Dr Leyden, and which has, in many instances, been made without foundation. All accounts agree, however, as to the existence of another truly savage custom, by which every man is debarred from the privilege of matrimony, till he has, with his own hand, cut off the head of an enemy. Those, therefore, who are desirous of entering into that state, form themselves into what Dr Leyden calls *head-hunting* expeditions. They make an inroad into the territories of a neighbouring tribe, and if their strength appears sufficient, endeavour to effect their object by force; if otherwise, they conceal themselves behind thickets, till an unfortunate individual passes, whom they can make their prey. Some are also said to immolate human victims on the altars of their divinities.

The inhabitants of the towns along the coast consist chiefly of that race so universally diffused through the Indian Islands, under the name of *Malays*. This name, to an European ear, has usually suggested every extreme of perfidy and atrocity. We have perused, however, a very different estimate of their character, formed by an intelligent gentleman, who spent several years in this part of India. He describes them as honest, frank, simple, and even gentle in their manners, decidedly superior, in a moral view, to the degenerate Hindoos. The sanguinary deeds, which have exposed them to so much reproach, he ascribes to a proud and almost chivalrous sense of honour, which makes them regard blows, or any similar personal insult, as an offence only to be expiated by blood. The coarse and unfeeling treatment which they often experience from Dutch and Chinese masters, drives them to these dreadful extremities. Piracy, however, is a vice of which this race cannot be acquitted; and the western coast of Borneo, situate on the great naval route to China, may be viewed as the grand field for its exercise. To a poor and hardy race, who see half the wealth of Asia passing along their shores, the temptation is almost irresistible. Like the Arabs, they have formed for themselves a code of morality, in which plunder is expunged from the list of vices. Yet, though individually brave, they possess no skill or discipline, which could render them formidable to an European crew. The cowardice of the Lascars, by whom Indian trading vessels are usually navigated, is the only circumstance which has made our trade suffer so severely from their ravages.

Next to the two classes above enumerated, the most numerous are the Chinese. These, by the gentleman above alluded to, are considered as the most valuable subjects whom an uncivilized state can receive into its bosom. The difficulty of finding subsistence in their own country, has led them to emigrate in vast numbers into Borneo. Nothing, perhaps, except the law which prohibits females from leaving the empire, could have prevented this almost unoccupied Island from being entirely filled with a Chinese population. From this circumstance, however, the colonists are composed entirely of men in the vigour of life, and of the most enterprising and industrious character. Their chief settlement

Borneo || Borromean Islands.

is at Sambas, on the western coast, where the numbers cannot be estimated at less than 30,000, composing a sort of independent state. Their almost sole occupation is that of extracting the gold, which abounds upon this coast. It is found in alluvial soil, and is purified by the simple process of passing a stream of water over the ore. The processes employed for this purpose are daily improving, and it is conceived that the produce here and at other quarters, will be sufficient to remove all future apprehensions of the East proving a drain upon the gold of Europe.

Commerce. The Commerce of Borneo, though not equal to its extent and natural capacities, is by no means inconsiderable. Gold is its principal export. Mr Milburn estimates the annual quantity exported at 200 peculs, or 26,000 lbs. avoirdupois, which would coin into upwards of 900,000 guineas. Like some other commodities, it is divided, by a grotesque scale, into three kinds, called the head, the belly, and the feet; the first being the best, and the two others gradually diminishing in value. Camphire is exported to the extent of 30 peculs (3990 lbs.), all to China, where it is more esteemed than that of Sumatra. The singular Chinese luxuries of *beech de mer*, or sea slug, and edible *birds' nests*, are found in Borneo, as over all the Indian archipelago. Pepper to a considerable amount, canes and rattans of various descriptions, sago, and a little tin, complete the list of exports. The chief import is opium to a very great extent, with piece-goods, hard-ware, coarse cutlery, arms, and toys. By far the greater proportion of the trade is in the hands of the Chinese.

BORROMEAN ISLANDS. Not far from the south-east termination of the Alps, there is a lake called Lago di Locarno, or Lago Maggiore, extending above fifty miles in length, by five or six in breadth. It contains several islands, among which are, the Isola Bella and Isola Madre, situate in a large bay towards the west, and designed the Borromean Islands. Towards Switzerland, the lake terminates in a canal, which is of much utility for commercial purposes; and near Cesti, which is ten leagues from the city of Milan, it discharges itself into the river Ticino, with a current rapid and dangerous to the navigation of small vessels. The Borromean Islands lie about fifteen miles distant by water from Cesti, and the passage to them displays a succession of curious and interesting objects, some of which are connected with their own history. Among these may be named a colossal bronze statue of San Carlo Borromeo, above the small town and port of Arona, which is sixty feet in height, and stands on a pedestal of proportional dimensions. This gigantic image was cast at Milan, and brought hither in pieces. The Borromean Islands are of inconsiderable size, but the artificial decoration they have received, has been the admiration of spectators since the middle of the seventeenth century, when both were barren and unprofitable rocks. About this time Vitaliano, Count Borromeo, a nobleman of illustrious descent, and Master-General of the Ordnance to the King of Spain, resolving on their embellishment, directed that they should be covered with earth from the neighbouring banks of the lake. His injunctions were fulfilled, and, at an immense expence, the Islands were converted into two gardens. Isola Madre appears in ten successive terraces, rising one hundred and thirty feet above the level of the water, each regularly decreasing in size from the base to the summit, which is an oblong surface, seventy feet by forty in extent, paved and surrounded by a balustrade. The whole are environed by gigantic marble statues of gods, goddesses, and horses, or other figures; and the walls are clothed with the finest fruit trees and evergreens, many of which belong to the southern climates. There is, besides, a magnificent palace towards the west end of the Island, close to the lake, which almost washes its walls. It is built on arches, which are formed into grottos, with a floor of Mosaic, representing various objects, and decorated also with shell-work and marble. The palace itself, contains a profusion of marbles and paintings, and some flower-pieces, executed on marble, have been particularly admired; as also busts and statues. At the angles of the garden, which has a southern exposure, there are two round towers with lofty chambers adorned with red and white marble; and in the vicinity are groves of laurels, orange-trees, lofty cypresses, and other odoriferous plants, rendering it a delightful retreat. But much of the embellishment is lost by the immediate neighbourhood of a miserable hamlet.

Isola Madre, which is the larger of the Islands, is between one and two miles from Isola Bella; it consists of a superstructure of seven terraces, apparently lower, but not less beautiful than the other. However, it is of equal height in reality; the base being a perpendicular rock, rising considerably out of the water, and on that account not having required so much covering. Here also there is a palace embellished with paintings and different ornaments; and in the gardens are groves of citrons, cedar, and orange-trees, besides a summer-house close to the lake. But all the decorations, as before, are necessarily on a limited scale from the size of the Island; and it excites the wonder of the spectator, that in a space so restricted, so much has been done. Pheasants were formerly bred in this Island, as they were deterred by the vicinity of the water on all hands from attempting to escape. There were some hydraulic exhibitions in Isola Bella, and large cisterns or reservoirs to preserve them in action. When any foreign Prince visited these Islands in the night, or resided upon them, they were illuminated with various coloured lights. Their decorations were not only completed at an enormous expence, but to keep them in the same state since 1671, about which time they seem to have been finished, the charge has proved equally great. They are frequently called the "Enchanted Islands." Keysler, a learned traveller, says, "these two Islands can be compared to nothing more properly than two pyramids of sweetmeats, ornamented with green festoons and flowers." And a later tourist, Coxe, who borrows largely from him, in speaking of the Isola Bella, observes, "if anything

Borromean Islands || Boswell.

justly gives this Island the appellation of enchanted, it is the prospect from the terrace. The gradual diminution of the mountains, from the regions of eternal snow to the rich plain; the sinuosity of the lake; its varied banks; the bay of Marzozzo, bounded by vast hills; the neighbouring borough of Palanza, and more distant view of Laveno, the numerous villages, the Isola Madre, and another Island sprinkled with fishermen's huts, form a delightful assemblage."

These Islands, after passing from the family of Borromeo, appear to have come into possession of the Emperor of Germany. More recently, both of them, together with the western coast of the bailliage of Locarno, are said to have been ceded by the Empress Maria Theresa to the King of Sardinia, in consideration of the assistance she had derived from him. The whole lake is environed by hills, covered with vineyards, and interspersed with summer-houses; beautiful rows of trees traverse its banks, and the scene is still farther embellished by cascades falling from the mountains. (s.)

BOSWELL (James, Esq. of Auchinleck, in the county of Ayr), whose life of Dr Samuel Johnson entitles him to a place among those who have contributed to the great stock of intellectual wealth, was the eldest son of Alexander Boswell (styled Lord Auchinleck), one of the Judges of the Supreme Courts of Session and Justiciary in Scotland. He was born in the year 1740; and, having received the rudiments of his education, partly in his father's house, and partly at Mr Mundell's school in Edinburgh, successively prosecuted his studies at the Universities of that city and of Glasgow. He was destined by his father for the Scottish bar; a pursuit with which his own inclinations did not much accord, and in place of which, he would gladly have substituted one of greater activity and enterprise. His father's wishes, however, and his own sense of filial duty, prevailed; and, as the study of Civil Law, at one of the foreign Universities, was then included in the most liberal plan of education for a Scottish Advocate, it was determined that Mr Boswell should repair, for that purpose, to Utrecht; with a permission, before his return, to make the tour of Europe.

Already, however, those traits of character might be observed, which gave the peculiar direction to his after life. He was, very early, ambitious of being admitted into the society and friendship of men distinguished by talent and public estimation, more especially those of eminence in the literary world; and his natural urbanity, as well as gaiety of disposition, rendered it no difficult matter to gratify his propensity. While at the University of Glasgow, he had formed a particular intimacy with Mr Temple, the friend of Gray, afterwards Vicar of St Gluvias in Cornwall; and he was known to many of the conspicuous characters at that time in Scotland, among others, Lord Kames, Lord Hailes, Dr Robertson, and Dr Beattie. But the most remarkable acquisition which he made of this kind was his acquaintance with Dr Johnson, which commenced in 1763, and was to prove at once the principal era in his own life, and the means of adding not a little to the fame of the philosopher.

Boswell.

Mr Boswell had visited London, for the first time, in 1760, when he accidentally became acquainted with Derrick, afterwards *King* Derrick, as the Master of Ceremonies at Bath was then fantastically titled; and by him was initiated into the arcana of London life. In 1763 he proceeded to Utrecht. Having passed a year at that university, he travelled into Germany and Switzerland, was entertained by Voltaire at his castle of Ferney, and conversed with Rousseau in the solitudes of Neufchatel. He continued his route to Italy; but, led by his natural enthusiasm, forsook the common roads of travel, and passed over to Corsica, which, after a contest of more than thirty years, was still struggling for independence with the republic of Genoa. He thus describes his feelings while he approached the island: "As long as I can remember anything, I had heard of the malecontents of Corsica; it was a curious thought that I was just going to see them." Rousseau had given him a letter of introduction to the romantic Paoli; and his tide was suddenly at the full. In the small court of this simple but dignified Chieftain, he found everything to gratify his taste for the virtuous and sublime in natural character. He became a favourite, too, in his turn; was caressed by the islanders, admitted at all times to the society of their leader, and not only witnessed the movements of their political machinery, but appeared to be himself an actor in the scene. Of his visit to this island, he published a narrative on his return to Scotland, entitled, *An Account of Corsica*, with *Memoirs of General Pasquale de Paoli*, printed at Glasgow in 1768. This book was translated into the Dutch, German, French, and Italian languages. He likewise printed, in the following year, a collection of *British Essays in favour of the Brave Corsicans*; and made such attempts as he could to interest the British Government in favour of that people, before they were finally crushed by the pressure of the French arms. His acquaintance and friendship with General Paoli were afterwards renewed in London, when that chief, having escaped with difficulty from his native isle, found an asylum in the British dominions.

From Corsica Mr Boswell repaired to Paris; and, returning to Scotland in 1766, was admitted to the bar. Soon after he published a pamphlet, under the title of *Essence of the Douglas Cause*; written while that great suit was depending in the Court of Session, with a view to excite the public interest in favour of Mr Douglas. In 1769 he was married to Miss Montgomery, daughter of David Montgomery, Esq.; an accomplished lady, in whose society he enjoyed every domestic happiness.*

In the year 1773 Mr Boswell was admitted into the Literary Club, which then met at the Turk's Head in Gerard Street, Soho, and of which Dr Johnson had been an original member. Here he

* He had a family by her of two sons and three daughters. Mrs Boswell died in 1790.

Boswell. had the pleasure of associating, among others, with Burke, Goldsmith, Reynolds, and Garrick.

Dr Johnson had long projected a tour to the Hebrides; and Mr Boswell at last prevailed upon him, in the course of this year, 1773, to put the plan in execution, and became the companion of his journey from Edinburgh. During this excursion, they saw whatever was most remarkable in the Western Highlands and Isles; and here Mr Boswell was again at large in his natural element. Conscious of the advantages which he enjoyed, and aware of their value, he improved every opportunity of knowledge and remark, and has preserved a faithful record of all. His feelings were like those which Dante ascribes to the pilgrim, who, having paid his vows,

> "Long gazes on the holy fane, and thinks
> How he shall paint it when he reaches home."

Both travellers gave the world an account of this tour. Mr Boswell's *Journal* was published in 1785. In the course of this work, he has given a simple and very interesting narrative of some minute circumstances attending the escape of Prince Charles Edward after the battle of Culloden, collected from the information of persons on the spot, and privy to his concealment; particularly from the celebrated Flora Macdonald, whom they visited at Kingsburgh, in Sky, and from Malcolm Macleod, who had been the faithful and intelligent companion of the Wanderer's flight.

Lord Auchinleck died in 1782; and, a few years after (1786), Mr Boswell, giving up his law pursuits at Edinburgh, removed with his family to London, towards which, as a great emporium of literature and theatre of varied life, his inclinations had always tended. He had recently before been called to the English bar. He did not, however, prosecute the profession, but gave himself up to his natural bent for society and letters. After Dr Johnson's death, in 1784, he was occupied for several years in collecting and arranging, with indefatigable diligence, the materials for a narrative, which he had long projected, of that eminent man's life.*

Besides the works which have been already mentioned, he was the author of two Letters addressed to the People of Scotland; being his only productions of a political character. In the first of these, which was published in 1784, he appeared as an advocate for the new administration, then recently formed. The second Letter, written in 1785, was a strenuous appeal against a measure brought forward under the sanction of the same ministry, for effecting a reform in the Court of Session in Scotland, by reducing the number of the Judges.

Mr Boswell died on the 19th June 1795. In his private character, he was loved by his friends, as well as a favourite in the circles of social life; and, if his attachments were often suddenly formed, they were not less durable on this account. Whatever he has written is favourable to virtue; and, during a course of living which naturally dissipates the mind, his moral principles remained entire, and his religious faith unshaken. "Few men," says his friend Sir William Forbes, in a Letter published in his *Life of Dr Beattie*, "possessed a stronger sense of piety, or more fervent devotion—perhaps not always sufficient to regulate his imagination, or direct his conduct, yet still genuine, and founded both in his understanding and his heart." His talents would probably have been rated higher, if they had not been obscured by certain eccentricities of character. Yet his writings bear sufficient testimony to his natural abilities, and to the delicacy as well as aptness of his intellectual touch. He has described himself as being of a temperament inclined to melancholy; but in society he was remarkable for the gaiety of his disposition, and his life was full of activity and stir. To be distinguished was his ruling passion, and he indulged it freely. He sought those whom the world, on whatever account, held in honour; and was desirous of being known as one with whom they assorted, and who possessed their friendship. He was fond of his pedigree and family connections, and he aspired after literary fame. While some of these propensities have been common to the great and good in every age, others, it must be confessed, are more frequently harboured than avowed. Mr Boswell adopted the latter and more unusual course.† He fairly owned his passion, and, if not thus secured from attack, had all those advantages, at least, which are gained by meeting an enemy in the field. But, in reality, he has dealt so openly, and with such candour, on every occasion which touches himself as well as others, that he wins not only our forgiveness but our affection, and maintains, by ingenuousness and complete truth of character, a kind of superiority over any person who should feel desirous of assailing him. Nor was evidence of a substantial sort wanting to show the independence of his mind. For, however attached to individuals of extensive influence, and however ambitious of exalted patronage, he was neither an instrument of party, nor a server of the time. What he gave in attention, he received back in kindness; and, while he associated with the learned and the philosophical, he contributed his share to the general stock of enjoyment. Of Dr Johnson's sincere attachment to him, there are many and unequivocal proofs in their correspondence.

But it is not on account of his private character, or of a certain domestic celebrity which he enjoyed during his life, that he is to be distinguished in a work of this kind. We commemorate him as an author, and particularly as a writer of Biography. Here he is almost an inventor; he has, at least, carried this species of composition to a degree of accuracy and detail formerly unattempted. Other writers, as the Abbé de Sade, in his *Memoirs of Petrarch*, and Mason, in his *Life of Gray*, had conducted the

* *Life of Samuel Johnson*, LL.D. 2 vols. 4to. London, 1791.

† "Egotism and vanity," says he, in his Letter published in 1785, "are the indigenous plants of my mind: they distinguish it. I may prune their luxuriancy, but I must not entirely clear it of them; for then I should be no longer as I am, and perhaps there might be something not so good."

Boswell.

course of their narratives partly by means of original letters. But Mr Boswell has, more than any preceding Biographer, made use of all the varied means by which such a history admits of being dramatized. He paints the whole man, presents the incidents of his life in their actual order of succession, and preserves him as it were entire; fulfilling in the history of the moral, what Bacon has assigned to Philosophy as her genuine work in that of the natural, world, faithfully to return its accents and reflect its image, neither to add any thing of her own, but iterate only and repeat.

The plan of keeping a Miscellaneous Journal had been recommended to him by Dr Johnson, on their first acquaintance; and he appears very early to have followed it, so far as writing down what was remarkable in the conversation of those whom he admired. From his frequent allusions to the discourses of Selden, commonly called his *Table Talk*, as preserved by Lilward, it is probable that he had the example of that work in his view; and by long use he acquired a great facility in this process. Of his first publication, containing an account of Corsica, the Journal of his residence with General Paoli is by far the most interesting part. It is a sketch remarkable for life and natural colouring; and is one of those productions which, though enhanced by their occasion, do not depend on this circumstance alone for the attraction which they possess. In his *Journal of a Tour to the Hebrides,* he pushed to a still greater extent, and even beyond its just limits, his favourite style of writing. Carried away by his natural enthusiasm, and delighting "to pour out all himself, like old Montaigne," he indulged in a more ample and unqualified disclosure, both of his own sentiments and of the opinions of others, than is consistent with a salutary prudence, or necessary for the purposes of instruction. Of this he himself became sensible, on cooler reflection, and not only acknowledged it with candour, but in his subsequent and more laboured compositions, profited by the general opinion, and imposed a greater restraint upon his pen.

For the task of writing Johnson's life he was in many respects peculiarly qualified. He had lived in habits of intimacy with the Sage for a period of twenty years, had early conceived the plan of such a work, and received from Johnson himself, to whom his intention was known, many particulars of his early life and personal history. As the writer was thus furnished for his undertaking, so there has seldom been a more fertile or interesting subject for the Biographer. Johnson was not a mere scholar, "deep versed in books, and shallow in himself," nor was he one of those unprofitable misers who hoard without expending. He was a general and a minute observer, and, while he possessed in a degree seldom equalled "the strenuous use of profitable thought," his talent for communicating knowledge was more remarkable even than the large capacity of his mind, or the accumulation of his learning.

According to Baker's character of King James, in that passage which Mr Boswell happily prefixed to his *Journal,* "he was of an admirable pregnancy of wit, and that pregnancy much improved by continual study from his childhood, by which he had gotten such a promptness in expressing his mind, that his extemporal speeches were little inferior to his premeditated writings. Many, no doubt, had read as much, and perhaps more than he, but scarce ever any concocted his reading into judgment, as he did." Johnson's conversation, accordingly, is the matter and substance of the book; and, as the Philosopher did not, in the midst of his studies, forget to cultivate his friends, nor gave up the advantages and comfort of society, there was in his discourse a range and diversity of subject not often found in combination with classical knowledge and habits of profound thinking. Nor does this work exhibit a series merely of witty and sententious sayings: it is interspersed alike with miscellaneous narrative and criticism; and, which constitutes its principal feature, it contains a mass of opinions on subjects of a more common nature, where the powers of reasoning and illustration are applied to familiar topics, and the ordinary occurrences of life. Valuable as a deposit of literary anecdote, it is still more so as a collection of ethical discourses, to which its popular form gives a singular currency and effect; so that there are few books extant where the religious and social duties, as well as the love of science, in its largest acceptation, are impressed more agreeably, or with greater force, upon the mind.

Among the many circumstances which have conspired to heighten our interest in this narrative, is the exhibition which it affords of illustrious characters in different walks of life. The period was distinguished by an unusual measure of genius and talent; and we are not only introduced to the closet of the Philosopher, but carried with him also into assemblages of the brilliant and the wise, with whom he associated. The tone of this society, moreover, is highly pleasing, and in harmony with our best principles and feelings; in which respect, it is impossible to avoid contrasting it with those more boasted Parisian societies during the same period, which were supposed to be the centre of French literature and wit, as they are displayed to us by some of the chief actors in that scene.* Mr Boswell's work has not yet, indeed, acquired all its interest; the period is still too recent; but, to estimate its value in after times, we have only to consider what we ourselves should have gained, if such a volume had been preserved to us from the rolls of ancient life.

In the great attainments of a Biographer, which are the truth and minuteness of his relation, Mr Boswell has been eminently successful. If, in this species of writing, an author is exempted from the formality, as well as comprehensive research, necessary in the higher classes of historical composition, it is well known that he has his peculiar difficulties to encounter; difficulties, too, which are the greatest where, by his intimate knowledge of the subject, he is best qualified for the task of writing. Nor does

* Particularly in the *Correspondence of the Baron de Grimm,* and the *Memoirs of Marmontel.*

Boswell. the partiality to which he is himself exposed constitute his only danger; since he is no less apt to be led away by the expectation of gratifying his readers. We are fond of seeing the picture of character completed according to our fancy; and, whatever be the feeling which has commenced, are impatient of any interruption to its train. In the case of those whom we respect and love, the disappointment is doubly ungrateful; we dislike being told of their frailties, because we are unwilling to believe that they were frail. But such is not the colour nor the tissue of human characters; and the artist who would represent them truly, must do perpetual violence to his inclination. The fidelity of Mr Boswell's portrait may be ascribed, in a great measure, to the form and method of his composition. Had he given us only the results of his observation, the effort at impartiality could scarcely have been preserved; but he has presented us with the whole materials as he found them, and allows us to work them up for ourselves.

In the other distinguishing quality of a Biographical work, namely, the minuteness of its information, he is so little deficient, that his observance of this requisite has been converted into an accusation against him. And it is certain, as already observed, that, in his early productions particularly, he left some room for such a charge; and that, while his veracity and candour were unimpeached, his prudence was not on all occasions equally conspicuous. Yet it must be remembered, that the great use of Biography is to bring instruction home; to give us examples, not of individual actions and conduct merely, but of that conduct as displayed in the common paths of life. The history of nations is too often a species of heroical romance. Its lessons are, at all events, of a different nature from those now in question, and its moral is far too remote to answer the necessities of individuals. General precepts, again, when delivered without the aid of story, commonly fail to produce their effect, either because they fail to excite attention, or because the power of applying them to particular cases remains difficult as before. Nor do works of fiction, however excellent, and even where the scene is laid as it were at home, and the characters are those of a private station, leave any very permanent impressions on the mind. They do not carry with them a sufficient presence and authority; for, the writer's first object is, not to instruct but to please; and, above all, they want that great requisite, truth, for which, in the time of need, all others are abandoned and forgot. A manual of instruction for human conduct, which, instead of being couched in general maxims, or calculated for situations of unusual occurrence, should descend to particular cases, and to the ordinary emergencies of private life, would certainly be one of the most valuable presents which Philosophy could offer to the bulk of mankind. Biography makes the nearest approach towards the compilation of such a code; and, as a commentary on moral duties, it is, when faithfully executed, invaluable. But it is so in proportion only to the closeness of the resemblance, and the exactness of the detail. Minuteness, therefore, is the characteristic and soul of biographical writing, if its proper uses are considered.

That such a plan of delineation may be carried to excess, indeed, is undeniable. He who is accustomed to set down whatever he sees and hears, may become indiscriminate in his choice, and forget the value of his store, in the pleasure of collecting it. To ascertain the just medium in this respect, is one of the many things for which rules are ineffectual. A sound judgment alone can determine the limits. As to the licence of publication, the Biographer is under one common restraint with authors of every class. He violates the due boundary, if he introduces into his work what is injurious to virtue, or, if he discloses, for the purposes of general information merely, anything which may probably affect the interests, or wound the minds, of the living. When that period has arrived which secures against dangers of the latter description, even individual characters become, to a certain extent, the property of mankind at large, and may be employed as a vehicle for instruction, if exhibited with fidelity. On this score, Mr Boswell, notwithstanding his natural promptness and want of reserve, has, in his latest and principal work at least, given little ground for animadversion. His habitual quickness of feeling and liveliness of fancy appear to have been corrected, where others were concerned, by his love of justice, and a general benevolence of mind.

With regard to his style of writing, a progressive improvement in it may be discovered through his different productions. It is, in general, well suited to his matter, is animated and easy where he is himself the narrator, and bears evident marks of being true to the original, where, as commonly happens, he is a reporter merely. On the whole, whatever blemishes may be found in it as a literary composition, his *Life of Johnson* is a very valuable work, fraught with information at once useful and pleasing. There are few books which present learning in a more attractive form; and few where the seeds of knowledge are scattered more profusely.

BOTANY.

Botany.

THE Linnæan System of Botany, the principles upon which it is founded, with its application to practice, have all been amply elucidated in the fourth volume of the ENCYCLOPÆDIA BRITANNICA. The reader will there find a general view of this celebrated system, including the generic characters, as well as some of the specific differences, of most plants hitherto discovered, with their qualities and uses. The terminology of Linnæus is explained; his arguments for the existence of sexes in flowers are detailed; his ideas of a natural method of classification, and of its utility in leading to a knowledge of the virtues of plants, are subjoined to a compendious history of Botanical Science.

Objects of this Article.

The writer of the present supplementary article proposes to take a different view of the subject. This study has, within twenty or thirty years past, become so popular, and has been cultivated and considered in so many different ways, that no dry systematic detail of classification or nomenclature is at all adequate to convey an idea of what Botany, as a philosophical and practical pursuit, is now become. The different modes in which different nations, or schools, have cultivated this science; the circumstances which have led some botanists to the investigation of certain subjects more than others; and the particular success of each; may prove an amusing and instructive object of contemplation. In this detail, the history of scientific Botany will appear under a new aspect, as rather an account of what is doing, than what is accomplished. The more abstruse principles of classification will be canvassed; and the attention of the student may incidentally be recalled to such as have been neglected, or not sufficiently understood. The natural and artificial methods of classification having been, contrary to the wise intention of the great man who first distinguished them from each other, placed in opposition, and set at variance, it becomes necessary to investigate the pretensions of each. The natural method of Linnæus may thus be compared with his artificial one, and as the competitors of the latter have long ceased to be more than objects of mere curiosity, we shall have occasion to show how much the rivals of the former are indebted to both. In the progress of this inquiry, the writer, who has lived and studied among the chief of these botanical polemics, during a great part of their progress, may possibly find an occasional clue for his guidance, which their own works would not supply. No one can more esteem their talents, their zeal, and the personal merits of the greater part, than the author of these pages; but no one is more independent of theoretical opinions, or less dazzled by their splendour, even when they do not, as is too often the case, prove adverse to the discovery of truth. Nor is he less anxious to avoid personal partiality. *Incorruptam fidem professis, nec amore quisquam, et sine odio, dicendus est.*

Necessity of a Botanical System.

About the end of the seventeenth century, and the beginning of the eighteenth, the necessity of some botanical system, of arrangement as well as nomenclature, by which the cultivators of this pleasing science might understand each other, became every day more apparent. Nor was there any deficiency of zeal among the leaders and professors of this science. Systems, and branches of systems, sprung up over the whole of this ample field, each aspiring to eminence and distinction above its neighbours. Many of these, like the tares that fell by the way side, soon withered for want of root; others, like the *herba impia* of the old herbalists, strove to overtop and stifle their parents; and all armed themselves plentifully with thorns of offence, as well as defence, by which they hoped finally to prevail over their numerous competitors. This state of scientific warfare did not, in the mean while, much promote the actual knowledge of plants, though it prepared the way for a final distribution of the numerous acquisitions, which were daily making, by the more humble, though not less useful, tribe, of collectors and discoverers. The success of the Linnæan artificial system is not altogether, perhaps, to be attributed to its simplicity and facility; nor even to the peculiar attention it commanded, by its connection with the striking phænomenon, brought into view at the same time, of the sexes of plants. The insufficiency, or at least the nearly equal merits, of the many other similar schemes that had been proposed, began to be most strongly felt, just at the time, when the great progress and success of practical botany, rendered the necessity of a popular system most imperious. While the cause of system was pending, some of the greatest cultivators of the science were obliged to have recourse to alphabetical arrangement. This was the case with Dillenius, the man who alone, at the time when Linnæus visited England, was found by him attentive to, or capable of understanding, the sound principles of generic distinction. These he probably understood too well to presume to judge about universal classification. It was the fashion of the time however for every tyro to begin with the latter; and the garden of knowledge was consequently too long encumbered with abortive weeds.

Services rendered by Linnæus.

Linnæus had no sooner published and explained his method of arranging plants, according to that which is generally termed the Sexual System, than it excited considerable attention. His elegant and instructive *Flora Lapponica* could not be perused by the philosopher or the physician, without leading its readers occasionally aside, from the immediate objects of their inquiry, into the paths of botanical speculation, and awakening in many a curiosity, hitherto dormant, on such subjects. But the scope of that limited Flora is by no means sufficient to show either the necessity or the advantages of any mode of arrangement. Linnæus may be said to have grasped the botanical sceptre, when, in the year 1753, he published the first edition of his *Species*

otany. *Plantarum;* and the commencement of his reign must be dated from that period. The application of his system to universal practice, in this compendious distribution of all the known vegetables of the globe; his didactic precision; his concise, clear, and certain style of discrimination; his vast erudition displayed in synonyms; and, perhaps as much as any thing else, the fortunate invention of trivial or specific names, by which his nomenclature became as evidently commodious, and indeed necessarily popular, as any part of his performance; all these causes co-operated to establish his authority. An immediate impulse was given to practical botany. The vegetable productions of various countries and districts were marshalled in due array, so as to be accessible and useful. A common language was established throughout the world of science; a common stock of knowledge and experience began to accumulate, which has ever since been increasing, and can now never be lost. Of these partial Floras to which we allude, those of Lapland and Sweden, the productions of Linnæus himself, were the models of most of the rest, and have never, on the whole, been excelled.

næan ool. Hence arose the Linnæan school of Botany, which though founded in Sweden, extended itself through Holland, Germany, and more or less perfectly in other parts of Europe, though not without impediments of which we are hereafter to speak. In Britain it was firmly established, by the influence of some of the most able pupils of Linnæus, and strengthened at length by the acquisition of his literary remains. But these are adventitious supports. The strength of philosophical, like political, authority is in public opinion, and the cement of its power is public good.

As we proceed to trace the practical influence of the Linnæan system, or rather of the facility which it afforded, in botanical studies, it will be useful at the same time to observe the effects of adventitious circumstances, which render botany almost a different sort of study in different parts of the habitable globe.

any of North. In those northern ungenial climates, where the intellect of man indeed has flourished in its highest perfection, but where the productions of nature are comparatively sparingly bestowed, her laws have been most investigated and best understood. The appetite of her pupils was whetted by their danger of starvation, and the scantiness of her supplies trained them in habits of economy, and of the most acute observation. The more obvious natural productions of such climates are soon understood and exhausted. But this very cause led Linnæus to so minute a scrutiny of Swedish insects, as had never been undertaken before in any country; in consequence of which a new world, as it were, opened to his contemplation, and the great Reaumur declared that Sweden was richer in this department than all the rest of the globe. Such indeed was its appearance, because it had been more carefully examined. When the ardour and acuteness of the pupils of the Linnæan school first sought matter of employment for their talents, some few had the means of visiting distant, and scarcely explored, countries; but this could not be the lot of many. The greater part were confined to their native soil; and it is remarkable that those who were longest so confined, have displayed in the sequel the greatest abilities, and have rendered the greatest services to science, independent of the accidents which made the labours of others imperfect or abortive. Such men as Ehrhart and Swartz were not to be satisfied with the general productions of the fields or gardens to which they had access. They had no resource but in the recondite mysteries of cryptogamic botany, in the first instance. To these they directed their microscopic eyes, and more discriminating minds, with the happiest success. When they had derived from hence an ample harvest, Ehrhart, limited in circumstances and opportunities, hindered moreover perhaps, in some degree, by a singularity and independence of character, not always favourable to worldly prosperity, opened to himself a new path. The native trees of the north, and especially the hardy shrubs and arborescent plants of the gardens, had not, as he judiciously discovered, received that correct attention, even from his master Linnæus, which was requisite to make them clearly understood. Difficulties attending the study of these plants, the various seasons in which they require to be repeatedly scrutinized, and the obscurity or minuteness of the parts on which their differences depend, were by no means calculated to deter this laborious and accurate inquirer. He submitted the supposed varieties of the shrubbery, the kitchen garden, and even of the parterre, to the same rigorous examination, and, for the most part, with the happiest success. His discoveries have not received the notice they deserve, for his communications were deformed with asperity and pedantry, and he did not always keep in mind the concise and sober principles of definition, which his preceptor had both taught and practised, and to which he owed so large a share of his well-merited fame. Ehrhart died prematurely, but his name ought to be cherished among those whose talents have advanced science, and who loved Nature, for her own sake, with the most perfect disinterestedness. Botany. Ehrhart.

The fate of Swartz has been far more propitious to himself and to the literary world. Having thrown more light upon the cryptogamic productions of Sweden and Lapland than they had previously received, and which has only been exceeded by the more recent discoveries of the unrivalled Wahlenberg, he undertook a botanical investigation of the West Indies. Carrying with him, to this promising field of inquiry, so great a store of zeal and practical experience, his harvest was such as might well be anticipated. Whole tribes of vegetables, which the half-learned or half-experienced botanist, or the superficial gatherer of simples or flowers, had totally overlooked, now first became known to mankind. Tropical climates were now found to be as rich as the chill forests and dells of the north, in the various beautiful tribes of mosses; and the blue mountains of Jamaica rivalled its most fertile groves and savannas in the beauty, variety and singularity of their vegetable stores. Swartz.

Nor must we pass over unnoticed the discoveries Thunberg.

of another illustrious disciple of Linnæus, the celebrated Thunberg, who has, now for many years, filled the professorial chair of his master, with credit to himself and advantage to every branch of natural science. The rare opportunity of examining the plants of Japan, and of studying at leisure the numerous and beautiful productions of the Cape of Good Hope, as well as of some parts of India, have thrown in the way of Professor Thunberg a greater number of genera, if not species of plants, than has fallen to the lot of most learned botanists; except only those who have gone round the world, or beheld the novel scenes of New Holland. These treasures he has contemplated and illustrated with great advantage, so far as he has confined himself to practical botany. We lament that he ever stepped aside to attempt any reformation of an artificial system. It is painful to complain of the well-meant, though mistaken endeavours of so amiable and candid a veteran in our favourite science; but what we conceive to be the interests of that science must form our apology. We cannot but be convinced, and the experience of others is on our side, that discarding those principles of the Linnæan system which are derived from the *situation* of the several organs of impregnation, and making *number* paramount, has the most pernicious and inconvenient effect in most respects, without being advantageous in any. This measure neither renders the system more easy, nor more natural, but for the most part the reverse of both. We have elsewhere observed, (*Introduction to Botany*, *ed.* 3. 358,) that the amentaceous plants are of all others most uncertain in the number of their stamens, of which Linnæus could not but be aware. "Even the species of the same genus, as well as individuals of each species, differ among themselves. How unwise and unscientific then is it, to take as a primary mark of discrimination, what nature has evidently made of less consequence here than in any other case!" When such plants are, in the first place, set apart and distinguished, by their monoecious or dioecious structure, which is liable to so little objection or difficulty, their uncertainty with respect to the secondary character is of little moment; their genera being few, and the orders of each class widely constructed as to number of stamens. Linnæus, doubtless, would have been glad to have preserved, if possible, the uniformity and simplicity of his plan; but if he found it impracticable, who shall correct him? Such an attempt is too like the entomological scheme of the otherwise ingenious and able Fabricius. The great preceptor having arranged the larger tribes of animals by the organs with which they take their various food, and which are therefore accommodated to their several wants, and indicative of even their mental, as well as constitutional, characters, Fabricius his pupil would necessarily extend this system to insects. But nothing can be more misapplied. Feeding is not the business of perfect insects. Many of them never eat at all, the business of their existence through the whole of their perfect state, being the propagation of their species. Hence the organs of their mouth lead to no natural distinctions, and the characters deduced therefrom prove, moreover, so difficult, that it is notorious they could not generally be applied to practice by Fabricius himself, he having, in the common course of his studies, been chiefly regulated by the external appearance of the insects he described. This external appearance, depending on the form and texture of their wings, and the shape of their own peculiar organs, the *antennæ*, affords in fact the easiest, as well as the most natural, clue to their arrangement and discrimination.

As we presume to criticise the systematic errors of great practical observers, it cannot but occur to our recollection how very few persons have excelled in both these departments. Ray, Linnæus, and perhaps Tournefort, may be allowed this distinction. We can scarcely add a fourth name to this brief catalogue. The most excellent practical botanists of the Linnæan school have been such as hardly bestowed a thought on the framing of systems. Such was the distinguished Solander, who rivalled his preceptor in acuteness of discrimination, and even in precision and elegance of definition. Such is another eminent man, more extensively conversant with plants, more accurate in distinguishing, and more ready in recollecting them, than almost any other person with whom we have associated. Yet we have heard this great botanist declare, that however he might confide in his own judgment with regard to a species, or a genus of plants, he pretended to form no opinion of classes and orders. Men of so much experience know too much, to be satisfied with their acquirements, or to draw extensive conclusions from what they think insufficient premises. Others, with a quarter of their knowledge, find no difficulty in building systems, and proceed with great alacrity, till they find themselves encumbered with their own rubbish; happy if their doubts and uncertainties will afford them a tolerable screen or shelter! But we here anticipate remarks, which will come with more propriety hereafter. We return from the consideration of the labours of particular botanists, to that of the diversities of nature and circumstance.

While it is remarked that in the cold regions of the north, the skill of the deep and learned botanist is chiefly exercised on the minute and intricate cryptogamic tribes, we are not to infer that Nature is not every where rich in beauty and variety. Mosses and Lichens afford inexhaustible amusement and admiration to the curious inquirer, nor are more gorgeous productions entirely wanting. Even Lapland boasts her *Pedicularis Sceptrum*, never seen alive out of her limits, and Siberia offers her own beautiful crimson *Cypripedium*, to console for a moment the miserable banished victims of Imperial caprice. Kotzebue, though ignorant of botany, did not pass this lovely plant unnoticed, even in the height of his distress. The authoress of the pleasing little novel called "Elizabeth," has represented in a just light the botanic scenery of that otherwise inhospitable country; yet it must be allowed that its rarities are not numerous, except perhaps in those microscopic tribes already mentioned.

New Holland.

Let us in imagination traverse the globe, to a country where the very reverse is the case. From the representations, or accounts, that have been given of New Holland, it seems no very beautiful or pic-

Botany.

turesque country, such as is likely to form or to inspire a poet. Indeed the dregs of the community which we have poured out upon its shores, must probably subside, and purge themselves, before any thing like a poet, or a disinterested lover of nature, can arise from so foul a source. There seems however to be no transition of seasons, in the climate itself, to excite hope, or to expand the heart and fancy; like a Siberian or Alpine spring, bursting at once from the icy fetters of a sublime though awful winter. Yet in New Holland all is new and wonderful to the botanist. The most common plants there are unlike every thing known before, and those which, at first sight, look like old acquaintances, are found, on a near approach, to be strangers, speaking a different language from what he has been used to, and not to be trusted without a minute inquiry at every step.

Cape of Good Hope.

The botany of the Cape of Good Hope, so well illustrated by Thunberg, and with whose treasures he scattered a charm around the couch of the dying Linnæus, most resembles that of New Holland. At least these countries agree in the hard, rigid, dwarfish character of their plants. But the Cape has the advantage in general beauty of flowers, as well as in a transition of seasons. After the dry time of the year, when every thing but the *Aloe* and *Mesembryanthemum* tribes is burnt up, and during which innumerable bulbs are scattered by the winds and driving sands, over the face of the country, the succeeding showers raise up a new and most beautiful progeny from those bulbs. The families of *Ixia*, *Gladiolus*, *Iris*, *Antholyza*, *Oxalis*, and many others, then appear in all their splendour. Some of them, the least gaudy, scent the evening air with an unrivalled perfume, whilst others dazzle the beholder with the most vivid scarlet or crimson hues, as they welcome the morning sun.

Alpine and Tropical Botany.

The lovely Floras of the Alps and the Tropics contend, perhaps most powerfully, for the admiration of a botanist of taste, who is a genuine lover of nature, without which feeling, in some degree of perfection, even botany can but feebly charm. Of one of these the writer can speak from experience; of the other only by report; but he has had frequent opportunities of remarking, that the greatest enthusiasts in the science, have been alpine botanists. The expressions of Haller and Scopoli on this subject go to the heart. The air, the climate, the charms of animal existence in its highest perfection, are associated with our delight in the beauty and profusion of nature. In hot climates, the insupportable languor, the difficulty of bodily exertion, the usual ill health, and the effects of unwholesome instead of salutary fatigue, are described as sufficient to counterbalance even the pleasure which arises from the boundless variety, and infinite beauty, of the creation around. The flowery trees of a tropical forest raise themselves far above the human grasp. They must be felled before we can gather their blossoms. The insidious and mortal reptile twines among their boughs, and the venomous insect stings beneath their shade. We who enjoy the productions of these climates in peace and safety in our gardens, may well acknowledge our obligations to the labour and zeal of those who, by arduous journies and painful researches, supply us with the riches of every country in succession. We do not, indeed, enjoy them in perfection, but we can study and investigate at leisure their various beauties and distinctions. We can compare them with our books, and profit by the acuteness of former observers. We can perpetuate, by the help of the pencil or the pen, whatever is novel or curious. We can preserve the plants and flowers themselves for subsequent examination, and return to them again and again in our closet, when winter has fixed his seal on all the instruction and pleasure afforded by the vegetable creation abroad. Yet let not the sedentary botanist exult in his riches, or rejoice too heedlessly in the abundance of his resources. A plant gathered in its native soil, and ascertained by methodical examination, is more impressed on the memory, as well as more dear to the imagination, than many that are acquired with ease, and named by tradition or report. The labours of its acquisition and determination enhance its value, and the accompaniments of delightful scenery, or pleasing society, are recollected, when difficulties and toils are forgotten.

America.

The western continent is, with respect to Botany, almost a world in itself. There exists, indeed, a general affinity between the plants of North America and those of Europe, and many species of the arctic regions, are the same in both; but there are few common to the more temperate climates of each. A considerable number communicated by Kalm to Linnæus, which the latter considered as identified with certain well-known plants of our quarter of the world, prove, on more accurate examination, to be corresponding, but distinct species. Instances occur in the genera of *Carpinus*, *Corylus*, *Quercus*, as well as in the *Orchis* tribe, and others. These points of resemblance are found mostly among the vegetable productions of the eastern regions of North America. Mexico, and what little we know of the intermediate space, abound with different and peculiar productions. So, in South America; Peru, Guiana, Brasil, &c. have all their appropriate plants, of which we know as yet enough to excite our curiosity, rather than to satisfy it. Whatever has hitherto been given to the world respecting American botany has had one considerable advantage. Each *Flora* has been founded on the knowledge and experience of some one or more persons, long resident, and in a manner naturalized, in the countries illustrated. Those regions commonly comprehended under the name of North America, have afforded materials for the *Flora Boreali-Americana* of Michaux, and the more complete and correct *Flora Americæ Septentrionalis* of Pursh. Michaux, Wangenheim, and Marshall, have particularly illustrated the trees of those countries. But all these works have been enriched by the communications and assistance of men who had much more extensive and repeated opportunities of observation than their authors, except Mr Marshall, could have. Such are the venerable John Bartram, the Reverend Dr Muhlenberg, Messrs Clayton, Walter, Lyon, &c. The Mexican Flora has received, for a long course of years, the attention of the able and learned Mutis, who long

Botany.

corresponded with Linnæus, and whose countrymen have prepared the sumptuous *Flora Peruviana;* each of the authors of which has repeatedly traversed, at various seasons, the rich and interesting regions, whose botanical treasures make so splendid and novel an appearance in those volumes. Of those treasures, we have still more to learn from the unrivalled Humboldt. The French botanist Aublet, after having gained considerable experience in the Mauritius, resided for many years in Cayenne and Guiana, for the purpose of studying the plants of those countries, of which his work, in four quarto volumes, gives so ample a history and representation.

All the writers just named have been practical botanists. They have generally excelled in specific discrimination, nor have they neglected the study of generic distinctions. Any thing further they have scarcely attempted. It is remarkable that they have all followed, not only the Linnæan principles of definition and nomenclature, but the Linnæan artificial system of classification. This same system was chosen by the veteran Jacquin, in his well-known work on West Indian plants, entitled *Stirpium Americanarum Historia*, as well as by Browne in his *History of Jamaica;* not to mention Swartz, in his *Flora Indiæ Occidentalis*, who only wanders a little out of the way, to adopt some of Thunberg's alterations. We cannot but observe, that in the very department of botany in which he has most signalized himself, and with which he is most philosophically conversant, the *Orchideæ*, he totally rejects the ideas of Thunberg.

East Indies.

If we now turn our eyes to the oriental world, we shall find that the seeds of Linnæan botany, sown by Koenig, have sprung up and produced successive harvests among the pious missionaries at Tranquebar, who still continue to interweave a sprig of science, from time to time, among their amaranthine wreaths which are not of this world. India too has long possessed a practical botanist of indefatigable exertion and ardour, who has thrown more light upon its vegetable riches, with the important subject of their qualities and uses, than any one since the days of Rheede and Rumphius. It is scarcely necessary to name Dr Roxburgh, whose recent loss we deeply lament, and whose acquisitions and learned remarks are given to the world by the munificence of the East India Company, in a style which no prince has ever rivalled. That enthusiastic admirer of nature, Colonel Hardwicke, and the learned botanist Dr Francis Buchanan, have also contributed greatly to increase our knowledge of Indian botany. The latter has enjoyed the advantage of investigating, for the first time, the remote and singular country of Nepaul; so prolific in beautiful and uncommon plants, that few parts of the world can exceed it, and yet meeting, in several points, not only the Floras of the lower regions and islands of India, but those of Japan, China, and even Siberia. The only systematic work on East Indian plants, is the *Flora Indica* of Burmann, which is classed according to the Linnæan artificial method. We cannot but wish it were more worthy of the system or the subject; yet, as a first attempt, it deserves our thanks. In speaking of Indian botany, shall we withhold our homage from that great and sublime genius Sir William Jones? who honoured this study with his cultivation, and, like every thing else that he touched, refined, elevated, and elucidated it, with a beam of more than mortal radiance. No man was ever more truly sensible of the charms of this innocent and elegant pursuit; and whenever he adverted to it, all the luminous illustrations of learning, and even the magic graces of poetry, flowed from his pen.

South S[ea].

But we must extend our view beyond the utmost bounds of India, and of the then discovered world, to trace the steps of those adventurous circumnavigators who sought out, not only new plants, but new countries, for botanical examination. The names of Banks and Solander have, for nearly half a century, been in every body's mouth. Their taste, their knowledge, their liberality, have diffused a charm and a popularity over all their pursuits; and those who never heard of botany before, have learned to consider it with respect and admiration, as the object to which a man of rank, riches and talents, devotes his life and his fortune; who while he adds, every season, something of novelty and beauty to our gardens, has given the Bread-fruit to the West Indies, and is ever on the watch to prompt, or to further, any scheme of public advantage. With the recollection of such men must also be associated the names of the learned Forsters, father and son, of Sparrmann, and of Menzies, who have all accomplished the same perilous course, and enriched their beloved science. The cryptogamic acquisitions of the latter in New Zealand, prove him to have attended to that branch of botany with extraordinary success, and at the same time evince the riches of that remote country. Indeed, it appears that any country proves rich, under the inspection of a sufficiently careful investigator. The labours of these botanists have all been conducted according to the principles and classification of Linnæus. Forster, under Sparrmann's auspices, has judiciously pointed out, and attempted to remedy, defects that their peculiar opportunities enabled them to discover, but with no invidious aim. They laboured, not to overthrow or undermine a system, which they found on the whole to answer the purpose of readily communicating their discoveries, but to correct and strengthen it for the advantage of those who might come after them. It is much to be lamented that, except the *Nova Genera Plantarum*, we have as yet so short and compendious an account of the acquisitions made in their voyage. To the technical history of these, however, the younger Forster has commendably added whatever he could supply of practical utility, and has thus given us all the information within the compass of his means.

Long since the voyages of these celebrated naturalists, the same remote countries have been visited, in our own days, by two learned botanists more especially; these are M. La Billardiere, and Mr Brown, Librarian of the Linnæan Society. The former has published an account of the Plants of New Holland, in two volumes folio, with fine en-

gravings; the latter has favoured the botanical world with one volume of a most acute and learned *Prodromus* of his discoveries. As his voyage was made at the public expense, we may trust that the government will consider itself bound to enable him to publish the whole of his acquisitions, in such a manner as to be generally useful. His own accuracy of observation, illustrated by the drawings of the inimitable Bauer, cannot fail to produce such a work as, we will venture to pronounce, has never been equalled. M. La Billardiere has disposed his book according to the system of Linnæus, a rare example in France, where any thing not French usually comes but ill recommended. Mr Brown, on the other hand, has written his *Prodromus*, at least, on the principles of classification established by the celebrated Jussieu, the great champion of a natural system of his own. On this subject we postpone our remarks for the present. Before we can enter on the subject of natural classification, it is necessary to consider the state and progress of botany, for some years past, in the schools, and among the writers, of Europe.

Botanists of Sweden; Sweden has continued to maintain her long established rank in the several departments of natural science, nor has Denmark been behind-hand with her neighbour and ancient rival. The son and successor of the great Linnæus endeavoured to follow his father's steps, and was ambitious of not being left very far in the rear; a commendable aim, which his short life, to say nothing of his talents or experience, disabled him from accomplishing. He completed, and gave to the world, the unfinished materials which his father had left, for a Supplement to his *Species Plantarum* and *Mantissæ*, and having enriched the book with many communications of Thunberg and others, as well as a number of original remarks, he felt a strong desire, not altogether unpardonable, of being thought the principal author of the work. All uncertainty on this subject, whereever other helps fail, is removed by the original manuscript of the *Supplementum Plantarum* in our possession. Ehrhart superintended the printing of this work, and made some alterations in the manuscript, traces of which are perceptible in the affected Greek names, given to some species of *Carex*, *Mespilus*, &c., as well as in their sesquipedalian specific characters. But he had introduced his own new genera of Mosses; which the younger Linnæus thought so alarming an innovation, that he ordered the sheet which contained these matters to be cancelled. We are possessed of a copy, which shows the genera in question to be almost all well founded, and what are now, under Hedwig's sanction, generally received, though by other names. The descriptions of Ehrhart are precise and correct, though his terminology is exceptionable, full of innovations, and crabbed expressions. Two years, almost immediately preceding the death of the younger Linnæus, were spent by the latter in visiting England, France and Holland, and were employed to very great advantage, in augmenting his collection of natural productions, as well as his scientific skill. During this tour, he attached himself strongly, through the medium of his old friend Solander, to Sir Joseph Banks; and while in France, he almost planted, or at least greatly advanced, a Linnæan school in that kingdom. He had scarcely resumed his professorial office at home, when he was unexpectedly taken off, by an acute disease, in his forty-second year. Of the talents and performances of his successor Thunberg, who still with honour fills the chair of the Rudbecks and the Linnæi, we have already spoken. Dr Swartz is the Bergian professor of Botany at Stockholm. The *Transactions* of the Upsal Academy, founded by the younger Rudbeck, are continued occasionally; and those of the Stockholm one, whose foundations were laid by Linnæus, are published regularly. Both are from time to time enriched with botanical communications, worthy of the pupils of so illustrious a school. A veteran in botanical science, Professor Retzius, still presides at the University of Lund. The worthy and accurate Afzelius, well known in England, who accomplished a hazardous botanical expedition to Sierra Leone, is the coadjutor of Professor Thunberg; and the difficult subject of Lichens, under the hands of Dr Acharius, is become so vast and so diversified, as to be almost a science of itself.

of Denmark; Denmark has alway possessed some acute and learned botanists, and has, more than most other countries, been supplied with dried specimens of plants, as an article of commerce, from her West or East Indian establishments. Oeder, the original author of the *Flora Danica*, and Muller its continuator, have distinguished themselves; but their fame is inferior to that of the late Professor Vahl, who studied under the celebrated Linnæus, and who is the author of several excellent descriptive works. He undertook no less than a new *Species*, or, as he entitled it, *Enumeratio*, *Plantarum*, an admirable performance, cut short by his death at the end of the second volume, which finishes the class and order *Triandria Monogynia*. It is almost superfluous to mention, that Afzelius and Retzius, as well as Vahl, in all they have given to the world, have followed the system of their great master. The *Flora Danica*, chiefly a collection of plates, with few synonyms and no descriptions, has come forth, from time to time, for above fifty years past, in fasciculi, without any order, and is still incomplete. It was undertaken by royal command, and, in a great measure, at the sovereign's expense; though regularly sold, except some copies presented to certain distinguished men, as Linnæus.

of Russia; After the example of Denmark, Sweden, &c. Russia has been desirous of promoting, throughout its vast dependencies, an attention to natural knowledge. Nor was any country ever more fortunate in the possession of an active and intelligent naturalist. The celebrated Pallas successfully devoted a long life to these pursuits, and to the communication of his discoveries and observations. He prompted the Empress Catharine to offer an unlimited sum for the museum, library, and manuscripts of Linnæus; but, fortunately for their present possessor, the offer was made too late. A *Flora Rossica*, on the most magnificent scale, was undertaken by Pallas, his Imperial mistress proposing to defray the cost of the whole undertaking, not merely for sale, but for gratuitous

Botany.

presentation, on the most princely scale, to all who had any taste or ability to make use of the book. This well-intended munificence was the cause of the ruin of the project. Half of a first volume was bestowed as the Empress intended. But the second part, instead of following the destination of the first, got into the hands of interested people, who defeated the liberal designs of their sovereign, misapplied her money, and by the disgust and disappointment which ensued, prevented the continuance of the work. Those who wished to complete their sets, or to obtain the book at all, were obliged to become clandestine purchasers, buying, as a favour, what they ought to have received as a free gift; and were moreover, like the writer of this, often obliged to put up with imperfect copies. In like manner the intentions of the great Mr Howard, respecting his book on prisons, were rendered ineffectual, by the disgraceful avarice of certain London booksellers, who immediately bought up, and sold at a greatly advanced price, the whole edition, which its benevolent author had destined to be accessible to every body at an unusually cheap rate. These examples, amongst others, show that it is the most difficult thing in the world to employ patronage, as well as gratuitous charity of any kind, to real advantage, except under the guidance of the most rigorous discretion. "All that men of power can do for men of genius," says Gray, if we recollect aright, "is to leave them at liberty, or they become like birds in a cage," whose song is no longer that of nature and enjoyment. The great and the affluent may foster and encourage science and literature, by their countenance, their attention, and a free, not overwhelming, liberality. But when princes become publishers of books, or directors of academies, they generally do more harm than good. They descend from their station, and lose sight perhaps of their higher and peculiar duties, which consist in promoting the general prosperity, peace, and liberty of their subjects, under the benign influence of which, every art, science, or pursuit, that can be beneficial to mankind, is sure to flourish without much gratuitous assistance.

of Germany;

Several of the immediate scholars of the illustrious Swedish naturalist were planted in different parts of Germany. Murray, to whom he entrusted the publication of that compendious volume, entitled, *Systema Vegetabilium*, and who printed two successive editions of the work, was seated as Professor at Gottingen. Giseke was established at Hamburgh, and, after the death of Linnæus, gave to the world such an edition as he was able to compile, from his own notes and those of Fabricius, of the lectures of their late preceptor, on the Natural Orders of Plants. His ideas on this subject Linnæus himself always considered as too imperfect to be published, except in the form of a sketch or index, at the end of his *Genera Plantarum*. The venerable patriarch, Professor Jacquin, still survives at Vienna, where he, and his worthy son, have enriched botany with a number of splendid and useful works. They have given to the public several labours of the excellent practical botanist Wulfen, and others, which might, but for their encouragement, have been lost. The highly valuable publication of Host on grasses, is conducted on the plan of Jacquin's works. His *Synopsis* of Austrian plants is an excellent *Flora*, disposed according to the Sexual System, as is the more ample *Tentamen Floræ Germanicæ* of the celebrated Dr Roth, one of the best practical European botanists, and more deeply versed than most others in cryptogamic lore. The best Linnæan *Flora*, as far as it goes, that the world has yet seen, we speak it without any exception, is the *Flora Germanica* of Professor Schrader of Gottingen, the first volume of which, comprising the first three classes of the sexual system, was published in 1806. The correct distinctions, well-digested synonyms, and complete descriptions of this work, are altogether unrivalled. If the whole should be equally well executed, for which the longest life would be scarcely sufficient, it must ever be the standard book of European botany. Its descriptions of grasses are worthy to accompany the exquisite engravings of the same tribe from the hand of Leers, published at Herborn in 1775, which excel every other botanical representation that we have examined. They will bear, and indeed they require, the application of a magnifying-glass, like the plants themselves. The purchaser of this little volume must however beware of the second edition, whose plates are good for little or nothing. The name of Schrader has long been distinguished in Cryptogamic Botany. In this pursuit, the industrious and accurate botanists of Germany, shut out from extensive opportunities of studying exotic plants, have had full scope for their zeal and abilities. In this field the Leipsic school has distinguished itself. Here the great Schreber first began his career with some of the most perfect cryptogamic works, especially on the minute genus *Phascum*. Here the same author published his excellent *Flora Lipsiensis*, his laborious practical work on Grasses, and finally his improved edition of the *Genera Plantarum* of his friend Linnæus. But, above all, Leipsic is famous for being the residence of Hedwig, whose discoveries, relative to the fructification and generic characters of Mosses, form an era in botanic science. Under the hands of such an observer, that elegant tribe displays itself with a degree of beauty, variety and singularity, which vies with the most admired herbs and flowers, and confirms the Linnæan doctrine of impregnation, which the more obvious organs of the latter had originally taught. Nor must we, in speaking of cryptogamic plants, neglect here to record the names of Weis, Weber, Mohr, Schmidel, Esper, and especially Hoffmann; the plates of the latter, illustrating the Lichen tribe, are models of beauty and correctness. His *Flora Germanica* is a most convenient and compendious manual, after the Linnæan system. *Fungi* have been studied in Germany with peculiar care and minuteness. The leading systematic author in this obscure tribe, Persoon, was indeed born, of Dutch parents, at the Cape of Good Hope; but he studied and published at Gottingen. Two writers, of the name of Albertini and Schweiniz, have published the most minute and accurate exemplification of this natural order, in an octavo volume, at Leipsic, in the year 1805, comprising the Fungi of the district of Niski in Upper Lusatia. If their fi-

gures are less exquisitely finished than Persoon's, or less elaborately detailed than Schrader's, their descriptions make ample amends.

The German school of botany has, for a long period, been almost completely Linnæan. This however was not always the case, for, in the earlier part of his career, the learned Swede was attacked more repeatedly and severely from this quarter of the world than any other; his ridiculous critic Siegesbeck of Petersburgh excepted, who would not admit the doctrine of the sexes of plants, because the pollen of one flower may fly upon another, and his purity could not bear the idea of such adultery in Nature. Numerous methods of arrangement appeared in Germany, from the pens of Heister, Ludwig, Haller, and others, and even Schreber adopted a system like some of these in his *Flora* above mentioned. It would be to no purpose now to criticise these attempts. They cannot rank as natural systems, nor have they the convenience of artificial ones. Part of their principles are derived from Linnæus, others from Rivinus. Their authors were not extensively conversant with plants, nor trained in any sound principles of generic discrimination or combination. They set off with alacrity, but were soon entangled in their own difficulties, and were left by Linnæus to answer themselves or each other. We here mention these learned systematics, for learned they were thought by themselves and their pupils, merely because they will scarcely require animadversion, when we come to canvass the great question of natural and artificial classification, they having had no distinct ideas of a difference between the two. Hedwig used frequently to lament, that his preceptor Ludwig had never perfected his system of arrangement; but from what he has given to the world, we see no great room to suppose he had any thing very excellent in reserve. Unexecuted projects are magnified in the mists of uncertainty. We have ventured elsewhere, in a biographical account of Hedwig, to remark, that even that ingenious man "did not imbibe under Ludwig, anything of the true philosophical principles of arrangement, the talents for which are granted to very few, and are scarcely ever of German growth. We mean no invidious reflections on any nation or people. Each has its appropriate merits, and all are useful together in science, like different characters on the theatre of human life."

Germany may well dispense with any laurels obtained by the very secondary merit of speculative schemes of classification, when she can claim the honour of having produced such a practical observer as Gærtner. This indefatigable botanist devoted himself to the investigation of the fruits and seeds of plants. Being eminently skilled in the use of the pencil, he has, like Hedwig, faithfully recorded, what he no less acutely detected. The path he struck out for himself, of delineating and describing in detail, with magnified dissections, every part of the seed and seed-vessel of each genus within his reach, had never been explored before in so regular and methodical a manner. Botanists of the Linnæan school are justly censurable for having paid too little attention to the structure of these important parts, in their generic characters. Indeed it may be said, that if they were able to establish good genera without them, and, after the example of their leader, merely preferred the more obvious and distinct organs, when sufficient for their purpose, their conduct was justifiable. If generic principles be natural and certain, it matters not on what parts of the fructification they are founded; nor is the inflorescence, or even the herb or root, rejected by sound philosophers, but because they are found to lead only to unnatural and uncertain characters. It is therefore extremely to the honour of Linnæus, Gærtner and Jussieu, that their conceptions of genera are almost entirely the same. They meet in almost every point, however different the paths by which they pursue their inquiries. Their labours illustrate and confirm each other. Even Tournefort, who conceived so well, on the whole, the distinctions of genera, which he could but ill define, receives new strength from their knowledge, which does not overturn his imperfect performances, but improve them. The accurate student of natural genera cannot fail to perceive, that where Gærtner differs from Linnæus, which is but in a very few material instances, such as his numerous subdivision of the genus *Fumaria*, and his distribution of the compound flowers, it arises from his too intent and exclusive consideration of one part of the fructification, instead of an enlarged and comprehensive view of the whole. In other words, he neglects the Linnæan maxim, that "the genus should give the character, not the character the genus." Such at least appears to us the case in *Fumaria*. In the syngenesious family, being so very natural in itself, the discrimination of natural genera becomes in consequence so difficult, that Gærtner and Linnæus may well be excused if they do not entirely agree, and they perhaps may both be satisfied with the honour of having collected materials, and disposed them in different points of view, for the use of some future systematic, who may decide between them. However exact Gærtner may have been in discriminating the parts of seeds, we believe him mistaken in distinguishing the *vitellus* as a separate organ, distinct in functions from the *cotyledons*. His readers will also do well, while they profit by his generally excellent principles, not to admit any of his rules as absolute. They may serve as a clue to the intricacies of Nature, but they must not overrule her laws. Still less is our great carpologist to be implicitly followed in physiological doctrines or reasonings; witness his feeble and incorrect attack on Hedwig's opinions, or rather demonstrations, respecting the impregnation of Mosses. His criticisms of Linnæus are not always marked with that candour which becomes a disinterested lover of truth and nature, nor can we applaud in general his changes of nomenclature, or of terminology; especially when he unphilosophically calls the *germen* of Linnæus, the *ovarium*, a word long ago rejected, as erroneous when applied to plants. These however are slight blemishes, in a reputation which will last as long as scientific botany is cultivated at all. Botanists can now no longer neglect, but at their own peril, the parts which Gærtner has called into notice, and to the scrutiny of which, directed by his faithful guid-

ance, the physiologist and the systematic must often, in future, recur.

of Prussia; We shall close this part of our subject with the mention of the Berlin school, where Gleditsch, who, in 1740, repelled the attacks of Siegesbeck on Linnæus, was Professor, and published a botanical system, founded on the situation, or insertion, of the stamens; the subordinate divisions being taken from the number of the same parts; so that it is, in the latter respect, a sort of inversion of the Linnæan method. In the former, or the outline of its plan, the system of Gleditsch is in some measure an anticipation of that of Jussieu. Berlin has of late been much distinguished for the study of natural history, and possesses a society of its own, devoted to that pursuit. Its greatest ornament was the late Professor Willdenow, who if he fell under the lash of the more accurate Afzelius, is entitled to the gratitude of his fellow-labourers, not for theoretical speculations, but for the useful and arduous undertaking of a *Species Plantarum*, on the Linnæan plan, being indeed an edition of the same work of Linnæus, enriched with recent discoveries. This book, left unfinished at the end of the first order of the *Cryptogamia*, by the death of the editor, wants only a general index to render it sufficiently complete. The *Musci*, *Lichenes*, and *Fungi*, are systematically treated in the separate works of writers devoted to those particular, and now very extensive, subjects, from whom Willdenow could but have been a compiler. With the *Filices*, which he lived to publish, he was practically conversant. His insertion of the essential generic characters, throughout these volumes, is an useful addition, and now become necessary in every similar undertaking.

of Holland; Little can be said of Holland in this review of the botanical state of Europe for a few years past. The Leyden garden has always been kept up, especially during the life of the late Professor David Van Royen, with due care and attention; we know little of its fate in the subsequent convulsed state of the country. Botany has long been on the decline at Amsterdam, though we are indebted to that garden for having first received, and afterwards communicated to other countries, such acquisitions of Thunberg in Japan as escaped the perils of importation.

of Switzerland; The botany of Switzerland may, most commodiously, be considered in the next place. Here, in his native country, the great Haller, after a long residence at Gottingen, was finally established. Its rich and charming *Flora* has been illustrated by his classical pen, with peculiar success. Every body is conversant with the second edition of his work, published in 1768, in 3 vols. folio, and entitled, *Historia Stirpium Indigenarum Helvetiæ*, with its inimitable engravings, of the *Orchis* tribe more particularly. But few persons, who have not laboured with some attention at the botany of Switzerland, are aware of the superior value, in point of accuracy, of the original edition of the same work, published in 1742, under the title of *Enumeratio Methodica Stirpium Helvetiæ Indigenarum*. This edition is indispensable to those who wish fully to understand the subject, or to appreciate Haller's transcendent knowledge and abilities. These works are classed after a system of his own, intended to be more consonant with nature than the Linnæan sexual method. We can scarcely say that it is so, on the whole; nor is it, on the other hand, constructed according to any uniformity of plan. The number of the stamens, compared with that of the segments of the corolla, or its petals, regulate the characters of several classes, and those are artificial. Others are assumed as natural, and are for the most part really so, but their characters are frequently taken from Linnæus, even from his artificial system, as the *Cruciatæ*, and the *Apetalæ*. Lord Bute has well said, that Haller was a Linnæan in disguise. His classification however was merely intended to answer his own purpose, with respect to the Swiss plants; for he was not a general botanist, nor had he a sufficiently comprehensive view of the subject to form a general system, or even to be aware of the difficulties of such an undertaking. He ought not therefore to be obnoxious to criticism in that view. His method has served for the use of his scholars, as the Linnæan one serves English botanists, by way of a dictionary. Some such is necessary; and those who should begin to decide on the merits of a system, before they know plants, would most assuredly be in danger of appearing more learned to themselves than to others. We cannot exculpate Haller from some degree of prejudice in rejecting real improvements of Linnæus, which are independant of classification; such as his trivial or specific names, by which every species is spoken of at once, in one word, mostly so contrived as to assist the memory, by an indication of the character, appearance, history, or use, of the plant. What did the great Swiss botanist substitute in the place of this contrivance? A series of numbers, burthensome to the memory, destitute of information, accommodated to his own book only, and necessarily liable to total change on the introduction of every new-discovered species! At the same time that he rejected the luminous nomenclature of his old friend and fellow-student, who had laboured in the most ingenuous terms to deprecate his jealousy, he paid a tacit homage to its merit, by contending that the honour of this invention was due to Rivinus. In this he was not less incorrect than uncandid, the short names of Rivinus being designed as specific characters, for which purpose Haller knew, as well as Linnæus, they were unfit. Useful specific characters he himself constructed on the plan of Linnæus, with some little variation, not always perhaps for the better, as to strictness of principle, but often strikingly expressive. Here, as in every thing connected with practical botany, he shines. The most rigid Linnæan, whose soul is not entirely shrivelled up with dry aphorisms and prejudice, must love Haller for his taste and enthusiasm, and the Flora of Switzerland as much for his sake as its own. No wonder that his pupils multiplied, and formed a band of enthusiasts, tenacious of even the imperfections of their master. The line of demarcation is now no longer distinctly drawn between them and the equally zealous scholars of the northern sage. The amiable and lamented Davall strove to profit by the labours of both. The Alpine botanists of France and Italy have served to amalgamate the Swedish and

Botany.

the Helvetian schools. The Flora of Dauphiny by Villars is nearly Linnæan in system, and the principles of the veteran Bellardi of Turin are entirely so; though he has been, in some of his publications, obliged to conform to the method of his late preceptor, the venerable Allioni, who in spite of all remonstrance, had the ambition of forming a system of his own. His *Flora Pedemontana* is disposed according to this system, an unnatural and inconvenient jumble of the ideas of Rivinus, Tournefort, and others. This work is also faulty in the neglect of specific definitions, so that its plates and occasional descriptions are alone what render it useful; nor would it perhaps, but for the uncommon abundance of rare species, be consulted at all.

Italy;

We may glance over the botany of Italy, to whose boundaries we have thus been insensibly led, as the eye of the traveller takes a bird's-eye view of its outstretched plains from the summits of the Alps. We may pass from Turin to Naples without meeting with any school of distinction. The northern states are not without their professors and patrons of botany, nor are their nobles destitute of taste, in various branches of natural knowledge. The names of a Castiglione of Milan, a Durazzo and Dinegro of Genoa, and a Savi of Pisa, deserve to be mentioned with honour, for their knowledge and their zeal. The unfortunate Cyrillo, and his friend Pacifico, at Naples, were practical botanists. There is also a rising school, of great promise, at Palermo. But since the time of Scopoli, Italy has contributed little to our stock of information; nor are the latter publications of this eminent man, while he resided at Pavia, commensurate in importance or merit with those earlier ones, the *Flora*, and *Entomologia*, *Carniolica*, which have immortalized his name. Scopoli, who at first adopted a system of his own, had the sense and liberality, in his second edition, to resign it, in favour of what his maturer experience taught him to prefer, the sexual system of Linnæus.

Spain and Portu-

Spain and Portugal claim our attention; the former for being the channel through which the gardens of Europe have been, for some years past enriched with many new Mexican and Peruvian plants; and likewise as the theatre of the publication of some important books, relative to the botany of those countries. In speaking of American botany, we have mentioned the *Flora Peruviana*, whose authors, Ruiz and Pavon, rank deservedly high for their industry and knowledge. The late Cavanilles, resident at Madrid, has also communicated to the learned world much information, from the same source. Spain seems anxious to redeem her reputation, which suffered so much from the neglect, or rather persecution, of the truly excellent but unfortunate Dombey, who, like many other benefactors of mankind, was allowed to make all his exertions in vain, and finally perished unknown, in the diabolical hands of English slave-dealers at Montserrat. Portugal is most distinguished at home by the labours of a learned benedictine, Dr Felix Avellar Brotero, author of a *Flora Lusitanica*, disposed after the Linnæan method, reduced entirely to principles of number; and abroad by the valuable work of Father Loureiro, entitled *Flora Cochinchinensis*, in which the plants of Cochinchina, and of the neighbourhood of Canton, are classed and defined in the Linnæan manner, with valuable descriptions and remarks. It is undoubtedly a disgrace to the possessors of such a country as Brasil, that they have not derived from thence more benefit to the world, or to themselves, from its natural productions. But they are satisfied with what the bowels of the earth afford, and they neglect its more accessible, though perhaps not less valuable, treasures. The jealousy, and innumerable restrictions of their government, render what they possess as useless to all the world as to themselves. A genius of the first rank in natural science, as well as in every thing which his capacious mind embraced, has arisen in Portugal, and has been domesticated in the schools of Paris and London, the amiable and learned Correa de Serra, now a traveller in the United States of America. What little impulse has been given to literature in Portugal, and particularly the foundation of a Royal Academy of Sciences, is owing to him; and though his name has chiefly appeared in the ranks of botanical science in an incidental manner, no one possesses more enlarged and accurate views, or more profound knowledge, of the subject.

English and French Schools.

In the extensive, though incomplete, review which we have undertaken of the recent history of botanical science, the individual merits of particular writers have chiefly hitherto been detailed and compared. The most difficult part of our task perhaps still remains; to contrast and to appreciate the influence and the merits of two great and rival nations, in the general school of scientific botany; to consider the causes that have led to the particular line which each has taken, and to compare the success, as well as to calculate the probable future consequences, of their respective aims. England and France have, from the time of Ray and Tournefort, been competitors in botanical fame, because each was ambitious of supporting the credit of the great man she had produced. This contest, however, as far as it regarded theoretical speculations, has entirely subsided on the part of Ray's champions. In practical science, likewise, the admirers of Ray and of Tournefort have shaken hands, like those of every other school. On the subject of system, the question is greatly changed; for though a phœnix has arisen from the ashes of Tournefort, its "star-like eyes," darting far beyond all former competition, have been met, if not dazzled, by a new light, rising in full glory from the north; a polar star, which has been hailed by all the nations of the earth.

England.

The Linnæan system of classification, with all its concomitant advantages of nomenclature, luminous technical definition, and richness of information, was planted, like a fresh and vigorous scyon, in the favourable soil of England, already fertilized with accumulations of practical knowledge, about the middle of the last century. If we may pursue the metaphor, the ground was entirely cleared for its reception; for all previous systems had been of confined and local use; the alphabetical index having become the resource of even the most learned; and the pupils of Ray, being held to his method of classification,

rather by their gratitude for his practical instruction, than any other consideration. Accordingly we have, in our own early progress, before they were all, as at present, swept off the stage, found them rather contending for his nomenclature, imperfect as it was, because they were habituated to it, than for his system, of which, it was evident, they had made little use. Hence the first attempt in England, to reduce our plants to Linnæan order, made by Hill, was chiefly a transposition of Ray's *Synopsis* into the Linnæan classes, the original nomenclature being retained, while the specific names of the *Species Plantarum* were rejected.

Hill's imperfect performance was superseded, by the more classical *Flora Anglica* of Hudson, composed under the auspices and advice of the learned and ingenious Stillingfleet, in which the botany of England assumed a most scientific aspect, and with which all the knowledge of Ray was incorporated.

Norwich.

At the same time, the principles of theoretical botany, and the philosophical writings of the learned Swede, were studied with no ordinary powers of discrimination and judgment, in a small circle of experienced observers at Norwich. A love of flowers, and a great degree of skill in their cultivation, had been long ago imported into that ancient commercial city, with its worsted manufacture, from Flanders; and out of this taste, something like the study of systematic botany had sprung. These pursuits were mostly confined to the humblest of the community, particularly among the then very numerous bodies of journeymen weavers, dyers, &c. Towards the middle of the eighteenth century, several of the opulent merchants seem to have acquired, by their intimate connection with Holland, not only the above-mentioned taste for horticulture, but likewise an ambition to be distinguished by their museums of natural curiosities. The former sometimes extended itself, from the flowery parterre, and the well-arranged rows of tulips, hyacinths, carnations, and auriculas, into no less formal labyrinths, or perhaps a double pattern of angular or spiral walks, between clipped hedges, exactly alike on each side of a broad gravel walk. Such was the most sublime effort of the art within the compass of our recollection. "Grove" could by no means be said to "nod at grove," for the perpendicular and well-trimmed structure was incapable of nodding; but that "each alley should have a brother" was an indispensable part of the design. Greenhouses of exotic plants, except oranges and myrtles, were at this time scarcely known; and the writer well recollects having seen, with wonder and admiration, above forty years ago, one of the first African Geraniums that ever bloomed in Norwich. If, however, the progress of natural science was slow in this angle of the kingdom, the wealthy manufacturers, become their own merchants, found it necessary to acquire a knowledge of various foreign languages, in order to carry on their wide-extended commerce. In learning French, Italian, Spanish, Dutch, and German, they unavoidably acquired many new ideas. Their sons were sent to the continent, and it were hard, indeed, if many of them did not bring home much that was worth learning. The society of the place, aided by some concomitant circumstances, and the adventitious acquisition of two or three men of singular talents and accomplishments, became improved. A happy mixture of literature and taste, for many years distinguished this city, above its rivals in opulence and commercial prosperity. Such Norwich has been in our memory, and if its splendour be gone by, a taste for mental cultivation, originating in many of the before-mentioned causes, still remains, and is fostered by the novel pursuits of chemistry and natural history, on which some arts, of great importance in the manufactory of the place, depend for improvement. We trust the reader will pardon this digression from the subject more immediately before us, to which we shall now return.

Some of the more learned students of English plants, among the lovers of botany in Norwich, had long been conversant with the works of Ray, and even the *Historia Muscorum* of Dillenius. They were prepared therefore to admire, and to profit by, the philosophical writings of Linnæus. Hence originated the *Elements of Botany*, published in 1775, by Mr Hugh Rose; who was aided in the undertaking by his equally learned friend, the Reverend Henry Bryant, of whose acuteness and botanical skill no better proof is wanting, than his baving found and determined, nine years before, the minute *Tillæa muscosa*, for the first time in this island. Numerous pupils were eager to improve themselves by the assistance of such masters, and amongst others the writer of these pages imbibed, from their ardour and their friendly assistance, the first rudiments of a pursuit that has proved the happiness and the principal object of his life.

London, Cambri[dge,] and Ox[ford.]

London became, of course, the focus of this science, as well as of every other. Of the English Universities, Cambridge most fulfilled its duty, in rendering its public establishments useful to the ends for which they were founded and paid. The names of Martyn, both father and son, have long maintained a distinguished rank in botany, and the latter, for many years, has inculcated the true principles of Linnæan science, from the professor's chair. A botanic garden was established, by a private individual, Dr Walker, about the period of which we are speaking. A Linnæan *Flora Cantabrigiensis*, by Mr Relhan, has renewed the celebrity of that field, in which Ray had formerly laboured; and there has always existed a little community of Cambridge botanists, though fluctuating and varying, according to circumstances. At Oxford, botany, so vigorously established by Sherard and Dillenius, slept for forty years under the auspices of the elder Professor Sibthorp, at least as to the utility of its public foundations. Yet even there the science had many individual cultivators, and if others were forgotten, the name of a Banks ought to render this school for ever celebrated. The younger Professor Sibthorp well atoned for the supineness of his father and predecessor. He published a *Flora Oxoniensis*, and extended his inquiries into the classical scenes of Greece, finally sacrificing his life to his labours, and sealing his love of this engaging study by a posthumous foundation, which provides for the publication of a sumptuous *Flora Græca*, and the subsequent es-

tablishment of a professorship of Rural Economy. Edinburgh, under the auspices of the late worthy Professor Hope, became distinguished for the cultivation of botany, as a branch of medical education. The physiology of plants was there taught, more assiduously than in almost any other university of Europe; and the Linnæan principles were ably enforced and illustrated, not with slavish devotion, but with enlightened discrimination. Nor must the dissenting Academy at Warrington be forgotten, where the distinguished circumnavigator Forster, of whom we have already spoken, was settled. Here many young naturalists were trained. The neighbouring family of the Blackburnes, possessed even to this day, of one of the oldest and richest botanic gardens in England, have steadily fostered this and other branches of natural knowledge. The same taste has spread to Manchester, Liverpool, and the country around. Westmoreland, Northumberland and Durham have their sequestered practical botanists, in every rank of life. Scenes celebrated by the correspondents of Ray are still the favourite haunts of these lovers of nature and science, who every day add something to our information, and to the celebrity of other parts of the same neighbourhood.

don ool.

We must now concentrate our attention to the London school, which, for about forty years past has maintained a rank superior to most other seats of botanical science; the more so perhaps for its being founded in total disinterestedness, both with respect to authority and emolument. Truth alone, not system, has been the leading object of this school; unbiassed and gratuitous patronage its support; and a genuine love of nature and of knowledge its bond of union, among persons not less distinguished from each other by character and opinion, than by their different pursuits, and various ranks of life. The illustrious Banks, from the time when, after his return from his celebrated and adventurous voyage, he devoted himself to the practical cultivation of natural science for the advantage of others, as he had long pursued it for his own pleasure and instruction, has been the head of this school. Here he fixed the amiable and learned Solander, for the remainder of his too short life. The house of this liberal Mecænas has ever since been, not only open, but, in a manner, at the entire command of the cultivators and admirers of this and other branches of philosophy; inasmuch as his library and museum have been devoted to their free use; and his own assistance, encouragement and information are as much at their service, as if his fortune and fame had all along depended on their favour. With such an establishment as this, aided by the perpetual resources of the numerous public and private gardens around, botany might well flourish. The liberal spirit of the leaders of this pursuit, gave a tone to the whole. The owners of nurseries, though depending on pecuniary emolument for their support, rivalled each other in disinterested communication. The improvement of science was the leading object of all. One of this latter description took his rank among the literary teachers of botany. Lee's *Introduction* was much approved by Linnæus, whose system and principles it ably exemplifies, and who became the friend and correspondent of its author. Travelling botanists were dispatched, under the patronage of the affluent, to enrich our gardens from the Alps, the Cape of Good Hope, and the various parts of America. Every new acquisition was scrutinized, and received its allotted name and distinction, from the hand of the correct and classical Solander, who one day was admiring with Collinson, Fothergill, or Pitcairn, the treasures of their respective gardens, and another labouring with the distinguished Ellis, at the more abstruse determination of the intricate family of marine productions, whether sea-weeds, corallines or shells. His own acquisitions, and those of his friend and patron, in the fairy land of the South-Sea Islands, the hazardous shores of New Holland, or the nearly fatal groves and swamps of Java, were at the same time recorded by his pen, as they were gradually perpetuating by the slow labours of the engraver. To this band of zealous naturalists the younger Linnæus was, for a while, associated, as well as the excellent and zealous Broussonet, who though not unversed in botany, devoted himself most particularly to the more uncommon pursuit of scientific icthyology.

The Banksian school, altogether intent upon practical botany, had adopted the Linnæan system as the most commodious, while it pursued and cultivated the Linnæan principles, as the only ones which, by their transcendent excellence, could support the science of botany on a stable foundation. In these Dr Solander was, of course, well trained; and, having added so wide a range of experience to his theoretical education, few botanists could vie with him, who had, as it were, caught his preceptor's mantle, and imbibed, by a sort of inspiration, a peculiar talent for concise and clear definition. Abstract principles of classification, or even such outlines of natural arrangement as Linnæus had promulgated, seem never to have attracted Solander. In following the chain of his ideas, discernible in the materials he has left behind him, one cannot but remark his singular inattention to every thing like botanical affinity, to which the artificial sexual system was, with him, entirely paramount. The genera which, for extemporaneous use, he named with the termination *oides*, comparing each with some well-known genus, till a proper appellation could be selected, are seldom thus compared because of any natural affinity, nor scarcely any external resemblance, but because they agree with such in their place in the artificial system, or nearly perhaps in technical characters. A great botanist therefore, it is evident, may exist, without that vaunted erudition in a peculiar line, which some would have us consider as the only road to knowledge and to fame. We allow that this sort of erudition is now, since the attention it has received from Linnæus, Jussieu, and others, become indispensable to a good theoretical or philosophical botanist, as is the study of carpology, in consequence of the labours of Gærtner; we only contend that it is possible to know plants extremely well without either.

The learned Dryander, less skilled than his predecessor as the coadjutor of Sir Joseph Banks, in a practical acquaintance with plants, exceeded him in theoretical lore and ingenious speculation, and far excelled every other man in bibliographic informa-

tion, as well as in the most precise fastidious exactness relative to every subject within the wide extent of his various knowledge. He furthered, upon principle, and with unwearied assiduity, every object of the noble establishment to which he was devoted; but he, like Solander, now sleeps with his fathers, and his place is supplied by a genius of British growth, who unites talents with experience, and theoretical skill, in the most eminent degree, with practical knowledge.

Although it is almost superfluous to name the most eminent disciples of the London school of botany, it might seem negligent to pass them over without some particular mention. The ardent and ingenious Curtis has left a permanent monument behind him, in the *Flora Londinensis*, to say nothing of the popular *Botanical Magazine*, continued by his friend Dr Sims. The *Flora Scotica* of Lightfoot first offered, in a pleasing and familiar garb, the botanical riches of that part of the island to its southern inhabitants. The lynx-eyed Dickson, so long and faithfully attached to his constant patron, has steadily traced, through all its windings, the obscure path of cryptogamic botany, with peculiar success. No more striking instance can be pointed out, to prove how totally the most consummate practical skill, even in the most difficult part of botany, is independent of theoretical learning. Even those who profit by the certain aids supplied by the discoveries of Hedwig, can with difficulty keep pace with this veteran in their pursuits, who, with conscious independence, neglects all those aids.

Museum and Library of Linnæus.

Just at the time when the school, whose history we are endeavouring to trace, had most firmly established its credit and its utility, a great additional weight was given to England, in the scale of natural science, by the acquisition of the entire museum, library and manuscripts of the great Linnæus and his son, which came amongst us, by private purchase, in 1784, after the death of the latter. Hence our nomenclature has been corrected, and our knowledge greatly augmented. These collections have necessarily been consulted by most persons, about to publish on the subject of natural history, and a reference to them, in doubtful cases, secures a general conformity of sentiment and nomenclature, among the botanists of Europe, Asia and America. We are seldom obliged to waste time in conjecturing what Linnæus, or the botanists with whom he corresponded, meant, for we have before us their original specimens, named by their own hands. An entire London winter was devoted to the almost daily labour, of comparing the Banksian herbarium throughout, with that of Linnæus, and to a copious interchange of specimens between their respective possessors, who, with the aid of Mr Dryander alone, accomplished this interesting and instructive comparison. Hence the *Hortus Kewensis* of the lamented Aiton, which was at that period preparing for publication, became much more correct in its names, than it, or any other similar performance, could have been, without this advantage. It could scarcely be imagined that Sweden would, unmoved, thus let the botanical sceptre pass from her; but it is much to the honour of the nation, that all her naturalists have ever preserved the most friendly intercourse with us, particularly with the person who deprived them of this treasure. They have not merely pardoned, but publicly sanctioned, the scientific zeal which prompted him to this acquisition, by associating him with all their learned establishments, without any solicitation on his part.

Linnæan Society.

The institution of the Linnæan Society at London in 1788, especially under that name, must be considered as a triumph for Sweden in her turn. By this establishment the intercourse of science is facilitated; essays, which might otherwise have never seen the light, are given to the world; and a general taste for the pleasing study of nature is promoted. Learned and worthy people are thus made acquainted with each other, from the remotest corners of the kingdom, and their information enriches the common stock. The state has given its sanction to this rising establishment. Its publications and its members are spread over the Continent, and other similar institutions have borrowed its name, imitated its plan, and paid respect to its authority. Yet it is not in the name alone of Linnæus, that the members of this society place their confidence; still less do they bow to that name or to any other, at the expense of their own right of private judgment. Their Transactions are open to the pupils of every school, and the observations of every critic, that have any prospect of being useful to the world. The writer of each communication, must, of course, be answerable for the particulars of his own performance, but the Society is responsible for each being, on the whole, worthy to be communicated to the public. The possession of the very materials with which Linnæus worked, his own specimens and notes, enable us very often to correct mistakes, even of that great man, many of which would be unaccountable without the means of thus tracing each to its source. At the same time, the acquisition of materials to which he never had access, tends to improve and augment the history of what he had left imperfect. His language, his definitions and characters were, for some time, held so sacred, that they were implicitly copied, even though manifestly inapplicable, in some points, to the objects to which they were referred. Synonyms were transcribed from his works by Rose, Hudson, Curtis, and even Gærtner, (we assert it on the positive proof of errors of the press, copied in the transcribing), without reference to the original books, to see whether such synonyms, or their accompanying plates, agreed with the plant under consideration. The example of Dr Solander first led the writer of this to avoid such a negligent and unfaithful mode of proceeding; yet he has ever considered as sacred the very words of Linnæus, where they require no correction. They are become a kind of public property, the current coin of the botanical realm, which ought not, with impunity, to be falsified or adulterated. To them we hope to be pardoned if we apply the words of the poet,

"The solid bullion of one sterling line,
Drawn to French wire, would through whole pages shine."

Of this it is needless to quote examples. We must be every day more and more sensible of the value of

the Linnæan style, in proportion as the number of those who can attain it is evidently so very small. By the light of our master alone can the science, which he so greatly advanced and refined, be preserved from barbarism, while long and tedious, loose and feeble, ill-contrasted and barbarously-worded definitions, press upon it from various quarters. New terms are invented to express old ideas; names and characters are changed for the worse, to conceal the want of new discoveries; and students are often deterred from adopting real improvements, because they know not which guide to prefer.

From the combined effects of the various causes which we have endeavoured to trace, the study of botany in England has, for a long period, been almost entirely practical. To determine the particular species intended, in every case, by Linnæus; to distinguish and to describe new ones; to improve scientific characters, and to correct synonyms; these have been the objects of our writers; and hence many publications of great utility, especially a number of critical and descriptive essays, in the Transactions of the Linnæan Society, not unworthy of the school which gave them birth, have enriched the general stock of knowledge. These are the sound fruits of skill and investigation, the solid advantages of real information, applied to practical use. They are independent of theoretical speculation, and will stand unshaken, amidst any possible changes of system. On such principles the *Flora Britannica* has been attempted, and continued as far as the present unsettled state of some of the latter orders, of the last class, will allow. Such impediments, which depend on the difficulties of systematic discrimination, among the Lichens especially, it is hoped will soon be removed. Meanwhile the *English Botany* of the same writer, illustrated by Mr Sowerby's expressive and scientific figures, has finished its course, and formed so nearly complete a body of local botany, as, we believe, no other country has produced. In this the liberal contributions of numerous skilful observers, from the Alpine heights of Scotland to the shores and circumambient ocean of the south, are preserved and recorded; evincing a degree of general inquiry and acuteness, which hardly any nation can rival. The memory of several benefactors to the science, otherwise in danger of passing away, is embalmed in this national work, which serves at once as their botanical testament, and the monument of their fame. Some of our botanists of the present day have thrown great light on several of the most obscure departments of the science; witness Mr Sowerby's work on *English Fungi;* the labours of the learned Bishop of Carlisle on *Carices*, and, in conjunction with Mr Woodward, on *Fuci;* of Mr Dawson Turner on the latter tribe, and on the *Musci* of Ireland; but especially Mr Hooker's inimitable display of the British *Jungermanniæ*. Nor shall the contributions of a Winch or an Abbot, a Withering, Knapp, Stackhouse or Velley, nor the more splendid labours of the indefatigable Lambert, be forgotten. Each, in one way or other, has enlarged the bounds of science, or rendered it easier of access. We cannot, in the compass of our present undertaking, pay the tribute due to every individual, our aim being a general picture of the whole. From what we have said, the zeal with which this lovely science has been cultivated in England, will sufficiently appear. Nor have public lectures, or botanic gardens, been neglected, in order to render the knowledge of botany as accessible as possible, and to diffuse a taste for its pursuit. The popularity of the study has, at least, kept pace with the means of instruction. The garden and green-house, the woods, fields, and even the concealed treasures of the waters, are now the resource of the young and the elegant, who in the enjoyment of a new sense, as it were, in the retirement of the country, imbibe health, as well as knowledge and taste, at the purest of all sources.

France alone now remains to be considered, in order to finish the historical picture which we have undertaken, of the state of botanical science in Europe. To do justice to this part of our subject, we must turn our attention to times long since gone by, or we shall scarcely render intelligible the state of affairs at present.

The great Tournefort, by the force of his character, his general and particular information, the charms of his pen, and the celebrity which his name gave to his country, through the popularity of his botanical system, was so firmly established, in the ideas of the French, as the *Grand Monarque* of botany, that they would have as soon allowed the greatness of Louis XIV. to be questioned, as that of this distinguished philosopher. So beneficial was this partiality, in some respects, that it gave an unprecedented impulse and popularity to the science; so disadvantageous was it in others, that it placed a formidable barrier in the way of all improvement. Vaillant, the able and worthy pupil of Tournefort, has never been forgiven for speaking, on some occasions, too freely of his master's defects. Hence his own merit has been kept in the background. The doctrine of the sexes of plants was discountenanced as long as possible, because it was proved by Vaillant, after having been rejected by Tournefort. Nevertheless, when the good seed of science is once sown, it can hardly be totally suffocated by the impediments of prejudice and ignorant partiality. Practical zeal sprung up by the side of speculative jealousy, and the tares withered, while the profitable plants flourished. Some botanists followed the steps of Tournefort to the Levant, exploring afresh those countries which he has forever rendered classic ground. Others visited America, which they traversed in different directions. The indefatigable Plumier performed three separate voyages to the western world, and though his discoveries have, in a great measure, suffered shipwreck from tardy and imperfect patronage, as a great part of his collections did, by the accidents of nature, yet something of value remains. His *Filices* are enough to insure his perpetual remembrance, and his *Nova Genera* are the basis of our knowledge of generic differences in West Indian plants. Most of all has been distinguished, among the French botanists who succeeded the times of Tournefort and Vaillant, the family of the Jussieus. One of these investigated the prolific regions of Peru, and discovered some things which no succeeding traveller has ga-

thered; other branches of this family, besides being eminent in medical science and practice, have pursued the study of botany with no ordinary success, on the most philosophical principles. Of these the most eminent are the celebrated Bernard de Jussieu, the contemporary of the earlier days of Linnæus; and his nephew Antoine Laurent de Jussieu, the pride and the ruler of systematic botany at present in France. The views and the performances of these great men lead us to a new branch of our subject, which indeed we have had in our contemplation from the beginning of this essay, the exposition of the principles of a natural scheme of botanical classification, as hinted, and imperfectly sketched, by Linnæus, and brought to the perfection of a regular system by the Jussieus.

Linnæan School in France.

Previous to our entering on this detail, and the remarks to which it will give rise, we must conclude all that belongs to the former part of our undertaking, by giving some account of those botanists who have formed and maintained a Linnæan school in France. We must shelter ourselves under the broad banner of truth when we observe that these have, till very lately, been almost the only French botanists that have supplied us with any practical information; and their labours have been useful in proportion as they have commendably shaken off the prejudices of their predecessors. Of this last proposition Duhamel is a witness, though we may perhaps excite some surprise in classing him among Linnæan botanists. His preface to his *Traité des Arbres* sufficiently shows how fearful he was of being taken for such, and yet how he was held by vulgar prejudice alone, to the nomenclature, or rather the generical opinions of Tournefort. He tells us, while he adopts these, that his judgment went with Linnæus, whom he follows in all new discoveries. The plan of his book, confined to hardy trees and shrubs, justifies his use of an alphabetical arrangement, in preference to any system, unless he had thought sufficiently well of Tournefort's to prefer that. But he has prefixed to his work, as a practical method of discovering scientifically what it contained, no other than a sexual classification. His practical botany was so limited, being entirely subservient to his great objects, of forest planting and vegetable physiology, that he had no attention to spare for the consideration of methodical systems. Accordingly he tells us, that some such is necessary for the use of botanists, especially of those who explore the productions of foreign countries, but whether the method of Ray, Tournefort, Boerhaave, Van-Royen, Linnæus, or Bernard de Jussieu be adopted, is of no importance. Six years before Duhamel's work came out, Dalibard had published, in 1749, his *Floræ Parisiensis Prodromus*, according to the Linnæan system.

It has always appeared to the writer of this, from the conversation and writings of French botanists, that the judgment of the learned Le Monnier, and the countenance of his patron the Duke D'Ayen, afterwards Marechal de Noailles, first established the reputation of Linnæus in France; not so much possibly for the sake of his system, as his discoveries, his commodious nomenclature, and his clear principles of discrimination. When Le Monnier botanized in Chili, in the company of the astronomers with whom he was associated, he soon found, like Dr Garden in South Carolina, that the classification of Tournefort was no key to the treasury of a new world. He however made his remarks and collections, and studied them subsequently under the auspices of a more comprehensive guide. The Marechal de Noailles, a great cultivator of exotic trees and shrubs, corresponded with the Swedish naturalist, and endeavoured to recommend him to the notice of the lovers of plants in France. Meantime Gerard and Gouan in the south, both introduced themselves to the illustrious Swede, and promulgated his principles and discoveries, though only the latter adopted his classification. Villars we have already noticed as the author of a Linnæan *Histoire des plantes de Dauphiné*. He died lately, Professor of Botany at Strasburgh, where he succeeded the very able and philosophical Hermann, one of the truest Linnæans, who had imbibed all the technical style of the Swedish school, as well as its accuracy of discrimination. We may now safely announce Hermann as the real author, in conjunction perhaps with Baron Born, of that ingenious but bitter satyr the *Monachologia*, in which the several *species* of monks are affectedly discriminated, and their manners detailed, like the animals in the Linnæan *Systema Naturæ*. This ludicrous performance has long since appeared in a, not very exact, English translation, and was rendered into French by the late M. Broussonet. As we are led again to name this amiable man, too soon lost to his country, after experiencing every vicissitude of revolutionary peril and alarm, we cannot help distinguishing him as one most zealous in the cultivation and diffusion of Linnæan learning, a taste for which he chiefly imbibed in England. He had no indulgence for those prejudices, which cramped the talents of his countrymen, and prevented their deriving knowledge from any quarter where it was to be had. He recommended the younger Linnæus to their personal acquaintance and favour, which service he also rendered, a few years after, to the person who now commemorates his worth, and who will ever remember, with affection and regret, his many virtues, his agreeable converse, and his various and extensive acquirements.

The intimacy which subsisted between this enthusiastic naturalist and the distinguished botanist L'Heritier, confirmed, if it did not originally implant, in the mind of the latter, that strong bias which he ever showed for the Linnæan principles of botany. According to these his numerous splendid works are composed. He moreover imbibed, if we mistake not, from the same source, a peculiar preference for uncoloured engravings of plants, instead of the coloured ones which had long been in use. It cannot be denied that the merit of these last is very various, and sometimes very small. They do, nevertheless, present to the mind a more ready idea of each species, than a simple engraving can do, nor is the latter less liable to incorrectness. When plates are taken from the delineations of such exquisite artists as L'Heritier employed, they have a good chance of excellence; but the engravings of

Cavanilles, done after miserable drawings, though they deceive the eye by their neat finishing, are really less exact than many a rude outline. Coloured plates, if executed with the uniformity and scientific exactness of Mr Sowerby's, or the characteristic effect of Jacquin's, speak to the eye more readily than most engravings. The art of printing in colours, practised formerly in England with small success, was revived at Paris by Bulliard, and is carried to the highest perfection in the recent publications of Redouté and Ventenat, which leave hardly any thing to be wished for, with respect to beauty or exactness. Many of the works of L'Heritier have remained imperfect, in consequence of the political convulsions of his country, and his own premature death. The learned and worthy Desfontaines, who travelled in Barbary, has been more fortunate in the completion of his labours. His elegant *Flora Atlantica*, in 2 vols. 4to, with finely engraved uncoloured plates, is classed and modelled on the plan of the Linnæan school. Such also is the plan of the works of that distinguished botanist La Billardiere, who, besides his account of New Holland plants, has published five elegant *decades* of new species from Syria. That scientific horticulturist M. Thouin, likewise a most excellent botanist, though he has scarcely written on the subject, is a correct pupil of the Swedish school. His general spirit of liberal communication, and his personal attachment to the younger Linnæus, led him to enrich the herbarium of the latter, with the choicest specimens of Commerson's great collection, destined otherwise to have remained in almost entire oblivion. A singular fate has attended the discoveries of most of the French voyagers, such as Commerson, Sonnerat, and Dombey, that, from one cause or other, they have scarcely seen the light. So also it has happened to those of Tournefort, Sarrazin, Plumier, and others, whose acquisitions have long slept in the Parisian museums. Happily there seems to have arisen of late a commendable desire to render them useful by publication, and thus many fine plants, known merely by the slight and unscientific appellations of Tournefort, and therefore never adopted by Linnæus, have recently been clearly defined, or elegantly delineated. The journeys of Olivier and Michaux towards the east have enriched the Paris gardens, and been the means of restoring several lost Tournefortian plants. We believe however that the English nurseries have proved the most fertile source of augmentation to the French collections, as appears by the pages of all the recent descriptive writers in France.

We dare not presume to arrange the indefatigable and very original botanist Lamarck among the Linnæan botanists of his country, but we beg leave to mention him here, as one who has thought for himself, and whose works are the better for that reason. His severe and often petulant criticisms of the Swedish teacher, made him appear more hostile than he really was, to the principles of that great man. Being engaged in the botanical department of the *Encyclopédie Méthodique*, he was obliged to conform to an alphabetical arrangement; but he surely might have chosen the scientific generic names for that purpose, instead of barbarous or vernacular ones, which, to foreigners, would have made all the difference, between a commodious and an unintelligible disposition of his work. In the detail of his performance, he has great merit, both with respect to clearing up obscure species, or describing new ones, and he had the advantage of access, on many occasions, to Commerson's collection. Lamarck's *Flore Françoise*, is arranged after a new analytical method of his own. This book however is valuable, independent of its system, as an assemblage of practical knowledge and observation. We have only to regret a wanton and inconvenient change of names, which too often occurs, and which is not always for the better; witness *Cheiranthus hortensis*, instead of the long established *incanus* of Linnæus; *Melampyrum violaceum*, which is not correct, for *nemorosum*, which is strictly so, and which preserves an analogy with the rest of the species.

We shall now undertake the consideration of the principles that have been suggested, and the attempts that have been made, respecting a

Natural Classification of Plants.

Sexual System.

The sexual system of Linnæus lays no claim to the merit of being a natural arrangement. Its sole aim is to assist us in determining any described plant by analytical examination. The principles on which it is founded are the number, situation, proportion, or connection, of the stamens and pistils, or organs of impregnation. These principles are taken absolutely, with the sole exception of their not being permitted to divide the genera, that is, to place some species of a genus in one part of the system, and others in another, though such may differ in the number, situation, proportion, or connection of their stamens or pistils; those characters being possibly artificial, while the genera are supposed, or intended, according to a fundamental law independent of all systems, to be natural assemblages of species. We need not here explain the mode in which Linnæus has provided against any inconvenience in practice, resulting from such anomalies of nature herself.

But though this popular system of Linnæus does not profess to be a natural method of classification, it is, in many points, incidentally so, several of its classes or orders whose characters are founded in situation, proportion, or connection, being more or less perfectly natural assemblages; nor can it be denied that, on the whole, it usually brings together as many groups of natural genera, as occur in most systems that have been promulgated. This fact would be more evident, if the various editors of this system, those who have added new genera to the original ones of Linnæus, or, in general, those who have any way applied his method to practice, had properly understood it. They would then have perceived that its author had always natural affinities in view; his aim, however incompletely fulfilled, according to our advanced knowledge, having constantly been, to place genera together in natural affinity or progression, as far as their relationship could be discerned. At the same time he uses an analytical method, at the head of each class in his *Systema Vegetabilium*, in which the genera are dis-

posed according to their technical characters. Murray, in compiling the fourteenth edition of that work, has been inadvertent, respecting this essential part of its plan. Indeed it is probable that he was not competent to judge of the affinities of the new genera, introduced from the *Supplementum*, or from the communications of Jacquin, Thunberg, &c. Yet surely he might have perceived the affinity of *Banksia* to *Protea*, rather than to *Ludwigia* or *Oldenlandia*; and indeed Linnæus himself ought to have discovered the relationship of the latter to *Hedyotis*, if he did not detect their identity, instead of inserting it between two such strict allies of each other as *Ludwigia* and *Ammannia*. To pursue these remarks would be endless. It is hardly necessary to indicate the natural classes, or orders, of the Linnæan system, such as the *Tetradynamia*, *Didynamia*, *Diadelphia*, *Syngenesia*; the *Triandria Digynia*, *Gynandria Diandria*, &c. Except the first-mentioned class, which, if *Cleome* be removed, is strictly natural and entire, the others are liable to much criticism. We are almost disposed to allow, what we know not that any one has yet observed, that the system in question is the more faulty in theory, for these classes being so natural as they are. Each order of the *Didynamia* presents itself as a natural order, though the character of that class, derived from the proportion of the stamens, serves to exclude several genera of each order, and to send them far back, into the second class. If all ideas of natural affinity be discarded from our minds, there is no harm whatever in this; but if the *Didynamia* claims any credit, as a class founded in nature, the above anomaly is a defect. So, still more, under the same point of view, is the *Diadelphia*, or at least its principal order *Decandria*, liable to exception. This order consists entirely of the very natural family of *Papilionaceæ*. They are characterized as having the ten stamens in two sets. Now it happens that there are many papilionaceous genera, indeed a great number of such have been discovered since Linnæus wrote, whose ten stamens are all perfectly distinct. These therefore are necessarily referred to the class *Decandria*, and they come not altogether amiss there, because they meet, in that class, some concomitant genera, which though, like them, leguminous, are less exactly, or scarcely at all, papilionaceous. But the greatest complaint lies against some genera of the *Diadelphia Decandria*, for having the stamens all really combined into one set, so as in truth to answer to the technical character of the preceding class, *Monadelphia*. There is mostly indeed some indication of a disunion upward, where they, more or less perfectly, form two sets; and some of them are so nearly diadelphous, that their complete union at the bottom may easily be overlooked; others, however, have only a fissure along the upper side of their common tube, without any traces of a separate stamen or stamens. The papilionaceous character of the *corolla* therefore, in such cases, is made to overrule that of the particular mode of union among the stamens, and is in itself so clear, as seldom to be attended with any difficulty; but the incorrectness of principle in the system, in the point before us, as being neither professedly natural, nor exactly artificial, cannot be concealed. Part of the objections, to which the sexual system was originally liable, have been obviated. We mean what concerns the last class but one, *Polygamia*. Dr Forster observed, in his voyage round the world, that this class was subject to great exception, on account of the trees of tropical climates, so many of which are constantly or occasionally polygamous; that is, each individual frequently bears some imperfect flowers, male or female, along with its perfect or united ones. Such a circumstance reduces any genus to the class *Polygamia*; and on this principle Mr Hudson, thinking perhaps that he made a great improvement, removed our *Ilex Aquifolium*, or Holly, thither, though *Ilex* is well placed by Linnæus in the fourth class. The author of the present essay has ventured to propose a scheme, which is adopted in his *Flora Britannica*, for getting clear of this difficulty. He considers as polygamous such genera only as, besides having that character in their organs of impregnation, have a difference of structure in the other parts of their two kinds of flowers. Thus *Atriplex* has, in its perfect flowers, a regular spreading calyx, in five equal segments; in the attendant female ones a compressed one, of two leaves, subsequently much enlarged.

The genera thus circumstanced are so very few, as far as we have discovered, that possibly the class might, but for the uniformity of the system, be abolished. We cannot indeed tell what future discoveries may be made; and its character, on the above foundation, is sufficiently clear and permanent; for flowers of an essentially different configuration, can hardly vary into each other. The orders of the last class of the Linnæan system, *Cryptogamia*, are natural, and preserved, all nearly the same, by every systematic projector. The original appendix to this system, the *Palmæ*, would be a great blemish therein, as an artificial arrangement: for such an arrangement ought to be so formed as to admit every thing, on some principle or other. But this stumbling-block is now removed. The palm tribe were placed thus by themselves, merely till their fructification should be sufficiently known. Now they are found to agree well with some of the established classes and orders, where they meet with several of their natural allies.

Natural Classification of Linnæus.

Whatever advantages might accrue to the practical study of botany, from the convenience and facility of his artificial system, Linnæus was from the beginning intent on the discovery of a more philosophical arrangement of plants, or, in other words, the classification of nature. This appears from the 77th aphorism of the very first edition of his *Fundamenta Botanica*, published in 1736, where he mentions his design of attempting to trace out fragments of a natural method. In the corresponding section of his *Philosophia Botanica*, he, fifteen years afterwards, performed his promise; and the same *Fragmenta*, as he modestly called them, were subjoined to the 6th edition of his *Genera Plantarum*, the last that ever came from his own hands. The interleaved copies of these works, with his manuscript notes, evince how assiduously and constantly he laboured at this subject, as long as he lived. He was accustomed to

deliver a particular course of lectures upon it, from time to time, to a small and select number of pupils, who were for this purpose domesticated under his roof. What this great botanist has himself given to the world, on the subject under consideration, is indeed nothing more than a skeleton of a system, consisting of mere names or titles of natural orders, amounting in his *Philosophia* to 67, besides an appendix of doubtful genera; and that number is, in the *Genera Plantarum*, reduced to 58.

Under the title of each order, the genera which compose it are ranged according to the author's ideas of their relationship to each other, as appears by some of his manuscript corrections; and some of the orders are subdivided into sections, or parcels of genera more akin to each other than to the rest. He ingenuously avowed, at all times, his inability to define his orders by characters. He conceived that they were more or less connected with each other, by several points of affinity, so as to form a map, rather than a series. The experienced botanist, who peruses the above-mentioned *Fragmenta*, will in most cases readily imbibe the ideas of their author, as to the respective affinities of the genera. In some few instances, as the *Dumosæ*, where he avows his own doubts, and the *Holeraceæ*, where he is unusually paradoxical, it is more difficult to trace the chain of his ideas. Such however was all the assistance he thought himself competent to afford. His distinguished pupils Fabricius and Giseke fortunately took notes of his lectures on natural orders; and by the care of the latter, to whom Fabricius communicated what he had likewise preserved, their joint acquisitions have been given to the public, in an octavo volume at Hamburgh, in 1792. Nor was this done without the permission of their venerable teacher, who told Giseke by word of mouth, when they took leave of each other, that "as he loved him, he had laboured with pleasure in his service;" adding, that "Giseke was at liberty to publish, whenever he pleased, any thing that he had retained from his own instructions."

Linnæus, according to a conversation with Giseke, recorded in the preface of the volume edited by the latter, declined to the last any attempt to define in words the characters of his orders. His reason for this appears in his *Classes Plantarum*, where he justly remarks, that no certain principle, or key, for any such definition can be proposed, till all the orders, and consequently all the plants, in the world are known. He has however so far expressed his opinion, in the work last quoted, as to point out the situation of the seed itself, with respect to other parts, and the situation and direction of its vegetating point, or *corculum*, as most likely to lead to a scheme of natural classification. Hence the system of Cæsalpinus stood very high in his estimation. He also, in the conversation above-mentioned, divides his own orders into three sections, or classes, *Monocotyledones*, comprising the first ten orders, with the 15th: *Dicotyledones*, (with two or more cotyledons), the 11th to the 54th order, inclusive, except the 15th; and *Acotyledones*, order 55th to 58th, with a hint that the last, or *Fungi*, ought perhaps to be altogether excluded. This distribution of plants, by the number or the absence of the cotyledons, or lobes of the seed, is the great hinge of all the professedly natural modes of arrangement that have been attempted. We shall for the present not enter on the consideration of this principle, as it will more properly be explained when we examine the system of Jussieu. Linnæus did not consider it as absolute, for he told Giseke that he knowingly admitted into his 11th order some plants that are monocotyledonous, with others that are dicotyledonous. The reason of this was the only secret he kept from his pupil, nor could the latter ever dive into it, though he afterwards endeavoured to learn it from the younger Linnæus, who knew nothing, neither did he, as Giseke says, much care, about the matter. We hope to be able to throw some light upon this mystery, when we come to the order in question.

The want of any avowed principle of distinction, precludes all criticism of these natural orders of Linnæus, as a regular system; we can therefore only take a cursory view of them as they follow each other, with such indications of their characters as Giseke has recorded, or as we may ourselves be able to trace. A great part of the substance of the lectures, published by him, consists of remarks on the genera of each order, as to their mutual distinctions; with numerous botanical and even economical matters, which do not all come within the compass of our present consideration. What we have to lay before the reader is not, in any manner, forestalled, by what he will find in the fourth volume of the Encyclopædia, above cited, which is taken from a different source.

Linnæus's exposition of his Natural Orders.

Order 1. Palmæ. "An entirely natural, and very distinct order." This tribe of plants, stationed by nature within the tropics, is considered by Linnæus as the original food of man; still supplying the place of corn to the inhabitants of tropical countries. Palms are the most lofty of plants, and yet it is a matter of doubt whether they ought to be called trees or herbs. They do not form wood in concentric circles, year after year, like our trees, though they are extremely long-lived. The author of the sexual system was, as we have just mentioned in speaking of that system, but little acquainted at first with the structure of the flowers of palms, or the number of their stamens or pistils. His predecessors in the establishment of genera of plants, Tournefort and Plumier, had published little or nothing illustrative of this tribe. He had himself seen no more than three or four species in fructification, nor had he any other resource, in founding genera, than the plates of the *Hortus Malabaricus*, (excellent indeed, but not delineated with any particular view of this kind,) and the less complete representations of Rumphius. The growth of these plants is quite simple. Each terminates in a bud, of a large size, called the heart, or by voyagers in general the cabbage, of the palm. When this is cut off, the tree dies, though the growth of many centuries. This bud has a gradual and nearly continual vegetation, unfolding its leaves, which Linnæus rather incorrectly terms fronds, one after another in succession, not all at any particular season. The bud therefore is perennial, not, as in our trees, annual, nor can it, for

this reason, be renewed. Fresh buds, in time becoming trees, are furnished from the generally creeping, perennial, and deeply descending roots. What have commonly been denominated the branches of Palms, Linnæus very properly declined calling so, because they never increase by producing lesser branches. He objected to calling them leaves, "because they are each attended by no separate annual bud, neither have they the texture of ordinary leaves, nor do they wither and fall off at any particular season." He adopted the term *frond*, which he always used when he could not decide whether the part in question were a branch, leaf, or stem. We cannot but think these are truly leaves, though it must be confessed they differ from the generality of such, in being destitute of any line of separation by which they are capable of falling, or being thrown off, from the stem. In this they agree with the foliage of *Musci* and *Jungermanniæ;* there being a perfect continuity of substance throughout. The hardened torn fibres, or rather vessels, which remain on the stems of palms, where the leaves have once been, are precisely the same as what occur in various mosses; and something similar may be observed in many liliaceous plants and their allies, which approach to the nature of palms.

In describing the fructification of this order, Linnæus considered as belonging thereto, what we should presume to be rather the inflorescence. Hence the great branching flowerstalk retains, in a technical sense, the name of *spadix*, derived from the ancients; and its ample containing sheath is denominated a *spatha*. The latter is reckoned a kind of calyx, as the former a sort of branched common receptacle. Linnæus strengthens his terminology in this case, by tracing an analogy between the *spatha* of palms, and the glume of grasses. We doubt whether any such particular analogy exists. Neither does his other comparison, of the part in question to the sheath of a *Narcissus* and its allies, at all, as far as we can judge, elucidate or confirm his principle. He surely swerves in these instances, as well as in his generic distinctions of the umbelliferous plants, from the correctness of an axiom, on which botany as a philosophical science depends, that generic characters, and much more those of classes and orders, should be exclusively derived from the parts of fructification. Surely a very slight consideration of the flowers and fruits of the *Palmæ*, as we have become acquainted with them since the time of Linnæus, will abundantly satisfy any person, that they afford clear characters, on which to found a sufficient number of distinct and very natural genera. Even that author, in the lectures before us, records that some genera have a three-leaved *calyx*, others none at all; some have a *corolla* of three, others one of six, petals; most have six *stamens*, some three, others nine, while the *Nipa* of Thunberg has only one. The *germens* are three in some, solitary in others, and the *style* and *stigma* are subject to like diversity in different genera. The *fruit* is in some, as the *Phœnix dactylifera*, or Date, a single drupa, in others composed of three; in some, like the Cocoa, a nut with a coriaceous coat. The *seeds* are mostly solitary, but in several instances two or three in each fruit. Hence, while the fructification affords sufficient materials for discriminating genera, Linnæus observes that no common character, exclusively descriptive of the whole order, can be founded upon it. The reader will find the essential characters of his genera in our Vol. IV. 288. His *Zamia*, concerning which he avowed considerable doubts, chiefly because it wanted a *spatha*, is now, by common consent among botanists, removed either to the Ferns, or to an intermediate order between them and the Palms, to which also *Cycas* belongs. The technical characters which have induced this alteration, are confirmed by circumstances attending the habit and qualities of these genera.

At the end of his proper *Palmæ*, Linnæus subjoins, in a distinct section, three genera, which he was doubtful whether to leave there, or to establish as a distinct order. These are *Stratiotes*, *Hydrocharis*, and *Valisneria*. He remarks in his lectures that "they have a *spatha* extremely like the palms; a calyx of three leaves, and a corolla of three petals; leaves perennial and evergreen, folded when they first come forth. *Hydrocharis* cannot be separated from *Stratiotes*, nor *Valisneria* from *Hydrocharis*. They produce their leaves crowded together at the base, like Ferns. Although their strict affinity with the larger Palms of India cannot be demonstrated, they ought nevertheless to be associated therewith. They are all aquatics, whence we may presume that India may afford some aquatic palms, smaller than the others, which may prove a connecting link between the latter and the plants of which we are speaking." Giseke points out several palms, in various authors, which though but imperfectly ascertained, confirm this conjecture of his preceptor. Linnæus in his own copy of the *Genera Plantarum*, enriched with his manuscript notes, to which we shall often refer, has marked this section, or appendage, of his *Palmæ*, as distinguished by "an inferior fruit, with many seeds." He has moreover added 4 genera to this assemblage, *Pandanus*, *Bromelia*, *Tillandsia*, and *Burmannia*. Giseke has amply illustrated the order of *Palmæ*, by observations of his own, or those of various writers; but the most solid acquisitions to our knowledge, in this interesting tribe, are derived from the labours of Dr Roxburgh, in his *Plants of Coromandel*.

Order 2. Piperitæ. "The plants of this order have an acrid flavour, whence the name." They afford no common character to discriminate the order, except possibly the elongated receptacle and sessile anthers, but some *amentaceæ* have the same. They consist of *Zostera*, *Arum* and its allies, *Orontium*, *Acorus*, *Piper*, and *Saururus*. The last is removed by Linnæus in his manuscript to his 15th order.

Order 3. Calamariæ. "These are closely related to the true grasses, and have almost the same kind of leaves. Their seed is solitary and naked; stamens three; style one, not unfrequently three-cleft at the summit. Their glume is of one valve (whereas most grasses have two valves), except *Schœnus*, which bears several valves irregularly disposed, though in other respects so near the rest of its order, as scarcely to be distinguished without accurate examination of the parts alluded to. The stem of these plants is

a *culm*, mostly triangular, rarely round, often leafless, or nearly so. Leaves rather rigid and rough. Flowers often disposed in an imbricated manner. Seed in a few instances surrounded with bristles. When these are extended into a kind of wool, hanging out beyond the scales, such a character marks the genus *Eriophorum*." Linnæus asserts that "*Scirpus* differs from *Carex*, in having all the flowers united, whereas in the latter some scales are accompanied with stamens only, others with pistils;" but he forgot the tunic, or *arillus*, of the seed, which makes the essential and clear character of *Carex*. He mistakes also in supposing the stamens are always three in this order; in several instances they are but two, in a few they are solitary. Much has been done respecting the genera and species of this order by Rottboll, Vahl, Brown, Schrader, and others. Linnæus has made a manuscript correction in the *Calamariæ*, excluding from thence *Typha* and *Sparganium*, which he would remove to the preceding order, principally, it seems, because he judged the latter to be very closely allied to *Zostera*; as well as on account of its anthers, but we can trace no resemblance in those to the *Piperitæ*. On the contrary they and their filaments agree with the *Calamariæ*. The stamens of *Typha* indeed are somewhat different, and Mr Brown, in his *Prodromus Floræ Novæ Hollandiæ*, has anticipated this alteration of Linnæus.

Order 4. Gramina. "The true grasses compose as peculiar a family as the palms. They are the most common plants in the world, making about a sixth part of the vegetable kingdom, especially in open situations. There they multiply, and extend themselves by their creeping roots, prodigiously. In confined and woody places they scarcely creep, but stand erect. They are the most important of all vegetables, for this reason, that they are the chief support of such animals as depend on vegetable food. They make the verdure of our summers, and the riches of rustic life. Their leaves are not easily hurt by being trampled on, and though the severity of winter may wither and fade them, so that in the early spring no appearance of life remains, yet they revive. The solicitude of the Author of Nature, for the preservation of this important tribe of vegetables, appears from their flowering stems being rendered unfit for the food of cattle, that nothing may hinder the perfecting of their seeds. Besides, the more they are cut and ill-treated, the more vigorously they grow, propagating themselves proportionably under ground; and in order that they may be enabled to thrive any where, their narrow leaves are so contrived, as to insinuate themselves between the divisions or branches of other herbs, without any mutual impediment. There are very few grasses agreeable to our palate. For the most part they are insipid, like pot-herbs; a very small number being fragrant. None are nauseous or poisonous. Grasses are the most simple of all plants; having scarcely any spines, prickles, tendrils, stings, bracteas, or similar appendages to their herbage."

"Their stem is termed a *culm*, being hollow, composed of joints which are separated by impervious knots. In our quarter of the world the culm is usually simple, unless in consequence of cutting away the flowering part; in the Indies most culms are branched. The leaves are mostly alternate, always undivided, and generally flat on both sides, with a rough edge, and either smooth or hairy surface. Each leaf stands on a sheath, which embraces the stem, and is crowned with a membrane, sometimes termed *ligula*, closely embracing the stem, to hinder the admission of water. The sheath springs from a knot, and (with its membrane) answers the purpose of a stipula."

"The fructification of Grasses differs so much from that of other plants, that it was supposed impossible to reduce them to scientific order. They were first distinguished into corn and grasses; but such a distinction is founded merely on the comparatively larger seeds of the former, on which we depend for food, as small birds do on the very minute seeds of the latter. Ray was the first botanist who undertook a regular examination of grasses. He distributed them according to their outward appearances, but distinctive characters failed him. Neither was Tournefort, however great a botanist, equal to the arrangement of this tribe. Monti followed Ray, but investigated such only as were natives of Italy. John Scheuchzer, first induced by Sherard, paid a most laborious attention to this subject, collecting grasses from all quarters, and describing them with the greatest exactness; but he was deficient in technical terms, and his very long descriptions are nearly all alike, till he arrives at the flowering part. The terms which he uses are *folliculus* for the corolla, *gluma* for the calyx, *locusta* for the spikelet contained in the latter. After him Micheli contrived a new method, dividing grasses according to their spikelets, which he observed to be either compound or simple. He subdivided them by their flowers being united or separated; and subjoined an order of plants "akin to grasses," which really do not belong to them. If their sexes be attended to, the arrangement of grasses becomes less difficult. They are either *monandrous*, *diandrous*, *triandrous*, or *hexandrous*. The two latter have either united, monoecious or polygamous flowers."

"The inflorescence in this order of plants is either spiked or panicled. Their spike, properly so called, consists of several flowers, placed on an alternately toothed *rachis*, or stalk. If such a rachis be conceived perfectly contracted, it will become a toothed common receptacle, as in compound flowers, so that grasses may thus be distinguished into simple and compound. Or if we imagine all the flowers to be sessile on one common base, such grasses as are properly spiked will have a scaly receptacle, the rest a naked one, according to the analogy of the syngenesious class; and by this means the corn family may be separated from the rest, for they are scaly.

"The calyx is a husk of two valves, one proceeding from within the base of the other, like the claw of a crab. These husks are concave, and truly the leaves of the plant in miniature. The calyx contains one, two, or more, florets, which are constructed in the same manner, of two leafy husks, called by Linnæus petals, to distinguish them from the former. Within the petals the receptacle bears two very

minute, roundish, pellucid, extremely tender, withering scales, often invisible without a magnifier, which Micheli termed petals, Linnæus nectaries. Stamens generally three, in a few one, two, or six, with capillary filaments, and oblong incumbent anthers, whose lobes become separated at each end. Micheli erroneously imagined those which have six stamens, to bear, as it were, doubled flowers. The germen is superior, with two styles, sometimes raised on a common stalk or elongated base, and they are usually reflexed to each side, being either longitudinally hairy, or tufted at the summit only. Seed universally solitary, without a capsule, *Lygeum* only having a nut, of two cells, which is very singular. A few have a simple style, as *Zea*, *Nardus*, and *Lygeum*. The seed is occasionally coated by the petals, which closely enfold it, and are almost united with it, witness *Hordeum* and *Avena*;" (to which examples indicated by Linnæus we may add *Briza*). "Many grasses are furnished with an awn, *arista*, mostly rough, like a prominent bristle, inserted into the back of the outermost petal, either at the bottom, middle, summit, or a little below the latter. This appendage is either straight, or furnished with a joint, and twisted backward, or simply recurved; in some it is woolly; in several it is accompanied by hairs at the base of the corolla. The use of these parts is to attach the ripe seeds to the coats of animals, that they may be the more dispersed."

"Although grasses are destitute of spines properly so called, a few have their leaves longitudinally involute, in such a manner that their rigid permanent points have all the properties of thorns, as in *Spinifex*, and some *Festucæ*. Their foliation is, for the most part, involute, but in some instances, as *Dactylis glomerata*, it is folded. This character has not as yet received sufficient attention, but ought to be noticed in future, as it may throw great light on the distribution of the family of plants in question. Very few indeed are furnished with setaceous leaves."

Order 5. Tripetaloideæ. "Scheuchzer and other authors have referred *Juncus* and its allies to Grasses, under the title of *Graminibus affines*. In truth, they are so similar to grasses, as scarcely to be distinguishable without fructification. The genera are *Juncus*, *Aphyllanthes*, *Triglochin*, *Scheuchzeria*, *Elegia* and *Restio* in the first place, then *Flagellaria*, *Calamus*, *Butomus*, *Alisma* and *Sagittaria*." Linnæus, in his manuscript, has hinted, that the three latter may possibly belong to the above-mentioned section at the end of his *Palmæ*; see Ord. 1.

Order 6. Ensatæ. "So called from the form of their leaves, resembling a sword, being perfectly simple, almost linear, alternate, mostly converging by the margins, often cloven longitudinally, so that the edge of one leaf embraces the other, thus constituting what is termed equitant foliage. The root in many cases is oblong and fleshy, lying flat on the ground, or creeping. But some species of *Iris* are truly bulbous, like *Crocus*, *Ixia*, *Antholyza*, &c. Stem, in these genera, simple, erect, zig-zag; but in *Commelina*, especially the annual kinds, it is branched, as in *Tradescantia*. *Crocus* and *Bulbocodium* have no stems. Leaves usually sword-shaped; very rarely quadrangular; in the bulbous species of *Iris* involute; in not a few *Commelinæ* ovate; in *Xyris* and various kinds of *Eriocaulon* awl-shaped. *Fulcra*, or appendages, are scarcely to be found in this order. The calyx is a *spatha*, though but of a spurious kind, being mostly a large concave valve, resembling a halved sheath in *Iris*; most beautiful in *Commelina*, where it is heart-shaped. In *Sisyrinchium* however this part is more perfectly bivalve. Corolla generally of six petals; though in *Iris* so united by their claws, as to constitute a monopetalous corolla. In *Commelina* and *Tradescantia* the petals are very distinct, but the three inferior being ruder in texture, and smaller, resemble a calyx. Style with three stigmas, except some *Commelinæ*. Pericarp a capsule of three cells and three valves, with many seeds; generally inferior, but not so in *Commelina*, *Tradescantia*, and *Callisia*. Hence it follows that this order affords no certain mark, on which a distinctive character could be founded."

Order 7. Orchideæ. "Orchis is a most ancient generic appellation, alluding to the testicular shape of the roots, in many plants of this family, which have, at all times, been believed to possess a stimulating, or aphrodisiacal virtue. All the *Orchideæ* might be comprehended in one genus, in which light also the *Umbellatæ*, *Semiflosculosæ*, *Papilionaceæ*, might each likewise be considered. But the science would be overwhelmed in confusion by such extensive genera, which it is therefore found necessary to subdivide.

"Many *Orchideæ* have a tuberous fleshy root; not properly to be termed bulbous, because its fibres are thrown out from the top, or crown, whereas true bulbs produce their fibres from the base. These tubers, or knobs, are mostly in pairs; some of them globose and undivided, others palmate, like the hand. One of these tubers, from whence the plant of the present year has come, being exhausted, will swim in water; the other, destined to blossom next season, is so solid as to sink. In the palmate kinds, the former is vulgarly called the hand of the Devil, the latter the hand of God. *Ophrys corallorrhiza* however has a threadshaped, branched, and jointed root; that of *O. bifolia* is perfectly fibrous. In other genera, particularly *Epidendrum*, the root consists of clusters of fibres."

"The stem is solitary and herbaceous, except in several kinds of *Epidendrum*, quite simple, often leafy. In some however there is merely a leafless, radical flowerstalk, generally round, though not so in *Ophrys Loeselii* and *paludosa*. The leaves are simple, alternate, undivided, sheathing the stem; sometimes wanting, as in *Orchis abortiva*. Appendages none at all, except bracteas. Inflorescence terminal, either spiked or racemose. Fructification irregular, and very singular, for it is impossible to say what is calyx, and what corolla; nor is this point of much importance, nature having placed no limits between them. There are five petals; besides a nectary, which makes, as it were, a sixth. These five seem to constitute an upper lip, the nectary an under one. Or it may be said that the corolla is composed of three outer, often ruder, petals; and three inner, the lowermost of which ought rather to be denominated a nectary. This last is various in

different genera, having its appropriate figure and dimensions, while the rest of the petals are more uniform. Sometimes the middlemost of the five petals, composing the upper lip, (like that of a ringent or helmet-shaped flower,) is more erect and dilated; but I have received some species from the Cape of Good Hope, in which these petals are united to each other, and elongated at their common base into a spur. Such will constitute a new division or genus, of this family, as it stands in the *Species Plantarum*, many of which have a spur from the base of the lower lip, or nectary. The petals however do not afford sufficient distinctions, for genera or species. The former are determined by the nectary, which is for that purpose principally to be regarded. There is indeed no occasion to advert to any other part than the flower of these plants, for distinguishing either genera or species. Vaillant therefore, and Seguier, have contented themselves with delineating their various flowers alone."

"The stamens consist of two anthers, nearly without filaments, very singular, and peculiar to this order, concealed in a double pouch or hood, but their pollen has not been ascertained. They are "contracted at the base, naked, or destitute of a skin, divisible like the pulp of an orange, and covered each by a cell open underneath, inserted into the inner margin of the nectary;" as described in the *Genera Plantarum*. It remains therefore for inquiry, whether the anthers burst in these as in other stamens, and whether the pollen explodes upon the female organs? or whether there be any internal communication between the anthers and germen?" This latter opinion Linnæus was inclined to adopt, because, (as he thought), "the pistil was so obscure, that no one was able to say whether there were any style or stigma." We cannot but remark here that the latter is sufficiently apparent, in the form of a shining glutinous depression or cavity, just below the anthers; nor is there any doubt that the pollen, though different in texture from other plants, and various in the different species of these, performs the office of impregnation by the stigma. It consists of naked elastic or granular masses, being what Linnæus terms the anthers.

"The germen is inferior in the whole order; the style short, inclining, in many hardly manifest, in some American *Orchideæ* very conspicuous. Stigma either obsolete, or funnelshaped, sometimes compressed. A small gland moreover is present, suspected to belong to the female organs of impregnation, but not very decidedly." (Linnæus surely errs in asserting that the sexes of the plants in question are very obscure.) "The fruit is a capsule, of one cell, and three valves, which last are connected by a lateral suture, to which the seeds are attached, as to a receptacle. The capsule does not burst in the usual manner, but the valves separate at their lateral sutures, while their extremities remain united at top and bottom. The seeds are numerous, of a chaffy appearance, like saw-dust."

"Many fine species of this order are found in Europe and America; the Cape of Good Hope is not rich in them;" (Mr Brown observed a considerable number there;) "both Indies abound with singular ones, especially with *Epidendra*. Their favourite soil is a spongy, moist, friable, rich, but not manured, earth, in rather shady situations. The species of *Epidendrum* are all, perhaps, parasitical, insinuating their roots into the bark of aged trees."

"*Orchideæ* are extremely difficult of culture." We refrain from transcribing the ideas of Linnæus on this subject, as it is now known that some of these plants may be propagated by seed, and that several succeed very well in our stoves, among the rotten bark of trees, accompanied by fresh vegetable mould. Our wild Orchises are best removed when in full bloom, when the mould should be entirely cleared away from their roots, and the latter planted immediately in fresh sifted soil from their native place of growth, with moderate subsequent watering. Thus treated they will come up and flower for many successive years in the same pot.

Order 8. SCITAMINEÆ. "These nearly approach the *Orchideæ* in aspect. The name of the order is an ancient word, synonymous with *aromatic*, and answers to the whole of the tribe, except *Musa*, *Heliconia*, and *Canna*." (The two former certainly do not belong to this order, and the last but imperfectly.)

"The roots of the *Scitamineæ* are fleshy, mostly acrid and aromatic, lying on the surface of the ground, and throwing out fibres from their under side, like some of the 6th order. Stem always quite simple," (to this there are exceptions in *Maranta*); "in some bearing alternate leaves; in others naked, and separate from the foliage. Leaves lanceolate, quite entire, even, stalked, convoluted contrary to the direction of the sun; their stalks sheathing the stem. Inflorescence either a spike or cluster, the flowers being separated by coriaceous or membranous bracteas. Flower superior. Calyx a perianth of three valves. Corolla always irregular. Pericarp in most instances a capsule of three cells and three valves, with many seeds in each cell." We pass over much of the Linnæan description, recent discoveries having enabled succeeding writers, particularly Mr Roscoe, in *Trans. of Linn. Soc.* Vol. VIII. and Mr Brown in his *Prodr. Nov. Holl.* to explain the flowers much better. The corolla is monopetalous, with a double limb, and more or less irregular; each limb in three deep segments; the inner most unequal, one of its segments being a dilated, lobed, ornamented lip, like that of the *Orchideæ*, the other two sometimes very small, or obsolete. Stamen one, inserted into the tube, opposite to the lip; its filament mostly dilated, and of a petal-like habit, by the diversity of whose shape Mr Roscoe has first reduced this order into natural genera, a matter in which preceding botanists had altogether failed. The anther consists of two parallel distinct lobes, united lengthwise with the filament, bursting longitudinally, sometimes spurred at the base. There are usually the rudiments of two abortive stamens, first asserted to be such by Mr Brown. Germen roundish, with a threadshaped style, lodged between the lobes of the anther, and a dilated, cup-like, often fringed, stigma.

"To this order belong the Ginger, Cardamoms,

Grains of Paradise, *Costus*, Galangale and Zedoary of the shops, all aromatic. We have nothing similar to them in Europe, except *Acorus*."

What Professor Giseke has subjoined to the lectures of Linnæus, relative to this order, is, to say the best of it, superfluous.

Order 9. SPATHACEÆ. "These are distinguished by their bulbous root, consisting of a radical bud, formed from the bases of the last-year's leaves, which envelope the rudiments of the future foliage. In a bud the scales are expanded into leaves; in a bulb the permanent base of the leaves becomes fleshy. In this order the leaves are sheathing at the root, so that they exhibit no instance of a scaly bulb, but only a coated one. Their leaves are, with a few exceptions, almost linear, or linear-lanceolate. Stem no other than a *scapus*, or radical flowerstalk, either round, two-edged, or triangular. The *spatha*, or sheath, is a terminal membrane, splitting lengthwise, except in *Hæmanthus*, where it divides into six segments, resembling an involucrum, and is permanent. The *spatha* sometimes contains many flowers, and where it naturally bears but one, is liable occasionally to produce more. The flowers are stalked within the *spatha*; in most instances they are superior, but not in *Bulbocodium*, whose corolla is divided to the very base. This plant therefore has erroneously been referred to *Colchicum*. *Tulbaghia* has a perfectly inferior flower, but cannot be referred to *Hyacinthus*, on account of its many-flowered *spatha*." (The nectary, or crown of the tube, abundantly distinguishes it.) "*Allium* has invariably an inferior flower, but its *spatha* shows that it belongs to the order before us. Some of its species bear flowers as big as a *Narcissus*."

"The corolla in most of the genera is monopetalous, inasmuch as the nectariferous tube bears the petals. Otherwise they might all be denominated hexapetalous, except *Colchicum* and *Crinum*; to say nothing of *Gethyllis*, distinguished from all the rest by its very long tube. Stamens six, except in the genus last mentioned, where they are twice that number. Pistil one, except *Colchicum*; but many have a three-cleft stigma, so that in *Colchicum* this part may be considered as only further divided even down to the germen. Capsule in all of three cells, with many seeds." (*Hæmanthus* has a berry.)

"The roots of this tribe grow best if they are dried after the leaves perish, either artificially, or by the arid nature of their place of growth. Many of these roots are nauseous and acrid, therefore poisonous, especially *Colchicum*. The bulb of a *Narcissus* will kill a dog. No analogy holds good between these plants and the Tulip, whose bulb may be eaten with impunity; because they are not of the same natural order. All the species of *Allium* are impregnated with their own peculiar pungent flavour, and nature being disposed to expel them with violence from the stomach, they prove most powerful sudorifics. Much of the substance of these last mentioned is mucilaginous, which involves and separates their acrid particles. Hence they are not dangerous in substance, but their expressed juice, deprived of viscidity, is fatal."

Order 10. CORONARIÆ. "A coronary or garland flower was anciently such as, on account of its beauty, was used for ornamental wreaths."

"*Ornithogalum* has much in common with *Allium*, but wants the *spatha*. *Scilla* is so nearly related to *Ornithogalum*, that they are scarcely to be distinguished but by the breadth" (some say the proportion) "of their filaments. *Hyacinthus* and *Scilla* are with difficulty distinguishable, though the latter has six petals, the former a monopetalous six-cleft corolla, but this is in some instances so deeply divided as nearly to approach the latter."

"In this order the root is either tuberous, a solid bulb, or, as in *Lilium*, a scaly one. The leaves of *Aloe*, *Yucca*, *Agave* and *Bromelia*, are, as it were, a bulb above ground, whose dilated, fleshy, permanent scales remain year after year; just as the bulb of the Lily consists only of the perennial bases of the foliage. In the *Aloe* tribe, not merely the base, but the whole leaf is perennial. Whoever is ignorant of this, cannot fail to go astray in studying the order in question."

"The stem is simple, often a mere *scapus*, occasionally leafy, in consequence of a partial elevation of the radical leaves."

"The flower, destitute of *spatha* or any sort of calyx, consists of six petals." (Linnæus terms them such, because they fall off when the flowering is over.) "In *Ornithogalum* some species have the under side of the corolla green, which part therefore is permanent here, as consisting of corolla and calyx united. In some kinds of *Anthericum*, and in *Veratrum*, the petals are likewise permanent, but in a faded condition. The stamens are universally six, three of them interior. Germen superior. In *Aloe* the pistil is solitary, and three-cleft; but the style is divided to the very base into three parts in *Melanthium*, *Helonias*, *Veratrum*, and one species of *Ornithogalum*. All the tribe have a capsule of three cells, and three valves, the seeds being placed one above another."

"There is no uniformity in the qualities of the *Coronariæ*, there being among them a great diversity of scent. The nauseous smell of *Fritillaria imperialis* and *Veratrum* indicates a very poisonous quality, of which likewise *Aloe* partakes. *Lilium* is mild; its root inodorous and mucilaginous; its qualities therefore are emollient and lubricating. *Scilla maritima* is in the highest degree acrid and diuretic, dissolving viscid humours. The root of *Ornithogalum umbellatum*, as well as of *O. luteum*, is eatable. The former appears to be the Dove's dung, sold for so high a price during the siege of Samaria, as recorded in the Second Book of Kings, chap. vi. v. 25; in the first place, because it is very abundant in Palestine, whence the English call it Star of Bethlehem; secondly, because the flower resembles the dung of pidgeons and other birds, in its greyish and white partycoloured hue, whence also comes the name *Ornithogalum*, or bird's milk, alluding to the white substance, always accompanying the dung of these animals; and lastly, because the root in question is to this day eaten in Palestine, at least by the poor." (See *English Botany*, t. 130.)

"Wepfer has proved, by many experiments, the very poisonous nature of the root of the Crown Imperial, which kills dogs, wolves, and various other

animals. The ancients relate that the honey of its flowers caused abortion. No flower, except *Melianthus*, produces more of this fluid, yet the bees do not collect it! We owe this fine plant, now so common, to Clusius, who more than two hundred years ago received it, along with the Horse-Chesnut, from the east. He likewise acquired many other bulbs, before unknown, now become the ornaments of our gardens. From his time, no one has taken the same pains. Certainly if any person could travel, for this object, into the interior of Persia and the kingdom of the Mogul, he would be likely to obtain many superb plants of this order, as recent travellers to the Cape of Good Hope have made us acquainted with so many novelties among the *Ixiæ*, *Antholyzæ*, &c. of which Hermann, Oldenland, &c. their predecessors, have not mentioned a word. *Tulipa Gesneriana* is so called, because it was procured by Conrad Gesner, from Cappadocia, whence it has become common throughout Europe: its endless varieties are the delight of florists, and some of them fetch a high price."

Linnæus in his own manuscript has, as we have already said, removed *Bromelia*, *Tillandsia*, and *Burmannia*, from this order to the *Palmæ*, or at least an appendix thereto.

Order 11. Sarmentaceæ. "Sarmenta among the ancients meant unarmed, prostrate, weak branches, unable to support themselves; hence this name is applied to the order before us, many plants belonging to which answer to that character, being of a long, weak, trailing or twining habit. The *Sarmentaceæ* are monocotyledonous. They differ much in fructification, and may be variously arranged; either by their calyx and corolla; the number of their stamens or of their pistils; the nature of their fruit; or the inferior and superior situation of their germen. Hence it appears that no common character, applicable to the whole order, can be deduced from the fructification."

"*Raiania*, *Tamus*, *Dioscorea*, *Smilax*, *Cissampelos*, *Menispermum* and *Ruscus*, form one assemblage, all except the last having the above-mentioned kind of stem, twining to the left, not to the right, except in one species of *Menispermum*. Such a difference is rare between plants of the same natural order. *Smilax* supports itself by two tendrils, springing from near the base of the footstalks; all the rest are spiral, and without examination of the fructification, may easily be confounded. The above are dioecious, except one or two species of *Ruscus*." (*Centella* ranged among these in *Gen. Pl.* is now referred to *Hydrocotyle*.)

"*Dracæna*, *Asparagus*, *Convallaria*, *Uvularia*, *Gloriosa* and *Erythronium*, compose another section. The last is intermediate, as it were, between the present order and the *Coronariæ*. *Gloriosa simplex* is a small plant, not unlike *Erythronium*, with reflexed petals." (What Miller, who is Linnæus's sole authority for this species, intended, nobody has ever been able to make out.)

"*Medeola*, *Paris* and *Trillium*, have whorled leaves, except *M. asparagoides*, which scarcely differs from the genus *Asparagus*, except in having three styles instead of one."

Aristolochia, *Asarum* and *Cytinus*, nearly akin to each other, are removed from this order, by the author in his manuscript, to the 27th, *Rhoeadeæ*, but not without a query. In the same place we meet with what may perhaps prove a solution of the mystery, which Giseke was so anxious to unriddle, and to which we have already alluded in the beginning of this part of our subject. Linnæus has here mentioned *Nymphæa*, as having in some of its species one cotyledon, in others two. He notes also that *Menispermum* and *Aristolochia* are dicotyledonous. *Nymphæa* however appears to be the great secret, which the worthy professor told his pupil, that he, or some other person, might chance to find out in ten, twenty or fifty years, and would then perceive that Linnæus himself had been aware of it. Accordingly, Gærtner and Jussieu have made the same discovery, or rather, fallen into the same mistake; describing *Nymphæa* as monocotyledonous, and *Cyamus* Sm. Exot. Bot. v. i. 59. (their *Nelumbo*, or *Nelumbium*), as in some measure dicotyledonous. The excellent De Candolle, in the *Bulletin des Sciences*, n. 57, published in 1802, has first rightly considered both as dicotyledonous, and akin to the *Papaveraceæ* of Jussieu, the Linnæan *Rhoeadeæ*.

Linnæus, in his lectures, proceeds to observe, that he "wanted to make further inquiry into the cotyledons of his *Sarmentaceæ*, for though he knew that several of these plants were monocotyledonous, he knew two, and did not doubt there were more, perfectly dicotyledonous. Hence he suspected the order might be separated into two, in other respects very closely related."

"The roots of all this family are oblong and fleshy, except *Erythronium*, whose radicles are long and quite simple; those of *Smilax Sarsaparilla* run very deeply into the ground, and are sometimes so thickened at the ends as to become tuberous. The stem at first coming forth is smooth and leafless, mostly branched, except in *Paris* and *Trillium*; in some prostrate. Leaves in every instance simple and undivided, sometimes linear, sometimes lanceolate and acute, or heartshaped, uniform, mostly alternate; except when three or more stand together in a whorl, and in *Dioscorea oppositifolia*. It is rare that alternate and opposite leaves occur in the same natural order. Flowers mostly on simple stalks, *Smilax* excepted, which has umbels; they are drooping except in *Paris*. Stamens universally six, except in *Menispermum*. Styles three, or three-cleft. All the genera, almost without exception, are deficient in either calyx or corolla. The fruit is generally of three cells. Inflorescence axillary in all except *Erythronium*, which has but one flower, and *Ruscus*, where it springs from the leaf."

"Their qualities are to be judged of by the smell. All of them betray something of malignity, except two insipid ones which are eatable, *Dioscorea* and *Asparagus*. *Gloriosa* is very poisonous; the dried flowers of Lily of the Valley cause sneezing, like *Veratrum*, that is, they produce convulsions. *Paris* has always been deemed poisonous. One kind of *Cissampelos*, named *Pareira brava*, and *Smilax*, are known by physicians to be highly diuretic, as

well as the roots of *Asparagus*. *Menispermum Cocculus* kills fishes, lice, and men."

"This whole order is entirely without pubescence, even the prickly *Smilaces*."

Next follow the Dicotyledonous Orders.

Order 12. Holeraceæ, pot-herbs, (erroneously printed *holoraceæ* in Gen. Pl. which has misled several writers). "This denomination is given to plants that are tender or brittle in the mouth, and easy of digestion, like many of the order before us." The order is divided into several sections. Of the first *Blitum*, *Atriplex*, *Chenopodium*, *Salsola*, *Salicornia*, &c. are examples. The second consists of *Petiveria*, *Calligonum*, *Ceratocarpus* and *Corispermum*. *Callitriche* was subsequently removed to the 15th order. In the third section *Axyris* stands alone. Of the fourth *Herniaria*, *Illecebrum*, *Amaranthus*, *Phytolacca*, may serve to give an idea. The fifth begins with *Begonia*, (of whose affinity Linnæus candidly confesses his ignorance, and to which no botanist has yet found an ally). Next follow *Rumex*, *Rheum*, *Polygonum*, &c. The sixth section has *Nyssa*, *Mimusops*, *Rhizophora*, *Bucida* and *Anacardium*; and the seventh *Laurus*, *Winterana* and *Heisteria*; in both which the fleshy receptacle appears, where he could trace it, to have guided Linnæus to an arrangement evidently paradoxical, which he labours, without satisfying us, to justify.

Order 13. Succulentæ. "Bradley wrote on Succulent Plants, by which he meant such as could not be preserved in a *Hortus Siccus*. When gathered, vegetables of this nature will live, often for a whole year, flowering as they hang up in a house, and throwing out roots afterwards if planted. All such plants, however, do not enter into the present order. *Stapelia*, *Euphorbia*, and *Aloe* are excluded. The *Succulentæ* grow, and become very turgid, in the driest soil, nor are any found in watery places. If moistened too much they perish, and their roots decay. They afford, in putrefying, a fine vegetable mould, whereas dry plants, like heath and fir, scarcely yield any."

Linnæus has distinguished these into four sections. In the first are *Cactus*, *Mesembryanthemum*, *Tamarix*, and others. *Nymphæa* placed here, in the Linnæan manuscript, as well as in Giseke's publication, was afterwards removed by Linnæus to his *Rhoeadeæ*. *Sarracenia* he conceived to be akin thereto. In his second section are *Sedum* and its numerous allies; in the third *Portulaca*, *Claytonia*, &c.; and in the fourth a very different assemblage, as we should think, composed of *Saxifraga*, *Adoxa*, &c. and even *Hydrangea*. Linnæus however thought all these sections nearly related. "They are," says he, "succulent, insipid, inert, and inodorous, therefore mere pot-herbs, widely different from the other fleshy plants, *Stapelia*, &c. whose fructification is so unlike them, and whose qualities are so poisonous. We find in this order, that opposite or alternate leaves is an indifferent circumstance. These plants have no true spines, no tendrils, nor climbing stems, neither stipulas nor bracteas." (Giseke well remarks, that *Sedum acre* is one exception to their alleged insipidity, though we can scarcely agree with him that *Sempervivum tectorum* is another.)

Order 14. Gruinales. The best known genera here are *Linum*, *Drosera*, *Oxalis*, *Geranium* and its relations. Linnæus admits also *Quassia*, *Zygophyllum*, *Averrhoa*, &c., and his editor inserts, with well-founded doubt, *Sparmannia*. Their roots and habits are various. Calyx usually of five leaves, and corolla of five petals. Stamens various in number and connexion. Pistils mostly five or ten. Fruits various. Linnæus professed himself unable to define the character of this order. Many of the plants have acid leaves.

Order 15. Inundatæ. "So called because they grow in water, many of them under its surface, except their blossoms." *Potamogeton* is the genus most generally known, to which Linnæus suspected *Orontium* to be related, but not correctly. *Myriophyllum*, *Proserpinaca*, *Hippuris*, &c. are placed here, and even *Elatine*, notwithstanding its numerous seeds. *Chara* and *Najas* form a section at the end. *Callitriche*, *Lemna*, and even *Pistia*, were proposed to be brought hither; with *Saururus* and *Aponogeton*.

"The qualities of the *Inundatæ* are very obscure. These plants are mostly inodorous, except a fishy scent in some; nor have they any particular taste; hence they are not used medicinally."

This order is out of its place with respect to the arrangement by the cotyledons, of which Linnæus seems aware, from the remarks subjoined to it, in his lectures, concerning that principle. To these we shall hereafter refer.

Order 16. Calyciflоræ. This consists of *Osyris*, *Trophis*, *Hippophäe* and *Elæagnus*. No observation relative to it is given in the lectures, except that these genera are removed elsewhere. A manuscript note before us indicates a suspicion of its relationship to the 6th section of the *Holeraceæ*. Linnæus sometimes referred *Memecylon* to one of these orders, sometimes to the other, but finally to his 18th; we should rather presume it belongs to the 19th notwithstanding the definite number of the stamens, which caused Jussieu to range this genus with the Linnæan *Calycanthemæ*; see the next order.

Order 17. Calycanthemæ. "The title of this order is precisely synonymous with the last, and is applicable in a different manner to the different genera of which the present consists. In those whose germen is inferior, the calyx bears the flower and enfolds the germen; in those where the latter is superior, it is unconnected with the calyx, into which the stamens are, in that case, inserted, like the *Senticosæ* and *Pomaceæ*, not into the receptacle. The germen is inferior in *Epilobium*, *Oenothera*, *Gaura*, *Jussiæa*, *Ludwigia and Isnarda*, as well as in *Mentzelia* and *Loosa*" (or *Loasa*); "in the rest, *Ammannia*, *Grislæa*, *Glaux*, *Peplis*, *Frankenia*, *Lythrum*, *Melastoma*, *Osbeckia* and *Rhexia*, it is superior. Some genera have four, others five or six petals. *Glaux* and *Isnarda* have none. *Ammannia* and *Peplis* have occasionally petals, or not, in the same plant. *Melastoma* has a berry; the rest a capsule, usually of four or five cells, in some genera of but two, or one." Linnæus mentions *Melastoma* as the only arboreous genus. The rest are herbaceous, (rarely shrubby), with opposite or alternate leaves;

stamens from four to twelve, pistil always solitary, the stigmas either four or one.

"These plants are mostly inodorous and insipid, except a styptic property in the root of *Lythrum;* none of them are used in the shops. It is remarkable in this order particularly, that some flowers are sessile and axillary, but towards the summit the leaves gradually diminish, and are finally obliterated, so that the inflorescence becomes a spike, as may be seen in *Epilobium.*"

Order 18. BICORNES. "So called," by Linnæus, "from the anthers, which in many of this tribe terminate in two beaks. The plants are rigid, hard and evergreen, almost all more or less shrubby; certainly perennial. *Diospyros* is arboreous. The leaves of this order are alternate, simple, undivided, scarcely crenate, permanent. Stipulas and bracteas wanting;" (certainly not always the latter). "Calyx of one leaf, more or less deeply four or five cleft. Corolla usually monopetalous; in *Pyrola, Clethra,* and their near allies, pentapetalous. Nectaries none, except in *Kalmia.*" (Linnæus can here mean only the pouches which for a while detain the elastic stamens, and those are by no means nectaries.) "Stamens from four to ten, answering to the divisions of the corolla, or twice their number. Pistil 1, except *Royena,* which is digynous. Germen in some superior; in others, as *Vaccinium,* inferior. Some have a capsule, others a berry; the cells of each four or five; but *Diospyros* has a fruit of eight cells. The seeds are either one or many in each cell, mostly small, chaffy." Linnæus remarks that "they can scarcely be raised in a garden, especially as the plants are many of them natives of boggy situations;" but our English gardeners are masters of their treatment, witness the abundance of *Ericæ* from the Cape, now common in every greenhouse, and many other charming shrubs, cultivated in a peat soil. He conceived the whole order to be nearly confined to one meridian, from the North Cape of Lapland, to the Cape of Good Hope; but he is incorrect in saying, there are very few in North America, and none in the East or West Indies.

Halesia, Styrax, Spathelia, Citrus and *Garcinia* are subjoined as an appendix to the *Bicornes,* but there is allowed to be a considerable distance between them, and the last is erased in the *Gen. Plant.* as having opposite leaves. Giseke records, p. 345, that when Linnæus said no *Erica* grew in America, he asked him whether *Hudsonia* were not an exception to this? On which he took that genus from his herbarium, and after contemplating and replacing it, wrote something, Giseke knew not what, in his *Genera Plantarum.* We find what he wrote to be as follows: "Videnda *Hudsonia, Empetrum, Ilex, Itea.*" It is interesting to be thus able to trace the thoughts of such a man. He was moreover correct as to the genus *Erica* itself, of which no species has been detected in America.

Order 19. HESPERIDEÆ. Of this nothing is said in the lectures. The original genera are *Eugenia, Psidium, Myrtus,* and *Caryophyllus;* to which Giseke has added *Calyptranthes* and *Legnotis* of Swartz. *Melaleuca* also strictly belongs to this tribe; though, by a strange error, referred in the *Mantissa* to the 40th order, and yet said to be akin in *Ginora,* which belongs either to this or the 17th. *Philadelphus* is subjoined as forming a section by itself, and still with a mark of doubt. The discoveries in New Holland have thrown much light on this fine order of aromatic and elegant shrubs, of which the Myrtle is a familiar type. Linnæus intended to remove *Garcinia* hither.

Order 20. ROTACEÆ. The lectures are also deficient as to this order. It consists of *Trientalis, Centunculus, Anagallis, Lysimachia, Phlox, Exacum, Chlora, Gentiana, Swertia, Chironia* and *Sarothra;* to which *Ascyrum, Hypericum* and *Cistus* stand as an appendix. The wheel-shaped corolla of many of the above plants, has evidently suggested the name.

Order 21. PRECIÆ. *Primula* and its elegant relatives form the basis of this order. "They are all destitute of stems. Leaves simple. Flowerstalk umbellate, except in *Cyclamen.* Flower regular. Calyx, as well as corolla, five-cleft. Stamens five. Style one. Fruit a simple superior capsule. The umbel is often accompanied by an involucrum. They are vernal-flowering plants, and have, except *Cyclamen,* nothing malignant in their qualities." *Limosella* stands alone in a second section of this order, but rather perhaps belongs to the 40th. *Menyanthes, Hottonia* and *Samolus* form a third section, attended by a mark of doubt. *Sibthorpia* was once inserted in manuscript, but afterwards erased.

Order 22. CARYOPHYLLEI. The Pink and Campion tribe. "Root fibrous. Stem herbaceous, scarcely shrubby, jointed; its branches commonly alternate. Leaves simple, more or less of a lanceolate figure, undivided, hardly crenate in any degree, sessile, with no other appearance of a footstalk than their elongated narrow base, opposite, obvolute. Stipulas none; neither are there any distinct bracteas, nor spines, prickles nor tendrils. The plants are mostly smooth, few are hairy, none prickly or bristly. Flower rarely sessile. Stamens never numerous, but either the same in number as the petals, or twice as many. Pistils from one to five, not more. Fruit a capsule, either of one cell, or of as many as there are styles; the cells usually with many seeds, *Drypis* only having a solitary seed. A few of these plants with separated flowers occur among the species of *Cucubalus, Silene* and *Lychnis.* The whole order is harmless, without any peculiar taste or smell, except in the flowers. It contains the *flores caryophyllati* of Tournefort, who defined these as having the calyx tubular, and the limb of the corolla flat; but he referred *Statice* and *Linum* hither, which differ widely from this order, while his character excludes the *Alsine,* or Chickweed, tribe." Linnæus thought *Velezia* had been wrongly placed here by Gerard, and was doubtful respecting *Cherleria;* but he was afterwards satisfied that both are *Caryophyllei.* He remarks that "the order consists, as it were, of two leading genera, or rather families, the *Caryophyllus,* or Pink tribe, such as *Dianthus, Saponaria, Gypsophila, Silene, Lychnis,* &c.; and the *Alsine,* or Chickweed family, consisting of *Spergula, Cerastium, Arenaria, Stellaria,* and others. In the first division, the calyx is tubular, of one leaf; in the second of five." A third section of this order has *Pharnaceum,*

Glinus, Mollugo, Polycarpon, Minuartia, Queria, Ortegia, Loeflingia ; to which were afterwards added *Gisekia* and *Rotala. Holosteum* also, having laciniated stipulaceous membranes, was intended to have been removed to this third section. *Scleranthus*, by itself, makes a fourth, but is erased by Linnæus, and removed to his 31st order. *Polypremum*, with a query, stands at the end.

A most extraordinary remark is subjoined by Professor Giseke at p. 354; that " *Alsine media* and *Holosteum umbellatum* are one and the same plant," and that " Linnæus had no specimen of the former in his herbarium in the year 1771." Swartz is cited in confirmation, who only says in his *Obs. Bot.* 118, that this *Alsine* is a species of *Holosteum.* We trust it is better referred to *Stellaria* in *Flo. Brit.*, and we can affirm that an authentic specimen of this common plant, which Linnæus had when he published the first edition of *Sp. Pl.*, in 1753, still exists in his collection. The real *Holosteum umbellatum*, a rare English plant, is well delineated in *Engl. Bot.* t. 27.

Order 23. Trihilatæ. " So called from its three-celled, and three-grained fruit, for all the cells are distinct. *Melia* however has five cells. The calyx in this order is either of four or five leaves, or of one leaf in five deep segments. Petals four or five. Stamens eight or ten. Pistil one. One part of the fructification is often diminished as to number, for instance the petals ; and when they become but four, the stamens are only eight. A nectary is always present; hence the corolla is frequently irregular. The leaves are disposed to be compound, and are both opposite and alternate. The whole order scarcely contains any thing acrid, except *Tropæolum*, nor any thing either fragrant or noxious ; on the other hand, the *Tricoccæ*, properly so called, are highly poisonous."

The first section consists of *Melia, Trichilia, Guarea* and *Turræa ;* to which Linnæus has added, from his 54th or miscellaneous order, *Cedrela* and *Swietenia.* The second is composed of *Malpighia, Banisteria, Hiræa, Triopteris, Acer* and *Aesculus.* Linnæus was inclined to bring hither, from his 14th order, the genus *Fagonia*, because of the likeness of its flower to *Malpighia*, but he found a difficulty in the five cells of its fruit. A third section consists of *Staphylea, Sapindus, Paulinia, Cardiospermum* and *Tropæolum ;* to which *Hippocratea* is added in manuscript, and a question subjoined, Whether *Staphylea* be not akin to *Celastrus?* Cavanilles has added many new genera to this order, but he is surely complimented to excess by the editor of the *Prælectiones.*

Order 24. Corydales. " The title of this order is synonymous with *Fumaria* amongst ancient writers."

" The genera are *Melianthus, Monnieria, Epimedium, Hypecoum, Fumaria, Leontice, Impatiens, Utricularia, Pinguicula*, and perhaps *Calceolaria.* The calyx is of two leaves ; except in *Pinguicula*, where it is only cloven ; and *Melianthus*, where it consists of four leaves. The flower of *Fumaria* is remarkable in its throat, and uniform in that respect throughout the genus, but the various species differ widely in their fruit ; which in some, as *officinalis*, &c. contains a solitary seed ; in *capnoides, claviculata*, &c. it is a genuine pod ; in *vesicaria* a large inflated capsule." *Monnieria* and *Melianthus*, (two very puzzling genera), were thought by Linnæus to be nearly related to each other, though differing from the order under consideration, in having several capsules, and a calyx in five deep divisions. But he judged the ringent corolla of *Monnieria* to betray an affinity to *Fumaria ;* while the nectary of *Melianthus* is similar to that of *Monnieria*, the combined stamens of the latter being exactly those of *Fumaria.* Hence a relationship is traced between *Melianthus* and this order, which, but for *Monnieria*, could not have been suspected.

" There is a certain fragility and delicacy of texture characteristic of the *Corydales*, with a glaucous hue, which points out their affinity ; as well as a bitter flavour. Scarcely any of the order are odoriferous, except *Melianthus*, which is extremely fœtid."

Linnæus professes his inability to point out any exclusive mark of distinction for this order. " The leaves indeed are alternate in all, *Calceolaria* excepted ; and many bear stipulas. Their mode of flowering is spiked, racemose, or solitary, their stalk naked or leafy, different in different species. All that we are acquainted with are smooth and unarmed ; a very few of them climbing by means of tendrils. *Melianthus* and *Monnieria* only are shrubby. All the tribe prefer shady, moist situations, where the soil is not disturbed." (Some however grow in cultivated ground, as the Fumitories.)

" The *Melianthus*, a Cape plant, produces more honey than any other plant, so that a tea-spoon full may be collected every morning, from each of its numerous flowers. But the offensive odour" (of the bruised plant) " indicates a poisonous quality, as in *Cimicifuga.*"

Order 25. Putamineæ. On this order, named from the strong rind of the fruit in several instances, there is no commentary in the *Prælectiones*, nor any manuscript note in the *Gen. Pl.* The genera are *Cleome, Cratæva, Morisona, Capparis ; Crescentia* and *Marcgravia* being added with hesitation. *Tanæcium* of Swartz, and *Possira* of Aublet, which last is *Rittera* of Schreber, are subjoined by Giseke.

Order 26. Multisiliquæ. This consists of four sections. In the first are *Pæonia, Aquilegia, Aconitum* and *Delphinium*, to which Linnæus, after much diversity of opinion, finally determined to add *Cimicifuga* and *Actæa.* The second contains *Dictamnus, Ruta* and *Peganum :* the third *Nigella, Garidella, Isopyrum, Trollius, Helleborus, Caltha, Ranunculus, Myosurus* and *Adonis :* and the fourth *Anemone, Atragene, Clematis*, and *Thalictrum.* " Most of the order, with a few exceptions, are of European growth ; rarely arboreous or shrubby, except such species of *Clematis* as climb trees. The roots are fibrous, sometimes tuberous. Leaves often many-cleft, or compound ; but in a few instances simple ; all alternate, except in *Clematis integrifolia.* There are no stipulas, spines, nor prickles. One or two kinds of *Clematis* bear tendrils. Flowers in no case monopetalous. Stamens always more than eight, except in the second section. Fruit in some capsu-

lar, in some single-seeded. An acrid taste prevails through the whole. Their odour is disagreeable, almost universally, so that none is esculent, and many, if not all, are poisonous, though there is no milky plant among the whole, nor any one with a twining stem." Linnæus remarks, that "a calyx is very rarely present, and when it occurs, manifestly originates from the leaves;" but this is not applicable to *Ranunculus* and its nearest relations, nor to any genus in the second section; that section indeed being a most distinct order of itself, called by Jussieu *Rutaceæ*, but not well defined by him.

Order 27. Rhœadeæ. The Poppy tribe. No remark on this order is found in the lectures of Linnæus, but he has made some manuscript notes. He wished to remove it next to the 24th and to place its genera thus, *Argemone*, *Chelidonium*, *Papaver*, *Podophyllum*, *Sanguinaria* and *Bocconia*. *Sanguinaria*, he observes, has the flower of *Actæa*, which last genus he had once brought hither. He has finally placed here *Aristolochia*, *Asarum* and *Cytinus*, as we have mentioned under the 11th order. *Nymphæa* also is indicated, but afterwards erased, which is unfortunate.

Order 28. Luridæ. The gloomy family of nightshades, henbane and tobacco. "This order is a most distinct and evident one. All the plants have alternate leaves; a five-cleft calyx; monopetalous corolla; stamens four or five; pistil one; germen superior; seed-vessel of two cells, in some a berry, others a capsule. Their corolla folds in a plaited manner."

Digitalis, *Celsia*, *Verbascum*, *Nicotiana*, *Atropa*, *Hyoscyamus*, *Datura*, *Physalis*, *Solanum*, *Capsicum*, are examples of this order. "They are none of them arboreous, though some are shrubby. Colour (of the herbage) mostly dull and lurid; the taste disagreeable, smell nauseous, hurtful to the nerves, hence their generally poisonous qualities." *Ellisia* is properly expunged in the manuscript, and *Nolana* with equal propriety removed hither from the 41st order.

Linnæus observes, that "the poisonous quality of *Verbascum* appears in its power of killing fish, if made up into balls with meal." "*Nicotiana rustica*," he says, "furnishes the Turks with their best tobacco, yet it is not cultivated by us, though it grows readily. *Atropa Mandragora*, a most poisonous and dangerous plant, becomes, under proper management an excellent and powerful medicine," for instances of which Linnæus referred his hearers to his lectures on the Materia Medica. These, as Giseke notices, were never published. On turning to the manuscripts used by the professor in that course, we find the *Mandragora* mentioned as "virose, acrid, bitterish and nauseous, useful in the gout and colic; the herb boiled in milk, and applied to scirrhous tumours, more active in dispersing them than hemlock or tobacco. Three of the berries boiled in milk, given to a potter, labouring under a dreadful cholic, threw him into a sleep for twenty-four hours, out of which he awoke cured. The ancients gave an infusion of this plant in wine, before they amputated a limb. Its narcotic qualities render it very useful in epilepsy and hysteria, though to be cautiously administered. Nothing can be more dangerous in a state of pregnancy. The editor of Hernandez, *Hist. Nat. Mexic.* Book viii. chapter 28, speaks of this fruit as eatable, without any soporific or injurious effect."

Linnæus himself appears to have been doubtful about *Catesbæa*, which he has marked as akin to his *Dumosæ*. Giseke has subjoined an observation, not well founded, of the *Solandra* of Swartz being hardly distinct from *Datura*.

Order 29. Campanaceæ. These Linnæus has noted as most nearly allied to the 24th order. "They never form trees, rarely shrubs. Leaves in every instance alternate; calyx and corolla five cleft; stamens five; pistil one, except *Evolvulus*, which has at least a deeply four-cleft style, if not four distinct ones. Fruit a capsule. They are milky plants, at least while young and tender. Their qualities therefore are purgative, and but slightly poisonous."

Convolvulus and *Campanula*, with their respective allies, constitute this order. To the latter *Viola* is supposed to be connected, through the medium of *Lobelia*. *Parnassia*, though in the manuscript rightly said to be not milky, stands at the end, its affinity being indicated by the nature of the flower-stalk, calyx, as well as the seeds and their situation, but especially the nectaries and stigma. The anthers come one after another and impregnate the latter, retiring subsequently in their turns. Their close application to that part, as Linnæus conceived, rendered the access of extraneous pollen impossible, "hence" says he "no more species of this genus can be produced." This alludes to his hypothesis of new and permanent species, or even genera, having been generated, from time to time, in the vegetable kingdom, by cross impregnation; which we are very unwilling to admit, nor do any of his instances prove satisfactory to us. As to *Parnassia*, we now know several American species, as distinct as those of any other genus.

Order 30. Contortæ. "This order derives its name from the corolla, which," (in all the species known to Linnæus,) "is twisted in the bud, contrary to the course of the sun, its limb being wheel-shaped, when expanded, in such a way that each of its segments, unequally proportioned in their margins, is curved inward under the next segment, the shorter side of the former being beneath the longer one of the latter. Europe is very poor in this tribe, India very abundant. Many of the plants are milky, and, like most other such, poisonous; some indeed so violently, as immediately to destroy animals that eat them. Their medical effects, rightly managed, may be very great. They have all, naturally, an injurious property, even *Asclepias Vincetoxicum*, though this plant, like *Nerium* and *Vinca*, is scarcely milky, but in its very youngest shoots." (It is singularly remarkable that the fruit of one of this family, at Sierra Leone, the size of an orange, yields a copious and wholesome milk, used by the colonists as cream to their tea. See *Sm. Introd. to Botany*, ed. 3. 316.)

"Many of the order of which we are treating are shrubby; the leaves opposite and evergreen, except the species of cold countries. The flower is, in many cases, intricate in structure, because of the

peculiar apparatus of the nectaries of various genera."

"The roots are perennial. Leaves all, as far as hitherto known, simple and undivided, and, with very few exceptions, opposite; sometimes ternate, or quaternate; rarely alternate. The inflorescence is often peculiar, in having its flowerstalk not axillary, but proceeding from the side of the stem between the insertion of the leaves. Calyx of one leaf, five-cleft. Corolla of one petal, regular, its segments contorted, as above described, and often notched in the margin. Nectaries, in many instances, singularly formed. Stamens five. Pistils two, or one with a double stigma. Germen superior in all, except *Gardenia*, *Genipa*, and *Macrocnemum*," (all now certainly not admitted into this order.) "The Fruit, in many genera, as *Vinca*, *Nerium*, *Echites*, *Plumeria*, *Tabernæmontana*, *Cameraria*, *Periploca*, *Apocynum*, *Cynanchum*, *Asclepias*, *Stapelia*, *Ceropegia* and *Pergularia*, consists of two distinct follicles, not observable in other plants. This sort of seed-vessel is like a *spatha* amongst the other kinds of calyx, of one valve, splitting longitudinally at the inner edge. But the seeds are not attached to the suture, there being a separate thread-shaped receptacle, extending the whole length of the seed-vessel, over the whole of which the seeds are imbricated, in a downward position. In all the above mentioned the seeds are crowned with a soft hairy tuft, except those of *Vinca*, which have no such appendage. The flowers of the *Contortæ* are usually very handsome, and there is something so singular in the structure of many of them, especially relative to the nectary and stigma, that it is difficult to say, in many instances, whether they have one or two stigmas; especially when two germens seem to bear but a single style. The corolla in all is five-cleft, and the stamens five. Jacquin contends that the latter are really ten. Linnæus from repeated examination of *Asclepias*, was confirmed in the former opinion, and especially from the investigation of *Periploca*, whose flower, evidently constructed on the same principle as *Asclepias*, has, no less evidently, but five stamens."

Giseke very improperly annexes *Embothrium* and *Rhopala* to this order, only because their fruit is a follicle; nor does any other genus which he, or Linnæus, has mentioned, really belong to it, except *Allamanda*, *Rauwolfia* and *Cerbera* of the latter; *Gynopogon* and *Melodinus* of Forster, with *Willughbeia* of Schreber. The first has a bivalve coriaceous capsule, as if formed of two follicles united, with imbricated seeds; the rest have pulpy fruits. Most of the other genera referred hither, as *Gardenia*, *Cinchona*, *Portlandia*, &c. belong to the great order of *Rubiaceæ* in Jussieu, of which the Linnæan *Stellatæ*, No. 47, make a part. It must be allowed, nevertheless, that the corolla of *Gardenia* answers to the character of the *Contortæ*. Mr R. Brown, in the *Wernerian Transactions*, has thrown much light on the principal genera of this family, under the title of *Asclepiadeæ* and *Apocineæ*, with the addition of numerous new ones.

Order 31. Vepreculæ. No explanation of this occurs in the *Prælectiones*. The genera are *Dais*, *Quisqualis*, *Dirca*, *Daphne*, *Gnidia*, *Struthiola*, *Lachnæa*, *Passerina*, *Stellera*, with *Thesium*, and in the manuscript *Scleranthus* and *Santalum*. These three last do not properly belong to the others, which constitute a most natural order of generally small shrubs, as the name implies. They are known by their tough branches; silky inner bark; simple entire leaves; acrid and even burning flavour; and sweet-scented flowers, whose calyx and corolla are united into one integument, most coloured within.

Order 32. Papilionaceæ. An extensive and very natural family, "consisting of the *Leguminosæ* of Ray; which Tournefort," (following an idea of Baptista Porta), "called *Papilionaceæ*; Rivinus *flores tetrapetali irregulares*; and Magnol *pentapetali*. They have not all five petals, for in many the claw of their keel is simple; in some the keel is separated towards the base into a double claw; while in a few only, the whole keel is composed of two distinct petals, as in *Spartium*."

"Their character is as follows. Perianth of one leaf, irregular, inferior, generally withering. Corolla nearly the same in all. Its standard either emarginate or entire, either reflexed or not at the sides, for the most part very large, compared with the other petals. Wings, if present, always two, opposite, frequently large, sometimes, as in *Colutea* and *Hedysarum*, very short. Keel simple, either pointed, obtuse, or abrupt. Stamens ten, nine of which have their filaments united, more than half way up, forming a membranous sheath to the pistil; the tenth sticking closely under the pistil, and being sometimes inserted into the base of the tube composed by the other nine. Hence arise two divisions of the order, without attention to which the genera are with difficulty defined. Pistil generally uniform; the style downy or woolly, either above or below; stigma either acute or capitate. Legume of two valves, which must not be confounded with a *Siliqua*, or Pod, though old writers have so termed it, applying that name equally to the fruit of this order and that of the *Tetradynamia* class. As these fruits differ widely in structure, Linnæus has restricted to the latter the term pod, whose character is to have the seeds attached to each suture of the valves; whereas in the legume, or fruit of the class *Diadelphia*, they are connected with one suture, or margin, only. The name of *legumen* indeed originally belonged to the seed itself of these plants; but for want of a better word, Linnæus has applied it to their seed-vessel. The legume is mostly of one cell, containing many seeds; except *Astragalus* and *Biserrula*, in which one suture is internally dilated, as it were, so as to make a partition, separating the fruit into two cells; whilst *Phaca* has the same part extended only half the breadth of the legume, rendering the separation incomplete. *Geoffræa* has a *drupa*, which still ought to be considered as a single-seeded legume, whose pulp is hardened," (or rather, whose coat is made pulpy.) "The ripe legume bursts along its sutures, and throws out its seeds. There are indeed some which do not open in this manner, but fall off in separate joints, each containing a seed, examples of which are *Hedysarum* and *Ornithopus*."

"The genera of this natural order so nearly approach each other, that it is difficult to detect their discriminative characters. Tournefort, though he distributed other genera by their flowers, divided and determined these by their foliage. But *Hedysarum* forms an objection to such a principle of arrangement, because some of its species have simple leaves, others ternate, conjugate, or pinnate."

"*Lathyrus*, *Cicer*, and *Vicia* are genera most nearly akin to each other, as are *Phaseolus* and *Dolichos*. *Coronilla*, *Ornithopus*, *Hippocrepis*, *Scorpiurus*, *Lotus*, and some species of *Trifolium*, agree in their umbellate inflorescence." (*Sophora*, and its many new-discovered allies, ought to make a section, at least, by themselves.)

"There is no poisonous plant in this whole order, except the seeds of *Lupinus*, with which the *Hippopotamus* is killed, and which fowls will not eat. Indigo becomes poisonous in its preparation, but the plant is originally harmless. On the other hand, none of this tribe is medicinal, except *Glycyrrhiza*. *Galega*, commended as antipestilential, is not to be trusted. These plants have no remarkable odour," (except in the flowers of a few species.) "Their seeds are flatulent; but afford nourishing food for labouring people."

Order 33. LOMENTACEÆ. "These are perhaps all shrubby," (or arboreous.) "Leaves alternate, compound, at least in the indubitable plants of this order; pinnate or bipinnate; without a terminal leaflet, *Moringa* excepted. Stipulas always large, particularly to be noticed. Calyx five-cleft. Corolla in some degree irregular, polypetalous, except *Ceratonia*, and several *Mimosæ*. Stamens differing in number; mostly ten. Pistil universally single. Fruit a legume, for the most part having transverse partitions. The leaves fold together at night, except those of *Ceratonia*, and that in a different manner according to the different species. Many of this order possess a purgative quality, while some have a virose or nauseous flavour about them, but this last is not at all the case with *Ceratonia*."

Of *Polygala*, which stands at the head of this order, nothing is recorded by Giseke from the lectures of Linnæus, nor has he himself made any note. It surely answers but indifferently to the *Lomentaceæ*. Genuine examples of the order are *Bauhinia*, *Hymenæa*, *Cæsalpinia*, *Cassia*, perhaps *Securidaca*; from which *Ceratonia*, *Mimosa*, *Gleditsia*, &c. considerably recede in character, though less in habit. *Cercis* ought to be ranged, with *Anagyris*, *Sophora*, &c. either in the preceding order, or rather in a separate one, intermediate between the two.

Order 34. CUCURBITACEÆ. "In this order there are, properly, no trees. Some of the plants indeed have a climbing, woody, perennial stem; others a perennial root only; whilst others again are entirely of annual duration. Leaves in all alternate, simple, always accompanied at their origin by stipulas. There are mostly glands, either on the footstalks, at the base of the leaf, or on its disk. All have tendrils, by which they climb if they have any opportunity; otherwise they are procumbent. These plants seem akin to the *Sarmentaceæ*, order 11th; but the latter have a twining stem, these not; they are monocotyledonous, these dicotyledonous; they are destitute of tendrils, with which these are furnished. The calyx is either of five leaves, or five deep segments. Corolla of one petal, in five deep divisions, but so much cut, in many instances, that it is scarcely possible, but from analogy, to say whether it consists of one or five petals. The stamens are inserted, not into the receptacle, but into the interior surface of the calyx, to which also the corolla is attached. Their filaments are often five, but frequently so combined as to appear three only. So also the anthers are often connected, the summit of one to the base of another, making a continued serpentine line. The style is of considerable thickness, with three, frequently cloven, stigmas. Fruit internally of three cells, fleshy, and somewhat juicy. The seeds are, for the most part, capable of being kept for a long time, though they appear of a dry nature; but that they are not really so, is evident from the emulsions prepared from some seeds of this tribe. Gardeners think them better for keeping. The sex of the flowers is, in several cases, distinct, and either monoecious or dioecious. The whole order is noxious and fœtid, hence it affords some of the most violent medicines, as Colocynth and Elaterium. Even melons themselves, if taken too plentifully, are said to be injurious, though in ripening they part with much of their unwholesome quality." The genera are *Gronovia*, *Anguria*, *Elaterium*, *Sicyos*, *Melothria*, *Bryonia*, *Cucurbita*, *Cucumis*, *Trichosanthes*, *Momordica*, *Feuillea*, *Zannonia*, *Passiflora*. "The last affords some of the most beautiful of all flowers; many of them are fragrant."

Order 35. SENTICOSÆ. The briar and bramble tribe. The genera are *Alchemilla*, *Aphanes*, *Agrimonia*, *Dryas*, *Geum*, *Sibbaldia*, *Tormentilla*, *Potentilla*, *Comarum*, *Fragaria*, *Rubus*, *Rosa*. *Poterium* and *Sanguisorba* are inserted at the head of this list, in the Linnæan manuscript. See the following order.

Order 36. POMACEÆ. The apple and plum kinds, consisting, in the first section, of *Spiræa*, *Ribes*, *Sorbus*, *Cratægus*, *Mespilus*, *Pyrus*; in a second, of *Punica*; and, in a third, of *Chrysobalanus*, *Prunus* and *Amygdalus*. These two orders are treated of together, in the *Prælectiones*, it is not said for what reason, though their strict affinity cannot be overlooked. "Many of these plants," says Linnæus, "are shrubs, most of the whole are perennial, very few annual. They are rarely smooth. The leaves are alternate, mostly compound. Stipulas always two, large. None of the plants properly climb, though some brambles support themselves on their neighbours. Their distinguishing character principally consists in the receptacle of the stamens being equally that of the germen, but raised, at the sides of the calyx, above the germen. Hence, the calyx bearing the stamens, they are *calycanthemi*. The fruit is either superior or inferior, therefore that distinction is not always important. In *Rosa*, for instance, the part in question seems inferior, but is in fact the contrary, for the seeds are really inserted into the inner side of the calyx, exactly as in *Mespilus*, with this difference only, that in the latter they are imbedded in the pulp, which fills the calyx. The

segments of the calyx are mostly in a double series, the innermost largest, the outer alternate therewith, and smaller, answering to the petals. Stamens for the most part numerous, but *Sibbaldia*, *Alchemilla*, and *Aphanes* form an exception, the first having five stamens, the two last only four," (or even fewer). "The pistils vary in number. There is nothing acrid in the whole order, nor much fragrance; there is much of a styptic, little of a mucilaginous quality; nothing poisonous; so that if the fruits are worth tasting, they may certainly be eaten with impunity."

Order 37. Columniferæ. "So called, not because the author meant to express, in the name, the essential character, but in allusion to some distinguished examples of this order, whose stamens are united into a columnar form. Linnæus was really the founder of the order in question, though Tournefort endeavoured to keep together as many of the same plants as possible, under his *Monopetali Campaniformes*. But the corolla has five petals, though they all fall off in one body, being connected with the combined stamens. Some have been denominated *akin to Malvaceæ;* indeed many of the class *Monadelphia* belong to this tribe."

"The root in all these plants is fibrous, in no instance bulbous or tuberous. Stem often herbaceous, but there are many arboreous, and amongst others the kinds of *Bombax*, or Silk Cotton, almost the largest trees in the world. Some of these only bear spines; but some species of *Hibiscus* are prickly. There is scarcely a perfectly smooth plant in the whole order. They have all stipulas, in pairs. The leaves are alternate, never opposite; in numerous instances stalked; plaited in the bud; and, what is remarkable, many of them have glandular pores under the rib. No tendrils are found in the order. The inflorescence is various. Calyx in several simple and five-cleft, but in some genera double, as *Malva*, *Alcea*, *Althæa*, *Lavatera*, *Malope*, *Gossypium* and *Hibiscus*. Petals generally five, but as they often adhere to the united filaments, the corolla seems monopetalous. This adhesion contradicts the opinion of Vaillant, who has said that stamens are never inserted but into a monopetalous corolla. Their connected claws often form a nectary between them. The corolla is somewhat abrupt, and twisted contrary to the sun's motion. Pistils usually corresponding in number to the parts of the fruit; as do the stigmas, where the style is simple. *Turnera* has as many styles, as there are cells in the capsule. The fruit is always superior, but differs in different genera. *Malva*, *Alcea*, *Althæa*, *Lavatera* and *Malope*, have numerous capsules, ranged like a wheel round the base of the style; nor is the latter placed upon, but in the midst of, them, as in the *Asperifoliæ*, order 41. Each capsule is single-seeded, and falls off with the seed; which is likewise the case in *Urena;* such seed-vessels might perhaps rather be named *arilli*, or tunics, as they burst at their inner side. Many of this order have solitary seeds in their cells, or capsules, like the above, and the genus *Ayenia;* but many others are polyspermous, as *Bombax*, *Hibiscus*, *Theobroma*, &c. A few of the genera produce woolly seeds, as *Bombax* and *Gossypium*; in the place of which appendage, *Adansonia* has a mealy powder. Some bear a capsule of five cells, containing many seeds; which in *Hibiscus Malvaviscus*," (now constituting the genus *Achania*,) "becomes pulpy. It is curious that *Hibiscus Moscheutos* bears its flowerstalk upon the footstalk, like *Turnera;* a rare circumstance in the whole vegetable kingdom."

"*Hermannia* has hooded petals, in a corolla twisted like that of *Malva*. They are auricled and dilated below, forming a nectary by their involution, as the true *Malvaceæ* do by the cohesion, or approximation, of their petals. The calyx is tumid. Capsule of five cells. All the species are shrubby. The flowers are so alike in all, as hardly to be distinguishable from one another; and hence perhaps it may be presumed, that the various species, all natives of the Cape of Good Hope, may in this, as well as other genera, have been produced from the hybrid impregnation of some original one. *H. pinnata* has the only compound leaves in this order." We must protest against this extensive speculation, of the production of permanent mule species, having seen many arise from such a cause, but none continue to propagate itself for any length of time. It is not the least curious particular, in the structure of the genus before us, that the flowers, which commonly grow together in pairs, have the corolla twisted in an opposite direction to each other.

The second section of this order, composed of *Camellia*, *Thea*, *Gordonia*, *Stuartia*, *Tilia* and *Kiggelaria*, are at least nearly akin to the foregoing genera.

"This whole order contains no disagreeable or hurtful plants, nor are they esculent. None are fœtid, but some agreeably fragrant. Many of the flowers are beautiful. Their quality is generally mucilaginous, particularly *Althæa*, *Malva* and *Alcea*. The ancients made considerable use of Mallows in their food, but these plants are now out of use in that respect."

Order 38. Tricoccæ. "Botanists apply this term to plants whose fruit is, in a manner, composed of three nuts, combined together like that of *Thea*. In the order under consideration, the seed-vessel is generally a roundish three-cornered capsule, rounded on all sides, with single-seeded cells, which bursting elastically, with considerable force, scatter the seeds to a distance. It must be observed, however, that as in this order some genera, like *Mercurialis* and *Cliffortia*, are dicoccous" (having only two cells, or lobes), "so there are tricoccous plants" (as *Thea*, and many more,) "that do not belong to it."

"The plants of this order bear alternate, mostly simple, leaves, often furnished with glands. Many afford a most acrid milk; they are generally offensive, nauseous, purgative, or poisonous. The style is in several highly remarkable, being more or less deeply three-cleft, and each of its branches divided. The calyx, as well as corolla, have always something unusual in their conformation, or in their nectary; and many of the genera are monoecious or dioecious."

"*Euphorbia*, as a familiar and most distinct genus, may serve as a principal example. It is certainly no

less singular than extensive. The calyx of one inflated leaf has four or five marginal teeth, and terminates in as many abrupt coloured glands. The latter are remarkably situated on the teeth themselves; but these teeth seem, together with their glands, to be rudiments of petals. In *Euphorbia corollata* the glands are actual petals, as thin, expanded, and delicate, as those of Flax; but scarcely another instance is known, of petals originating in teeth of a calyx."

"*Plukenetia*, a very rare plant, has a four-cleft flower, and four-celled fruit, with a climbing stem."

There are numerous genera besides. *Rumphia* and *Trewia* are added to the list in the Linnæan manuscript.

Order 39. SILIQUOSÆ. "All botanists have acknowledged the common affinity of the genera constituting this order, and have denominated them *Siliquosæ* and *Siliculosæ*. Tournefort called them cruciform flowers; Linnæus, *Tetradynamia*. These plants have mostly inversely-heartshaped cotyledons, except some Cresses, in which those organs are three-cleft; the rest agree with the genus *Convolvulus*; so this character is no proof of affinity."

"The stems are herbaceous, except some species of *Alyssum*, and one *Vella*. There is no real tree among the whole. The roots are all fibrous, none bulbous or tuberous," (except perhaps *Dentariæ*.) "Leaves universally alternate, without stipulas, tendrils, prickles, or venomous stings. Inflorescence usually a *corymbus*, which gradually elongates itself into a *racemus*, so that the flowers are corymbose, and fruit racemose. Calyx always of four leaves, deciduous, except in *Alyssum calycinum* and *Brassica Erucastrum*. Petals four, with claws; some species of *Lepidium* and *Cardamine* only having flat, or straight petals. The receptacle in most, but not in all, is furnished with glands. Stamens six, the two opposite ones shorter, or at least more spreading." (A very few species have only four or two stamens.) "Fruit commonly a pod, with two valves, two cells, and many seeds. A few genera have a solitary seed, either imbedded in pulp, as *Crambe*; or in a lamellated flat seed-vessel, as *Isatis*; or in an angular one, as *Bunias*."

"The plants of this order are distinguishable into *Siliquosæ* and *Siliculosæ*, the former having an oblong, the latter a rounded pod. But it being difficult to define the precise limits of each, Linnæus refers to the *Siliquosæ* such as have a stigma without a style, and to the *Siliculosæ* such as have a style to elevate the stigma, which character is conspicuous in every instance, except in *Draba*, where the style is but short."

"It is of importance to observe whether the calyx in the present order be closed or spreading; that is, whether the leaves composing that part be parallel, so that their sides touch each other, or horizontally distant."

"The nature of a *Siliqua*, or Pod, appears from what has been already mentioned. It differs from a Legume, in having the seeds attached to each suture, or margin."

"All these plants have a more or less acrid watery juice; hence their external application excites redness in the skin, and their internal use irritates the finer fibres. Nature therefore is solicitous to expel them, and, in consequence of their watery nature, by the kidneys, hence they are all diuretic. Salt being of a corrosive quality, produces scurvy; but salt is secreted from the body by the promotion of urine, though it must first be dissolved in a watery menstruum; consequently the herbs in question rank among the chief antiscorbutics, especially water-cresses and scurvy-grass. They ought never to be used in a dried state, as their acrimony and medical virtues are destroyed by drying. Boiling likewise is destructive of acrimony, especially in these plants; they ought therefore to be taken recent. Their diuretic powers render them eminently serviceable for evacuating water in the dropsy. Yet their use ought not to be too long continued, as their acrimony abrades the minuter fibres, rendering the vessels, and the intestines, in a manner, callous. This appears from the rigidity and torpidity of stomach induced by too much use of mustard."

"There is scarcely any thing odoriferous about these plants, except in their flowers. When they are bruised, indeed, something volatile ascends, of an acrid, rather than odorous nature, irritating the coats of the nerves, and inducing spasms, which do not originate in the medullary substance of the nervous system, but in its coats."

No alteration or addition respecting the genera of the *Tetradynamia* occurs in the Linnæan manuscript.

Order 40. PERSONATÆ. There is no commentary on this order in the lectures of Linnæus. Giseke has given a synoptical arrangement of the genera, according to the shape of the corolla, which is not in every part precisely correct. He justly expresses his doubts respecting *Melaleuca*, of which we have spoken under the 19th order; and he truly observes that there is no order in which so many genera are named after botanists as in the present.

The only manuscript additions or corrections, which occur in the *Genera Plantarum* of Linnæus, are the following: *Martynia*, *Craniolaria*, *Torenia*, and *Scrophularia* are pointed out as akin to *Pedalium*, in order 28th; *Hyobanche*, *Lindernia*, *Pæderota*, *Manulea*, *Premna*, and *Calceolaria* are inserted, with a question, certainly not well founded, whether the latter should not rather be referred to the 24th order. *Brunfelsia* also is placed among the *Personatæ*, at the suggestion of Van Royen.

Order 41. ASPERIFOLIÆ. "These plants were first collected into an order by Cæsalpinus, and received the above appellation from Ray, because of their generally harsh or rough habit. Their root is fibrous. Cotyledons two. Stem branched; the branches alternate and round. Leaves alternate, simple; neither divided nor compound, for the most part nearly entire, rough with rigid scattered hairs; convolute before they expand. Stipulas none; nor are there, except very rarely, any other *fulcra*, or appendages. Common flowerstalk having the flowers ranged along one side. Before flowering it is rolled spirally backwards, gradually expanding as the flowers are ready to open, and divided into two parts, each bearing the flowers on its back, in the

form of an unilateral spike. Calyx in five divisions. Corolla inferior, of one petal, regular except in *Echium*, five-cleft; its mouth either furnished with vaulted valves, or crowned with teeth, or naked. Stamens five, equal; in *Echium* only they are unequal. Fruit superior. Germens four, naked, except in *Cynoglossum*, *Tournefortia* and *Nolana*; inserted into the receptacle by their base; hence the lowest part of each seed is of a tapering form, as if artificially rounded. Pistil one. Style not standing upon the germens, but occupying the central space between them; often divided into two equal parts; not one longer than the other as in the class *Didynamia*. Seeds four, rarely combined into two; but it is singular that *Nolana* has five seeds." Linnæus has, as already mentioned, removed this genus to his *Luridæ*, order 28th.

"The *Asperifoliæ* are distributed according to the mouth, or throat, of their corolla, which is naked, or pervious, in *Echium*, *Pulmonaria*, *Lithospermum*, *Heliotropium*, *Cerinthe*, and *Onosma*; toothed in *Symphytum* and *Borago*; closed with vaulted valves in *Cynoglossum*, *Asperugo*, *Anchusa*, *Lycopsis*, *Myosotis* and *Tournefortia*."

In the *Gen. Plant. Messerschmidia*, *Coldenia*, *Hydrophyllum*, and *Ellisia* are inserted in manuscript.

"All the *Asperifoliæ* are mucilaginous, and act only as such. The ancients selected their four cordial flowers out of this order, seeming not to have been aware that the motion of the heart depends upon the nerves, which therefore must be strengthened if the force of the heart is to be increased. This end however is not to be attained by either the flowers or the herbs of this tribe, which nevertheless have long been used for the purpose. The leaves may be eaten as food, by which their small medical use may be estimated. The root is perennial and mucilaginous;" (we would rather say "if perennial, is mucilaginous," which perhaps were the original words of the lecture.) "Among the whole, *Symphytum* abounds most with mucilage, equalling, in quantity as well as quality, the monadelphous plant *Althæa* in this respect. *Symphytum tuberosum* has been recommended in the gout. Possibly its mucilaginous quality may hinder the crystallization of the gouty matter. The root in almost all the *Asperifoliæ* is red, but for the most part externally only. The root of *Lithospermum tinctorium*, now *Anchusa tinctoria*, is used for its colouring properties. Of all plants, the herbs of this order yield the largest proportion of ashes. There is hardly an odoriferous, nor one fragrant, herb in the whole tribe; though *Cynoglossum* has a somewhat fœtid scent. Their taste is nothing, the great quantity of mucilage involving the stimulating particles. These herbs are esculent, especially when young and tender, although their rough surface renders them less agreeable to delicate palates. They generally grow in dry mountainous situations; and it is singular that in proportion as they are found nearer to water, they become smoother."

Order 42. VERTICILLATÆ. "Ray, in constructing his system, founded three classes, which all succeeding botanists hitherto have approved, the *Stellatæ*, *Asperifoliæ*, and *Verticillatæ*; but he was unable to give proper characters of the genera. Hermann subsequently, establishing a system upon the fruit, called the *Verticillatæ* of Ray *Gymnotetraspermæ*, plants with four naked seeds, but he could not by this means distinguish them from the *Asperifoliæ*, which have the same character. The generality of *Asperifoliæ*, in fact, differ from the *Gymnotetraspermæ*, in their corolla, which in the former is regular, in the latter irregular, though likewise monopetalous. But *Echium*, though it belongs to the *Asperifoliæ*, has still an irregular corolla. The *Asperifoliæ* have alternate leaves, the *Gymnotetraspermæ* opposite ones. These classes might therefore be distinguished from each other, according to Hermann's method, were not *Echium* an obstacle. Linnæus, however, that he might avoid all confusion between the orders in question, has borrowed a character from the stamens, and has referred to his class *Didynamia* such plants as have two stamens longer, and two shorter. He has moreover divided that class into two orders, the first of which comprehends Hermann's *Gymnotetraspermæ*, whose stamens easily distinguish them from the *Asperifoliæ*. But the consideration of the stamens has further obliged the author of the sexual system to refer certain genera, of the natural order under our present consideration, to his class *Diandria*: These are *Verbena*, *Lycopus*, *Amethystea*, *Ziziphora*, *Cunila*, *Monarda*, *Rosmarinus*, *Salvia*, and *Collinsonia*; of which *Verbena* and *Collinsonia* perhaps ought rather to be placed in the other order of the *Didynamia*, called *Angiospermia*." This is correct with regard to *Verbena* only.

"The calyx of the *Verticillatæ* is of one leaf, inferior. Corolla of one petal, irregular, in most instances gaping, with two lips, the uppermost of which was called by Rivinus the *galea*, or helmet, the lowermost the *barba*, or beard. Stamens four, except in the several genera just mentioned, where they are only two, inflexed, ascending under the upper lip. Germens four, from between which the style arises, as in the *Asperifoliæ*, which is wavy, solitary, except in *Perilla*, where there are two, and bearing two acute stigmas. Seeds four, naked, *Prasium* excepted, whose seeds have a succulent skin, causing them to resemble berries. A berry, properly speaking, is a seed-vessel; but in *Rosa* it is the calyx, in *Fragaria* the receptacle, and in *Prasium* the skin of the seeds."

"Many of this order are humble shrubs, none are trees, most of them are annual or perennial herbs. The stem is generally square. Leaves in every instance opposite, simple, mostly undivided. None of the plants are furnished with tendrils, nor of a climbing nature. The scent of nearly all of them is highly fragrant, the odoriferous matter being contained in minute cells, which, when the leaves are held against the light, appear like numerous perforations."

"The flowers usually stand in whorls, encircling the stem as with a ring. When these whorls approach very closely together, the stems appear spiked, as in *Origanum*."

"This order is in the highest degree natural; whence arises great difficulty in determining the genera. Linnæus has derived a character from the

calyx, according to which the whole order is divided into two sections."

"The first of these comprehends such as have a five-cleft calyx, that is, where all the teeth of this part are nearly of equal size and shape. The second consists of those with a two-lipped calyx, which is indeed five-cleft, but its two upper segments are, in a manner, united into one, which might almost be termed emarginate only; while between these two united segments and the remaining three, there is so deep a fissure, at each side, that the calyx is nearly divided into two parts, or lobes. Linnæus has bestowed great attention in searching for the essential characters of genera in this natural order, and has detected several, which are marked in the *Systema Vegetabilium* with a sign of exclamation."

Order 43. Dumosæ. "*Dumus* and *nemus* are synonymous, meaning a thicket; or wood consisting of shrubs, not of large trees. All the plants of this order are shrubby, but none of them, except in the genera of *Sideroxylum* and *Chrysophyllum*, grow to large trees."

"*Rhamnus* is supposed to be familiar to every body. Its calyx is tubular, five-cleft at the margin, occasionally coloured, like a corolla, but not perforated at the bottom. A monopetalous corolla falls off, with a perforated tube; which is not the case here. But betwixt every two segments of the calyx is stationed a delicate little scale, which any person might easily take for so many petals. The stamens however, being placed under each scale, are therefore alternate with the divisions of the calyx; whereas if these scales were real petals, the stamens ought, by a general rule, to be alternate with them, and not with the parts into which the calyx is divided. Some species, as the Buckthorn, *R. catharticus*, have four-cleft flowers, but they are mostly five-cleft. This last-mentioned, like *R. alpinus*, is dioecious; *Zizyphus* is polygamous. The stigma in some *Rhamni* is emarginate, in others three or four-cleft. The fruit of this genus is various; a berry in some with four seeds, in others, as *Paliurus* and *Alaternus*, with three; in others again it has a single seed with two cells, as in *Zizyphus*. *Paliurus* has not, properly, a berry, but a depressed, bordered, shield-like capsule. The stem in some is thorny, in others prickly, in others unarmed."

"French botanists have recommended the dividing of this genus into several, a measure which appears highly proper to those who have not seen the Indian species. If such genera are to be distinguished by their fruit, species most resembling each other will be put asunder, and widely different ones brought together, as any person making the experiment will find. Besides, the structure of the flower, and the habit of the plants, are respectively so alike in all the species in question, and so different from all the rest of the order, that any peasant might perceive their affinity."

"*Phylica* agrees in almost every point with *Rhamnus*, except that its flowers are aggregate, and florets superior. This genus is so nearly akin to *Brunia*, that without seeing the fruit, which very rarely occurs, they can scarcely be distinguished. *Phylica radiata* therefore, universally esteemed a *Phylica*, proves, on the detection of its fruit, to be a *Brunia*."

"*Ceanothus*, with its three-lobed fruit, like that of *Rhamnus Alaternus*, agrees in every character with *Rhamnus*; but the scales of that genus are here drawn out into vaulted petals, supported by long claws."

"*Büttneria* differs in hardly any respect from *Rhamnus*, except its anthers; for the calyx, prickles, and every thing else, answer so well, that at first sight one would decidedly take it for a species thereof."

"*Sideroxylum* has a five-cleft calyx, and at the same time a monopetalous corolla; but between all the segments of the latter stands a little serrated tooth, analogous to the scales of *Rhamnus*. The flowers are likewise sessile on the stem, but the berry has only one seed."

"*Chrysophyllum* is so nearly akin, and so similar, to *Sideroxylum*, as hardly to be distinguishable by its general aspect; but its fruit contains many seeds, though indeed they are disposed in a circle."

"*Achras* differs from *Chrysophyllum* in having a six-cleft flower; and to this genus *Prinos* is very nearly related, differing in the flat form of the corolla, and fewer cells of the fruit."

"*Ilex* so nearly accords with the last-mentioned genus, that the only *Prinos* then known was originally taken for an *Ilex*; but the flower of *Ilex* is four-cleft, not six-cleft."

"*Tomex* and *Callicarpa* only differ from *Ilex* in having a single style, and not four stigmas. The berry of *Callicarpa* is like that of *Ilex*. In *Tomex* the stamens are inserted into the receptacle, whereas in *Callicarpa* they are attached to the tube of the monopetalous corolla." These genera have since been united by the author himself.

"*Euonymus* is so nearly allied to *Tomex*, as scarcely to be distinguishable, except by having a capsule instead of a berry. Its seeds moreover have a pulpy tunic."

"*Celastrus*, though differing from *Euonymus* in having alternate leaves, is so much akin to that genus, as to have been called *Euonymus* by all systematic writers. Yet its fruit differs in number and proportion from *Euonymus*, just as *Peganum* does from *Ruta*. The tunic of the seeds however, though not pulpy, confirms the affinity to which we allude. Some botanists, especially the French, are unwilling to admit plants with opposite leaves and alternate ones into the same natural order, and they are right; yet this character is not absolute, for such a difference often occurs in one and the same genus."

"*Viburnum* and *Cassine* come so near together, that there is rather a question respecting the distinction of the genera themselves, than of their natural order. *Cassine* has three seeds, *Viburnum* one, which seems two combined. The former is akin to *Sambucus*, and, like that genus, emetic in quality. Concerning the affinity of *Viburnum* to *Ilex* and *Callicarpa*, any person, who considers their fructification and habit, can have no doubt. Thus far therefore the matter is clear."

"*Sambucus* may excite some mistrust, because of its inferior fruit; yet this is the case in *Phylica*,

about which nobody has ever doubted. The leaves, aspect, and stipulas indeed seem to indicate something extraneous, and leave us in uncertainty."

"So *Rhus* has much the same sort of fructification, and a berry with one seed; as well as the closest affinity to *Sambucus*, insomuch that if *Sambucus* be kept in this order, *Rhus* must accompany it. So also must the sister shrubs *Schinus* and *Fagara*."

"The *Dumosæ* all agree in malignant qualities. They are either purgative, or altogether poisonous, as *Sideroxylum* is known to be at the Cape. Nor are the species of *Sambucus* clear of this charge, for their qualities are either nauseous or fœtid, and therefore sudorific, especially the berries and flowers. The bark, taken internally, is either emetic, or powerfully purgative, as its vinous infusion proves in the dropsy; externally it is a powerful repellent."

"*Rhus* is the most venomous of trees, particularly its American three-leaved species, called *Toxicodendra*, or Poison-trees. Their fumes in burning are said to have proved mortal, and their effluvia to have blinded an artist who was at work upon some of the wood. Those who, being in a perspiration, hold a branch of one of these shrubs in the hand, are seized with an eruption over the whole body."

"The bark of *Rhamnus Frangula* is our best indigenous purge, and a syrup of *Rhammus catharticus* is safely used for children."

"In this tribe, therefore, some have opposite, others alternate, leaves, nor is any general character to be derived from the parts of fructification. The corolla affords none, being either of one or five petals, or altogether absent, as appears from a contemplation of the characters of the different genera. No mark is to be obtained from the nature of the fruit, that being either a berry, drupa, or capsule. The seeds in some instances are solitary, in others numerous, though never more than one in each cell; and it is well worthy of observation that they are attached, as in the *Gymnotetraspermæ*, by their base. These plants betray some affinity to the *Tricoccæ*, but can never be referred to the same order."

In the Linnæan manuscript before us *Diosma* and *Hartogia* are introduced between *Callicarpa* and *Euonymus*; see our remark on the 26th order. *Staphylea* is also subjoined, near *Celastrus*, but with two marks of doubt, and a note of its having a nectary, as well as opposite leaves.

Order 44. Sepiariæ. "All these are shrubby or arborescent. Leaves opposite, with scarcely any evident stipulas. Flowers disposed in a more or less dense panicle. Calyx four-cleft. Corolla four-cleft, regular. Stamens two. Pistil one, with a cloven stigma. Fruit either a drupa, with one, two, or many, seeds, or a capsule."

No manuscript remark occurs here, nor is there any observation worth copying in the lectures, except that *Olea* is said by Linnæus to be scarcely a distinct genus from *Phillyrea*.

Order 45. Umbellatæ. "The name of this order is derived from the form of its inflorescence, whose stalks all spread from a centre, like the ribs of an umbrella."

"These plants are either perfectly umbellate or not. The former are required to have a compound umbel, each stalk, or ray, of which ends in a receptacle, producing other stalks bearing flowers, or florets; the latter have a simple umbel, whose stalks are not subdivided. The latter constitute a separate section in Tournefort's system. They are comprehended by Linnæus in one natural order with the former."

"An umbel is properly a receptacle of a compound flower, elongated into stalks; which manifestly appears in *Eryngium*, whose florets are united into a head, just like the proper compound flowers, see the 49th order; nor are they supported by elongated stalks. Hence an umbel may accurately be considered as a compound flower. Those who controvert the opinion of Linnæus in this point contend, that many umbellate plants, having male and hermaphrodite flowers in the same species, ought to be placed in his class *Polygamia*. But this is a mistake; for no other plants ought to find a place in that class, than such as have distinct male, or female, as well as hermaphrodite, flowers, in the same species. This is not the case with the *Umbellatæ*, in which all the florets of one universal umbel, that is, the whole umbel itself, constitutes but one flower, and this flower is never altogether barren, that is, its florets are never entirely male. On the contrary, these florets are to be considered as the parts of a compound flower; and there being male and hermaphrodite ones intermixed, is exactly a parallel case with the polygamy of the Syngenesious class."

"This order is eminently natural, though all plants which bear umbels do not belong to it, but only those with five stamens, two styles, and two seeds."

"The germen is inferior, simple, solitary, separating, when arrived at maturity, into two equal naked seeds; each of which is furnished with a thread, inserted into its summit. These two threads combine to form a very slender receptacle, at the top of the stalk of the floret. Each floret has a superior perianth, with five teeth, which is often so small as scarcely to be discerned, even with the help of a magnifier. Petals five, caducous, often unequal; hence Rivinus referred these plants to his class of pentapetalous irregular flowers. Stamens five, inserted into an elevated annular or circular receptacle, that surrounds the pistils, deciduous. Styles two, often very short, and hardly visible. Seeds naked, without any seed-vessel."

"The stem is mostly hollow, sometimes filled with spongy pith; rarely shrubby, very rarely arboreous, of which last character *Phyllis* is the only example, see order 47. Leaves generally alternate, and repeatedly compound. Root mostly quite simple; in *Oenanthe* tuberous; in *Bunium Bulbocastanum* globose."

"Nothing is more arduous than to distinguish the genera of umbelliferous plants by appropriate characters. Tournefort himself, who excelled in the knowledge of this tribe," (perhaps Linnæus meant rather to say, in the discrimination of genera, but his auditors did not take his words accurately,) "has distributed them according to the shape and size of their seeds. But this is a very fallacious mode, as the seeds often differ much in proportion, though

not in any other respect. Morison wrote an entire book on umbellate plants; but with little success, their genera not being, as yet, established. Artedi first paid attention to the *involucrum*, which is either universal as well as partial, or only partial, or entirely wanting. This principle has likewise been adopted, as fundamental, by Linnæus, and his three primary divisions are regulated accordingly. The inequality of the petals affords him a principle for his leading subdivisions, some of the umbelliferous family having the outermost petals of their external florets larger than the rest; while in others all the petals are equal. The former are termed radiant flowers. Another subdivision is taken from the sex of the florets. Some of these, having no germen, are furnished with stamens only; and such florets are termed abortive; others, having both germen and stamens, bring their fruit to perfection, and are therefore denominated fertile."

On these principles Linnæus has arranged the umbellate plants, as may be seen in his works. Nothing occurs in his manuscript, except the insertion of *Hermas* next to *Eryngium*.

Order 46th. Hederaceæ. The lectures give no new information concerning this order. The six genera stand as in the *Genera Plantarum; Panax, Aralia, Zanthoxylum, Hedera, Vitis*, and *Cissus*.

Order 47th. Stellatæ. "This order was founded by Ray, and received its name from the leaves of most of the plants which compose it being placed, four, six, or eight together, in the form of a star, round the stem. It is unusual to see more than two leaves opposite to each other, nor is it the case here. For two of these only are properly leaves, the rest being no other than stipulas, grown to the size of leaves. This appears evident in several Indian plants of the present order, as *Knoxia, Diodia*, &c. which have only two opposite leaves, though between these some small acute stipulas are found, being the same that in the rest of the order attain the magnitude of leaves. Ray believed all the plants of this order to have whorled leaves, which is generally the case, as far as regards those of European growth, but rarely with the Indian ones, of which few were known in his time."

"In this order there is no tree, unless perhaps *Lippia;* there are very few shrubs, most of the tribe being small herbs, growing in barren earth, or coarse sand."

"The roots are in many instances perennial. Leaves opposite, horizontal, mostly rough. Stipulas of the form and aspect of leaves, so that it is impossible to say whether they be truly such or not, hence the leaves appear whorled; but this does not hold good universally. In those however which have no leafy stipulas, there is found, at each side, a sort of toothed membrane, connecting the leaves together, and occupying the place of stipulas."

"The stem is jointed, with mostly tumid knots. Corolla of one petal, either flat, wheel-shaped, or funnel-shaped; in one genus bell-shaped; mostly four-cleft, sometimes almost down to the base; rarely five-cleft. Stamens four, never eight, though sometimes five or six, in which case the corolla has a parallel number of segments. Pistil solitary, divided; in *Richardia* three-cleft, because that genus has a six-cleft corolla, six stamens, and a three-grained fruit, its parts of fructification being all augmented in a similar proportion. Those parts are not augmented with the same regularity in genera furnished with a three-cleft corolla, and five stamens, for their pistil is still bifid, and their fruit two-grained, as is the case with such as have a four-cleft corolla and four stamens.

"The fruit is, for the most part, inferior; though superior in *Houstonia;* and in *Crucianella* superior with respect to the calyx, though inferior to the corolla." This is incorrect, for *Crucianella* has a real superior perianth, like the rest of the order, though so small as to be hardly discernible; what Linnæus here terms calyx, being an involucrum, or perhaps bracteas. "The sexes are rarely separated in this order, though *Valantia*, which is polygamous, can by no means be excluded from it. Many of the genera have a two-grained fruit, of two cells, with a solitary seed in each. But in *Hedyotis* and *Oldenlandia* the cells contain many seeds; while in *Cornus* both cells are united into one seed, which, nevertheless, has two cells. The fruit has a green, fleshy, but not juicy, coat, nor does it usually become coloured in ripening; though in *Rubia* the fruit is a perfect berry."

(Of the remarks on particular genera, we find nothing to extract except the following.)

"*Asperula tinctoria* is used in Gothland instead of Madder, and is preferable."

"*Sherardia* has an oblong fruit, which the permanent calyx renders toothed, or crowned with three points. It was the fate of William Sherard, a man worthy, in the highest degree of botanical honour, to have two different genera distinguished by his name, both which were afterwards referred to others. Pontedera, Vaillant, and Dillenius each published, at the same time, a *Sherardia*. *Pontedera* described his plant so very obscurely, that it was ten years before Linnæus made it out to be his own *Gallenia*. Vaillant called the two-seeded *Verbenæ* by the name of *Sherardia*, but he was to blame in separating them from their proper genus. Dillenius named a *Sherardia*, from among the *Stellatæ*, which Linnæus has retained, though not very certainly distinct. Being unwilling that so meritorious a botanist should remain without a memorial, Linnæus declined referring the plant in question to *Asperula;* especially as the three teeth, at the top of each seed, may serve, if not very satisfactorily, to keep it separate."

"*Valantia* was so named by Tournefort; but Vaillant, perceiving it to be the same with Tournefort's *Cruciata*, thought it a bad genus, which could not support itself. He therefore wished to abolish all generic names, given in honour of botanists, because he supposed his own was untenable. But Tournefort confounded several genera under the appellation of *Cruciata*, so that Linnæus has been enabled to establish a *Valantia* from among them, referring the rest to their proper places."

Order 48. Aggregatæ. "These constitute a natural order, first established by Vaillant in the Memoirs of the French Academy of Sciences. They agree so far with the *Compositæ*, that they have generally a common calyx, as well as receptacle, con-

taining many sessile flowers, each of which has always an inferior germen. But there is a total difference with respect to the remaining parts of fructification, nor can these two orders be, by any means, united."

"The calyx, as we have just said, is common to many flowers. Common receptacle either naked, villous, hairy, or scaly. In the place of a partial calyx is the corolla, generally of one petal, regular or irregular, in four or five divisions, rarely polypetalous. Stamens four, with separate anthers. Germen inferior. Fruit single-seeded. The flower is therefore complete in this tribe, except only *Valeriana*, whose calyx is scarcely apparent. The leaves are often opposite, and the stem shrubby."

Order 49. Compositæ. "A compound flower generally consists of a common calyx, containing several florets. But this definition is not sufficiently discriminative, for there are certain flowers termed *Aggregate*, which though they have numerous florets in one common calyx, are connected by no affinity whatever with these; witness *Cephalanthus, Dipsacus, Scabiosa, Knautia, Allionia*. Hence botanists have tried to discover an appropriate and distinguishing character for a compound flower, but they have scarcely succeeded. There are indeed flowers of this order, furnished with solitary florets in each calyx, as *Seriphium, Corymbium, Strumpfia*. All of them have a monopetalous corolla, but so has *Scabiosa* and others. Most have five stamens, but some have only four. The greater number bear their anthers united into a cylinder, but *Kuhnia*, which belongs to them, has separate anthers; while *Jasione, Viola* and *Impatiens*, which do not, have combined ones. The united anthers burst internally, by which means their pollen is communicated to the stigma; but the anthers of *Kuhnia* open at the extremity, and resemble the corolla of an *Aristolochia*. All the florets are superior, but this holds good likewise in *Scabiosa*. Hence it appears that no essential character of compound flowers is to be detected, though no order can be more natural than that before us."

"Tournefort first divided the compound flowers into three sections, according to the shape of their partial corollas. These are either ligulate or tubular. Such as consist of ligulate florets only, are called by this writer *semiflosculosi*; such as are formed only of tubular ones, *flosculosi*; while those which have ligulate florets in the radius, and tubular ones in the disk, are denominated *radiati*. This division seems natural enough, and yet is not so. For it refers both the discoid and capitate compound flowers of Linnæus to the *flosculosi*, which nevertheless are too dissimilar to be possibly admitted into the same section. The *discoidei* of Linnæus, Ray's *aggregati*, having aggregate florets, seated on a hemispherical receptacle, are, in fact, more allied to the *radiati*; while the *capitati*, such as Thistles, are widely different, so as necessarily to constitute a division by themselves."

"Vaillant attempted a new botanical system; but it is to be lamented that we are possessed of no more of his labours, than what concerns the compound flowers. In this performance, published in the *Memoirs of the Parisian Academy* for the years 1718, 1719 and 1720; he has displayed an extensive knowledge of species, and has treated the subject admirably. As the *Memoirs of the Academy* are not within the reach of every body's purse, a German named Von Steinwehr has collected the anatomical, chemical and botanical papers, into an octavo volume, published in 1754 at Breslaw. In this Vaillant's treatises are preserved entire," (but in the German language.)

"The florets of compound flowers are threefold with respect to sex, being either *hermaphroditi*, perfect, having the organs of both sexes; female, destitute of anthers; or neuter, deprived of both organs, and barren."

"Tournefort, Vaillant, Ray, and almost every botanist who has treated of this tribe, divide it into three or four orders, some of them adding the aggregate flowers to the compound ones, whence arises the fourth order. But they have not fixed limits to their orders, such being scarcely discoverable. The *semiflosculosi* and *capitati*, for instance, though apparently widely different, are proved nearly akin by *Scolymus* and *Elephantopus*. The former of these has all the habit of a *Carduus*, and yet all its florets are ligulate; the latter is intermediate between the *semiflosculosi* and *capitati*, nor are we certain to which of these divisions it belongs. *Perdicium*, a new genus, connects *Inula*, which is radiated, with the semiflosculous genus *Hieracium*, so that accurate limits are hardly to be drawn between them. Most of the *semiflosculosi* are milky, but *Lapsana* and *Cichorium* want this quality."

"Section 1. *Semiflosculosi*; all the florets ligulate."

"These genera are distributed, first by their receptacle, which is either chaffy, villous, or naked. In the next place, they are subdivided by the down of their seeds, *pappus*, which is either absent, or bristle-shaped, or hairy, or feathery. Thirdly, a peculiar distinguishing character is borrowed from the form or nature of their calyx."

"The quality of the *Compositæ* in general is innocent; but some of the present section are milky, which secretion proves, by experience, somewhat of a poisonous nature. So *Lactuca virosa*, in a wild state, is as poisonous as opium; yet by culture it becomes esculent and culinary, though still causing sleep by its debilitating power." Linnæus surely could not mean that this and the garden lettuce are one species. It is possible his hearers mistook him.

"There are no trees, and few shrubs, among the *semiflosculosi*; no bulbs, scarcely a tuberous root, except in some species of *Hieracium*. Their flowers are mostly yellow; sometimes red underneath, as in *Leontodon, Hieracium* and *Crepis*;" (very rarely pink, in *Geropogon* and *Crepis*); "sometimes blue, in *Cichorium* and *Catananche*; never white."

"Section 2. *Capitati*; all the florets tubular, assembled into a head, in one common calyx."

"All these are prickly or spinous, and vulgarly called *Cardui*, Thistles. If however they were all considered as one genus, such a genus would prove too ample; hence it is best to separate them into several, though the task is very difficult. *Centaurea*

belongs to them, though necessarily referred, in the sexual system, to the order *Polygamia-frustranea.* Its calyx, always tumid, and often spinous, proves its affinity. The most extensive genera of this section, *Carduus*, and *Serratula*, are the most difficult to distinguish; hence it is best to study the rest, in the first place, that those puzzling ones may prove easier."

"Vaillant divided this capitate tribe by the spines of their calyx, whether simple, spinous, or leafy. But the gradation is so imperceptible, that no accurate principles of discrimination are hence to be obtained. No plant of this section is milky, or poisonous, or arboreous. Some of the *Serratulæ* are shrubby; many of the herbs are destitute of stems, as in *Carlina*, *Atractylis*, *Onopordum*, *Carduus*, and *Centaurea*."

"*Atractylis* has a radiant flower, and the florets of the radius have each both stamens and pistil, a solitary instance among compound flowers, rendering the genus very distinct. The elongated and coloured scales of the calyx in *Carlina* have misled Tournefort to rank it among radiant flowers."

"The *capitati* have a character peculiar to themselves, in the dilatation, or inflation, of the tube of each floret, just below the limb, which causes their florets to project, in a more elongated manner, than in the *discoidei*, or other compound flowers."

"Section 3d. *Discoidei.* The first subdivision of these, *polygamia æqualis*," (consisting of such as have all the florets furnished with stamens and pistils, and all producing seed,) "are distributed according to the receptacle, whether naked, chaffy or hairy, and their seed-down, like the *semiflosculosi*."

"The second subdivision, *polygamia superflua*, have female florets in the circumference, but these are tubular, not ligulate or radiant. So that the flowers, though they have a marginal series of female florets, cannot be called radiated." We have here extracted the ideas of Linnæus from his remarks on *Artemisia*, which seem to refer to the whole of this subdivision, and are certainly correct, though they interfere with the distribution of the order before us in the *Genera Plantarum*, and seem to have been unintelligible to the editor of the *Prælectiones*; see his note in p. 539 of that work.

"Section 4th. *Radiati.*" (Marginal florets radiant.) "The first subdivision is *polygamia superflua*," (all whose florets are capable of producing perfect seed, though the marginal radiant ones have no stamens.)

These are distinguished by the presence or absence of seed-down, or of a membranous border to the seed, and by the nature of their receptacle, whether naked or chaffy.

The second, *polygamia frustranea* has imperfect or defective female or neuter florets in the circumference, producing no seed. These in *Centaurea* are tubular, and neuter; in the rest ligulate, furnished with rudiments, more or less evident, of a pistil.

The third, *polygamia necessaria*, have effective seed; bearing female florets in the circumference only.

"Section 5th. *Monogamia.*" (Such as have but one floret in each partial calyx.)

Seriphium, *Corymbium*, and *Strumpfia.*

"None of the *Compositæ* are poisonous, except *Tagetes*, *Doronicum*, and *Arnica*; the latter is more so than *Doronicum.* They contain much of a bitter flavour; hence many of the order are medicinal and strengthening. Some, less bitter, as *Arctium*, *Cynara*, *Carduus*, are therefore esculent. Many *semiflosculosi* are used as food, though furnished with a milky juice, which in them is not poisonous," (see a remark under Order 30th.) "except *Lactuca virosa*, whose juice as above mentioned, has the quality of opium, and *L. sativa* has a soporific virtue. Boiling entirely destroys the power of this, as well as of the other *semiflosculosi*."

Order 50th. AMENTACEÆ. "An *amentum*, catkin, is a species of calyx, and very like a spike, consisting of a common receptacle, drawn out like a thread, on which the flowers stand in alternate order, subtended by scales or bracteas. Such a calyx is found in the plants of this order, whence Linnæus gave it the above name. They are all either trees or shrubs, with alternate leaves, and separated male and female flowers, being either monoecious or dioecious. Many of them produce but one seed from each flower; but *Salix* and *Populus* bear a seed-vessel of two valves, with many seeds. The styles are usually two or three. The flowers come before the leaves, that the latter may not hinder the access of the pollen of the male to the female blossoms."

"Monoecious genera are *Betula*, *Carpinus*, *Corylus*, *Quercus*, *Juglans*, *Fagus*, and *Platanus*."

"Dioecious ones *Pistacia*, *Myrica*, *Populus* and *Salix*."

Order 51st. CONIFERÆ. "These are generally evergreen trees of cold climates. In the Indies almost all the trees are evergreen, and have broad leaves; but in our cold regions most trees cast their foliage every year; and such as do not, bear acerose, that is, narrow and acute, leaves. If they were broader, the snow which falls during winter would collect among them, and break the branches by its weight. Their great slenderness prevents any such effect, allowing the snow to pass between them. This precaution is unnecessary in India, where snow is unknown. Nevertheless, *Liquidambar* is to be referred to this order, though it bears no such slender, but rather broad, foliage; nor is it a native of a cold country."

"The plants of the present order are denominated *Coniferæ*, because they bear *Strobili*, which the older botanists called *Coni*, Cones. A cone and a catkin are closely related to each other. The latter bears several imbricated flowers about a common receptacle or axis. Under each flower a membranous scale or bractea is attached, which if it hardens and becomes woody, the catkin becomes a cone. Hence a cone is nothing more than a permanent or hardened catkin."

"All the *Coniferæ* properly bear cones, though in some instances their fruit seems of a totally different nature. For instance the fruit of *Juniperu* has

Botany.

all the appearance of a berry, and is universally so called. Yet it is no other than a *strobilus*, whose scales are replete with pulp, and do not split asunder; being in fact six fleshy united scales, in each of which is concealed a solitary seed. *Taxus* has a berry, which is merely a fleshy receptacle, dilated so as nearly to cover the seed, so that the apex of the latter only appears. *Liquidambar* has a singular kind of fruit, which nevertheless is a *strobilus*, whose scales are combined, each of them containing several seeds; whereas in other instances one or two seeds only belong to each scale."

"Some have united this order with the last, but they differ essentially. The *Coniferæ* have not only hardened scales, but likewise monadelphous stamens, the filaments of all of them being combined at the base."

"The fruit in this whole order, *Liquidambar* excepted, is biennial. It is produced in the spring, remaining in an unripe state through the summer, and till the following spring, when it gradually ripens, and the gaping scales allow the seeds to escape."

Order 52d. Coadunatæ. On this order there is no observation in the lectures. *Illicium* is added in manuscript to the genera in *Gen. Pl.*

Order 53d. Scabridæ. Here also the lectures are silent. *Forskohlea* and *Trophis* are added in the manuscript.

Order 54th. Miscellaneæ. Here, although no remark is preserved in the lectures, great corrections are made in the manuscript. The genera in the second section, *Poterium* and *Sanguisorba*, are referred to the 35th order, immediately before *Agrimonia*. *Pistia* and *Lemna* constituting the 3d section, are transferred to the 15th order. The six genera which compose the 5th section, are sent to the 4th section of the *Holeraceæ*, order 12th. *Nymphæa* and *Sarracenia*, the only plants of the 6th section, are referred, as already mentioned, first to the 27th order, but finally, not without a doubt, to the 11th. See the observations under those orders. *Cedrela* and *Swietenia*, which make the 7th section, are removed to the *Trihilatæ*, order 23d. *Corrigiola*, *Limeum* and *Telephium*, the 8th and last section, are transferred to the 5th section of the 12th order, *Holeraceæ*. No genera therefore remain in this 54th order, but *Reseda*, *Datisca*, *Coriaria*, and *Empetrum*.

Order 55th. Filices.
——— 56th. Musci.
——— 57th. Algæ.
——— 58th. Fungi.

Nothing occurs here, either in the *Prælectiones* or the manuscript, to the purpose of our present inquiry, concerning the ideas of Linnæus on natural classification. These orders are all natural, and acknowledged as such by all systematics. His particular observations on each, although in many points curious, are now superseded by the advanced state of botanical knowledge in the cryptogamic department.

Remarks on the foregoing Arrangement.

From the foregoing copious exposition of the general principles, and many of the particular opinions, of Linnæus, respecting a natural classification of plants, it will appear how far he was from considering his performances, in this line, as complete. His leading ideas may, nevertheless, be traced, and they will often be found to throw great light upon the subject. It must be remembered that he never thought his own, or any other, scheme of natural classification, could or ought to interfere with his artificial system, nor does he ever advert to the one, in treating of the other. It is evident, likewise, that he studiously discouraged any attempt at an uniform definition, or technical discrimination, of his several orders. He perceived that plants were not yet sufficiently known to render such a scheme practicable. Possibly he might be aware that the accomplishment of that scheme at present would only turn his natural system into an artificial one.

The authors of most plans of botanical classification have, on the other hand, seldom considered the questions of natural and artificial arrangement, as opposed to each other. The system of every such author seems to have appeared to himself the most consonant to nature, as well as the most convenient in practice; yet nothing betrays a more absolute incompetency to the subject than such an idea, whereever it makes itself manifest. To pretend that the elaborate speculations of a proficient, on a subject of which he can see but a part, and on which his knowledge must necessarily be inferior to that infinite wisdom which planned and perfected the whole, should be an easy and certain mode of initiation for a learner, evinces no more than that the professor wishes his pupil should not be wiser than himself. To teach composition without a grammar, or philology without an alphabet, would be equally judicious. Plants must be known before they can be compared, and the talent of discrimination must precede that of combination. Clearness and facility must smooth the path of the tyro; difficulties, exceptions, and paradoxes must be combated and unravelled by an adept. The knowledge of natural classification therefore, being the summit of botanical science, cannot be the first step towards the acquirement of that science. No person surely, who has published a natural system, without knowing all the plants in the world, will suppose that he has removed every present obstacle, much less, anticipated every future obscurity, so that no insuperable difficulty can occur to the investigator of plants by such a system. Neither can any artificial system claim such perfection. But they may combine their powers, and cooperate in instruction. The one may trace an outline which the other may correct and fill up. The first may propose, and the second elucidate; the former may educate and improve the memory and observation, for the use of the latter. When they oppose each other, their several defects and weaknesses appear; by mutual assistance they strengthen themselves.

French Systematics.

Whether the leaders of natural system in the French school of botany have thought with us on this subject, it might seem invidious to inquire too nicely. It were too much to expect that every one of their pupils, half learned and half experienced, however commendable their zeal and enthusiasm, should have done so. Nor is science in any danger if they do not. They must improve the system of

Jussieu, before they can overturn that of Linnæus; and if this were accomplished, the nomenclature and definitions of the learned Swede would still form an impregnable fortress, before which they must perish, or seek for shelter within. This dilemma has been, long ago, but too clearly perceived by the rivals of the fame of Linnæus, particularly by such of the French school as have been actuated by a truly contemptible national partiality, instead of a disinterested love of science and truth. Hence the so often repeated exclamations against Linnæus, as a mere nomenclator. Of his didactic precision, and philosophical principles of discrimination, such critics were not jealous, for they could not estimate the value nor the consequences of these. But they could all feel that the nomenclature of Tournefort was giving way, and that their efforts to support it were vain. The writer of these remarks has perceived traces of this feeling in almost every publication and conversation, of a certain description of botanists. He has likewise perceived that it would gradually subside, and that the interests of science were secure. The nomenclature of Linnæus has in the end prevailed, and it were unjust now, to the greatest botanists of the French school, to deny them the honour of liberality on this head.

It is time for us to close this article, with a view of the principles, upon which the eminent systematics, to whom we have so often alluded, have planned and executed their schemes of botanical classification.

Here the learned and truly estimable Bernard de Jussieu, the contemporary of Linnæus in the earlier part of his career, first claims our notice. This great practical botanist, too diffident of his own knowledge, extensive as it was, to be over anxious to stand forth as a teacher, did not promulgate any scheme of natural arrangement till the year 1759, when the royal botanic garden at Trianon was submitted to his direction. His system was published by his nephew in 1789, at the head of his own work, of which it makes the basis. It appears in the form of a simple list of genera, under the name of each order, without any definition, just like the *Fragmenta* of Linnæus, at the end of his *Genera Plantarum.*

In 1763 a very active and zealous systematic, M. Adanson, made himself known to the world, by the publication of his *Familles des Plantes.* In this learned and ingenious, though whimsical and pedantic, work, the great task of defining natural orders by technical characters is first attempted. His affected orthography and arbitrary nomenclature render it scarcely possible, without disgust, to trace his ideas; which however, when developed, prove less original than they at first appear. His work is written avowedly to supersede the labours of Linnæus, against whom, after courting his correspondence, he took some personal displeasure; and yet many of his leading characters are borrowed from the sexual system. The discriminative marks of his 58 families are taken from the following sources—leaves, sex of the flowers, situation of the flowers with respect to the germen, form and situation of the corolla, stamens, germens, and seeds. Every family is divided into several sections, under each of which the genera are in like manner synoptically arranged, and discriminated by their leaves, inflorescence, calyx, corolla, stamens, pistil, fruit, and seeds. In the detail of his system, Adanson labours to overset the principle, so much insisted on by Linnæus and his school, and to which the great names of Conrad Gesner, and Cæsalpinus are chiefly indebted for their botanical fame, that the genera of plants are to be characterized by the parts of fructification alone. The experienced botanist knows that this is often but a dispute of words; Linnæus having, in arranging the umbelliferous plants, resorted to the inflorescence, under the denomination of a receptacle; see his 45th natural order. But it appears to us that the characters deduced from thence are in themselves faulty, being often uncertain, and not seldom unnatural; and that the plants in question may be better discriminated by their flowers and seeds. Adanson however prefers the inflorescence, even in the *Verticillatæ* of Linnæus; for no reason, that we can discover, but because Linnæus has so much better defined the genera of those plants by the *calyx* and *corolla.* It were a needless and ungrateful task to carp at the mistakes of this or any writer on natural classification, with regard to the places allotted for difficult genera, because the human intellect must faulter in unravelling the intricate mysteries of Nature. But surely, when *Plantago* is placed with *Buddlæa* in one section of the *Jasmineæ*, and *Diapensia* with *Callicarpa* in another; when the most natural genus of *Lavandula* is divided and widely separated; when *Cassytha* is ranged with *Statice, Eriocaulon*, and the *Proteaceæ*, in one place; *Geoffræa* with *Melia, Rhus, Sapindus* and *Ruta* in another, we may be allowed to wonder, and to doubt whether we are contemplating a natural or an artificial system. It does not appear that Adanson made many proselytes. He haunted the botanical societies of Paris in our time, without associating with any; nor was his extensive knowledge turned to much practical account. Linnæus has made but one slight remark, that we can find, in his own copy of the *Familles des Plantes*, nor could he study deeply what was, undoubtedly, very difficult for him to read. He certainly never noticed Adanson's attacks, unless the satyrical sketch of the *Botanophili*, at the end of his *Regnum Vegetabile*, (see the beginning of *Syst. Veg. ed.* 14.) be partly aimed at this author. To apply the whole of it to him would be unjust, though much is very characteristic.

The study of Botany had never been entirely neglected in France since the days of Tournefort; because one department in the Academy of Sciences was allotted to that and other branches of Natural History, and the seats in the Academy being pensioned places under government, there was something to be got by an apparent attention to such pursuits. Buffon and his pupils engrossed Zoology. Botany was allowed to exist, so far as not to interfere with his honours; but nothing of foreign origin, and above all, nothing Linnæan, dared to lift up its head. Something of true science, and practical knowledge, did nevertheless imperceptibly work its way. Le Monnier, and the Marechal de Noailles,

corresponded, as we have already said, with Linnæus, and acquired plants from England, of which they dared to speak, and to write, by his names. A most able and scientific botanist and cultivator, Thouin, was established in the Jardin du Roi, who studied the Linnæan system, and even ventured, though secretly, to communicate new plants to the younger Linnæus when at Paris. Cels, an excellent horticulturist, was unshackled by academic trammels. L'Heritier, Broussonet, and others came forward. An original letter of Rousseau, the idol of the day, in which he paid the most flattering homage to Botany and to Linnæus, was published in the Journal de Paris, and had a wonderful effect on the public mind, and on the conversation of literary circles. In short, a Linnæan party had been, for some time, gaining ground; and every thing was done by party at Paris. The old French school was roused from its slumbers. Of the family of the Jussieus one individual remained, who, though he venerated the names and the pursuits of his uncles, had never devoted himself to their studies any further than to sit in their professorial chair. He possessed however an inherent taste for Botany; he had leisure, opulence, and eminent talents; and though his religious principles, and his rather strict devotional habits, might interfere, which they still do, with his credit in certain philosophical circles, and his predilection for animal magnetism might exclude him from the Royal Society of London, yet he has risen above all such obstacles, to the summit of botanical fame and authority in his own country; and his name stands conspicuous, as the leading teacher of a natural classification of plants. The most indefatigable study for about five years, and the constant assistance and encouragement of numerous pupils and correspondents, enabled Professor Antoine Laurent de Jussieu to publish, in 1789, his *Genera Plantarum secundum ordines naturales disposita.* This octavo volume was received by acclamation throughout Europe, and hailed as the most learned botanical work that had appeared since the *Species Plantarum* of Linnæus.

Antoine de Jussieu.

Before we enter into systematic details, we must remark, that the author of the work before us has judiciously availed himself of the mode of defining genera, by short *essential* characters, as introduced by Linnæus in the 10th edition of his *Systema Naturæ,* and since adopted by Murray, Willdenow, and the generality of botanists, instead of the full or *natural,* characters, of the Linnæan *Genera Plantarum.* These short characters however are not servilely copied by Jussieu, but wherever he had materials they are revised and studied, so as to acquire all the merit of originality. Secondary characters and remarks are subjoined, in a different type, illustrative of the habit, history, or affinities, of the several genera. In his nomenclature Jussieu almost entirely follows Linnæus, retaining only here and there a name of Tournefort's in preference, and swerving from classical taste and correctness principally with regard to the new genera of Aublet, whose intolerably barbarous names are nearly all preserved. But a note in the preface, p. 24, informs us, that this adoption is only temporary, till the genera themselves shall be perfectly ascertained and defined. Where Jussieu differs from Linnæus, in certain generic appellations, it is principally because the latter fails in respect for his own laws; as in the use of adjectives, like *Gloriosa, Mirabilis, Impatiens.* The inordinate abuse of generic names in honour of botanists, of which Linnæus is, too justly, charged with setting the example, meets with due reprobation from the French teacher; but he has not as yet stemmed the muddy torrent, nor prevented a great additional accumulation of subsequent impurities. His commendation of Linnæus, as the author of a new and commodious system of specific nomenclature, as well as of technical definition, on the best principles, is liberal, manly and just, no less honourable to the writer, than to the illustrious subject of his remarks. The whole preface of Jussieu is a concise and learned review of the physiology and distinctions of plants, more particularly explaining the progress of the author's ideas and principles of botanical classification. The main end of the whole book, besides defining the characters of all known genera, is to dispose them in a natural series, in various classes and orders, whose technical distinctions are throughout attempted to be fixed and contrasted. With this view, copious explanations and commentaries accompany each other. We learn more from the doubts of Jussieu, than from the assertions of Adanson. The latter has presented us with a finished system, where every genus is referred, at all hazards, to some place or other. Jussieu, on the contrary, has not only a large assemblage of *Plantæ incertæ sedis,* at the conclusion of his system, like Linnæus; but at the end of most of his individual orders we find some genera classed as akin thereto, without answering precisely to the character, or idea, of each. This circumstance, though highly creditable to the candour and good sense of the author, greatly interferes with the practical use of his book, except for the learned. His judicious doubts, critical remarks, and especially the laxity, and consequent feebleness, of his definitions, though eminently instructive to those who want to define, or to class, a new, or obscure genus, could only bewilder a learner of practical botany. A person must already be deeply versed in plants, before he could, by the work of Jussieu, or by any book, that we have seen, classed according to his method, refer any genus to its proper place, or detect any one that may be there described. Nor does the difficulty to which we allude consist so much in the intricacy of the subject, as in the uncertainty, hesitation, and insufficiency of the guide; because that guide, learned as he is, chooses to conduct us by a path, to which neither he nor any other mortal has a perfect clue. His index indeed must be the resource of a young botanist; who, if he knows a *Rosa,* a *Convolvulus,* or an *Erica,* may, by finding their places and their characters, trace out the allies of each, and proceed step by step to acquire more comprehensive ideas. The analytical mode of inquiry, which serves us in the artificial system of Linnæus, is here of no avail but to an adept. This will abundantly appear as we trace the leading principles of this celebrated method, of which we shall now attempt a concise exposition.

The System of Jussieu

Consists of fifteen classes, which are composed, all together, of one hundred orders. The characters of the classes depend first on the number of cotyledons; next the number of petals, and the situation, or place of insertion, of the stamens and corolla.

The author uses the term *stamina hypogyna* for such stamens as are inserted into the receptacle, or below the germen, which therefore we shall call *inferior stamens; stamina perigyna*, (around the germen), are inserted into either the corolla or calyx, the germen being superior; these we must denominate *perigynous; stamina epigyna, superior stamens*, are inserted above the germen, which latter is therefore, in Linnæan language, *inferior*. The same terms apply to the corolla, which when inserted into the calyx is denominated *perigynous*. The following table will show the characters of Jussieu's Classes:

Cotyledons none,

Class 1st.

Cotyledon one.

Class 2d. Stamens inferior.
—— 3d. Stamens perigynous.
—— 4th. Stamens superior.

Cotyledons two, (or more).

Class 5th. Petals none. Stamens superior.
—— 6th. —— —— Stamens perigynous.
—— 7th. —— —— Stamens inferior.
—— 8th. Corolla of one petal, inferior.
—— 9th. ———— ————, perigynous.
—— 10th. ———— ————, superior. Anthers combined.
—— 11th. ———— ————, ————. Anthers distinct.
—— 12th. Corolla of several petals. Stamens superior.
—— 13th. ———— ————. Stamens inferior.
—— 14th. ———— ————. Stamens perigynous.
—— 15th. Stamens and pistils in separate flowers.

In the first place, it is evident that the great hinge, on which this system turns, is the number of the cotyledons. The importance of this character has, from the time of Cæsalpinus and Jungius, been much insisted on. Linnæus, in his *Prælectiones*, p. 329, declares his opinion, that "the monocotyledonous and dicotyledonous plants are totally different in nature, and cannot be combined;" and that "if this distinction falls to the ground, there will never be any certainty. Not that characters should be taken from hence, but sections when formed should be confirmed by the cotyledons." So jealous was this great man of any definition of his natural orders! He subjoins an exception to the above rule, in *Cuscuta* and *Cactus*, which having no leaves, he supposes have no occasion for cotyledons. Linnæus proceeds to observe that "the germination of parasitical plants requires investigation, but that he should greatly wonder if they have any cotyledons." We have already, under the 11th of his natural orders, pointed out other exceptions, made by himself, to the rule just mentioned; but in these he was partly, as we have shown, mistaken; and had he been explicit about the *Sarmentaceæ*, he probably would have proved himself in an error likewise with respect to them. So Adanson asserts the *Juncus* to have two cotyledons, though the rest of its natural order have only one. But Gærtner has demonstrated this genus to be monocotyledonous. Adanson mentions *Orobanche* and *Cuscuta* as monocotyledonous, which answers to the opinion of Linnæus, but we know not how far this is just.

It appears that the line is distinctly drawn by nature between plants with a simple or no cotyledon, and others with two, or more, and that, so far, the principle of Jussieu's classification is correct. Whether all the genera that he has considered as monocotyledonous be truly so, is another question, which does not at all invalidate the distinction. Some have not been examined, and seem principally to be referred to that tribe, because, like others that indubitably belong to it, they are aquatics; or, at least, because of the apparent simplicity of their general structure. Doubts are expressed on this subject by Jussieu himself respecting *Valisneria*, *Cyamus* (his *Nelumbium*), *Trapa*, *Proserpinaca*, and *Pistia*. Some other genera, ranked as acotyledonous, are involved in similar uncertainty.

But with regard to the bulk of the *Acotyledones*, composing the first of Jussieu's classes, there seems to us much greater difficulty. Of his first three orders, *Fungi*, *Algæ* and *Hepaticæ*, nothing indeed is correctly known, except perhaps what Hedwig has published concerning *Marchantia* and *Anthoceros*, and that is hardly sufficient for our purpose. With the fourth order, *Musci*, this great cryptogamist has made us so well acquainted, that they prove to be any thing else than acotyledonous, or monocotyledonous; at least if his idea of the parts be right. The parts which he takes for cotyledons are peculiarly numerous and complicated; but we are ready to allow with Mr Brown, at the conclusion of the preface to his *Prodromus Floræ Novæ Hollandiæ*, that these organs are of a most uncertain nature, rather subsequent to germination than its first beginning, like what has been judged the cotyledon of Jussieu's 5th order, the *Filices*. Yet hence a new difficulty arises. The parts in question so complex in *Musci*, are simple in *Filices*, insomuch that no analogy between these orders, otherwise so nearly akin, is to be traced in those parts. On the other hand, it cannot be concealed that the plants termed *monocotyledones* have no cotyledon at all analogous to those of the *dicotyledones;* what Jussieu and others call such, being the *albumen* of the seed, absorbed in the first stage of vegetation. The minute plants assumed to be acotyledonous, must be presumed to be furnished with something analogous, or we cannot conceive how vegetation can take place. By all these observations we mean only to show, that the primary divisions of Jussieu's system, are at least totally insufficient to answer that practical purpose, which a student has a right to expect from any methodical arrangement. If the learned be still uncertain, whether the distinctions, on which such divisions are founded

Botany.

do, in a great number of cases, really exist, how can a beginner regulate his first inquiries thereby? We are not the less ready to confess, that the difficulty in question is rather a philosophical speculation, than of any great practical importance. It gives a venerable air of mystery, which may procure respect for other parts of a system, that are more intelligible and more useful, though not free from exception. We allude to the next subdivision of the method of the great French teacher, founded on the petals. This should seem to be obvious and certain, but we soon find ourselves bewildered in an old labyrinth of dispute, concerning the difference between a *calyx* and a *corolla*. We are obliged to submit to a sweeping decision, which allows no *corolla* to monocotyledonous plants; a decision which we cannot safely combat, because of the difficulty of deciding what are such, but which shocks our senses and our judgment, and seems refuted in many instances by Nature herself, as decidedly as any of her laws can be established. Nor do we get clear of this perplexity among the declared dicotyledonous tribes, where the evident *corolla* of the Marvel of Peru is assumed to be an inner *calyx*, there being a real *perianth* besides, subsequently indeed called an *involucrum*. Yet we are at a loss to discern why the terminology here used, should have been different from that applied to the next order, *Plumbagines*. We are ready, most unreservedly, to admit the great difficulty of decision in these cases, as well as in others, occurring in Jussieu's 5th, 6th, and 7th classes; but that very difficulty evinces the precariousness of making any thing connected with this most disputable of all questions, a primary guide in a system of methodical arrangement. When we proceed a step further, and come to the insertion of the stamens, the convenience and clearness of the system indeed improve upon our view; but we must not hope to escape exceptions or inaccuracies, the connection of the *filaments* with the *corolla* being, by no means, uniform or constant, in the orders so characterized, nor even in all the species of particular genera, classed upon that principle. So likewise the insertion of the *stamens* into the *calyx* is attended with such inveterate difficulties, that one of the warmest promulgators and defenders of Jussieu's system, Mr Salisbury, has thought it easier to deny the existence of any such insertion, than to make it subservient to practical use. We are indeed satisfied that the characters throughout the celebrated method of classification now under our contemplation, are attended with as much difficulty and exception as those of any other system, and we cannot but agree with Mr Roscoe, *Trans. of the Linn. Soc.* Vol. XI. 65, that it forms several as unnatural assemblages as even the professedly artificial system of Linnæus. With regard to practical facility, no person of judgment has ever attempted to invalidate the superiority of the latter.

Having fulfilled the invidious task, which truth has required of us, let us turn to the more pleasing one of pointing out some of the great practical advantages of the labours of Jussieu. We do this with the more readiness, because we conceive that his real merits are better understood in England than any where else. The writer of this cannot disclaim the honour of being the first who announced to his countrymen the performance of his illustrious friend and correspondent, as one of the most learned books ever published. He humbly conceives that few persons, in any country, have studied the work more, or applied it so much to practice. If he has been fortunate in establishing genera, which have not been controverted, he allows his obligations to Jussieu, as much as to Linnæus. The treasures of neither lie on the surface, nor are they to be appreciated by a superficial observer. The foolish contentions of party can neither exalt nor invalidate the reputation of such men; nor is it the counting of stamens and pistils, nor the enunciation of the names of natural orders, implying ideas which do not always exist in the mind of the speaker, that can entitle a pedant or coxcomb to rank as the pupil of either.

We confess ourselves somewhat partial to the Linnæan notion, of conceiving the idea of a natural order in the mind, rather than to the Jussieuan attempt at very precise technical limitation of its characters. If we contemplate the generality of Jussieu's orders in this light, we shall be struck with his profound talents for combination, as well as discrimination; and as we peruse his critical remarks, subjoined to several of these orders, we shall profit more by his queries and difficulties, than by those definitions, at the head of each order, which are, too often, so clogged with exceptions, as to bewilder rather than instruct a student, however intelligible they may be to an adept.

Comparison of the Orders of Jussieu and Linnæus.

The uninformed reader may, possibly, be surprised to see how great a conformity there is between most of the Natural Orders of Linnæus and those of Jussieu. This will appear by a cursory view of the latter, which, after the detail we have given of the former, will more elucidate the subject than any other explanation that our limits will allow. We shall take the orders of Jussieu in their regular series.

CLASS 1.

The first five orders, *Fungi*, *Algæ*, *Hepaticæ*, *Musci*, and *Filices*, are the same in both systems, except that Linnæus does not separate the *Hepaticæ* from *Algæ*.

6. *Naïades* are analogous to the *Inundatæ*, ord. 15, of Linnæus.

CLASS 2.

7. *Aroideæ* answer to the Linnæan *Piperitæ*, ord. 2, though *Piper* itself is removed far away, to the *Urticæ*.

8. *Typhæ* consist of *Typha* and *Sparganium*, two genera first referred by Linnæus to *Calamariæ*, then to *Piperitæ*.

9. *Cyperoideæ* are the Linnæan *Calamariæ*, ord. 3.

10. *Gramineæ* are the *Gramina*, ord. 4. grasses, an order about which there cannot be two opinions, nor do these authors differ, except in the denomination of the integuments of the flower; Jussieu calling the *calyx* a *gluma*, and the *corolla* a *calyx*. This alteration is made, chiefly that he might not allow a *corolla* to monocotyledonous plants.

CLASS 3.

11. *Palmæ*, palms, necessarily the same in both systems.

12. *Asparagi* answer to the bulk of the *Sarmentaceæ*, ord. 11.

13. *Junci* agree less exactly with *Tripetaloideæ*,

ord. 5, both being liable to exceptions, and having undergone subsequent corrections by their respective authors.

14. *Lilia* consist of the latter portion of Linnæus's *Coronariæ*, ord. 10, with the beginning of his next order *Sarmentaceæ*.

15. *Bromeliæ* embrace some others of the *Coronariæ*, about which Linnæus had his doubts to the last, nor is Jussieu satisfied with this order.

16. *Asphodeli* are likewise chiefly *Coronariæ*, except *Allium*.

17. *Narcissi* are Linnæan *Spathaceæ*, ord. 9. We say nothing of anomalous or doubtful genera, subjoined to this or any other order, and which are sometimes numerous, not unfrequently paradoxical. In the present instance they are *Hypoxis*, *Pontederia*, *Polianthes*, *Alstroemeria*, and *Tacca*, concerning which, the intelligent reader will readily concur with the learned author, that they are "*genera Narcissis non omninò affinia*."

18. *Irides*—Linnæan *Ensatæ*, ord. 6.

Class 4.

19. *Musæ*—consist of *Musa*, very mistakenly referred by Linnæus to his *Scitamineæ*; with *Heliconia* and *Ravenala*, Schreber's *Urania*, both nearly akin to *Musa*.

20. *Cannæ* are the *Scitamineæ* of Linnæus, ord. 8.

21. *Orchideæ* are his *Orchideæ*, ord. 7.

22. *Hydrocharides* are an assemblage of water plants, having little else in common. *Valisneria*, *Hydrocharis*, and *Stratiotes*, make a sort of appendix to the Linnæan *Palmæ*. For *Nymphæa* and *Nelumbium* (now called *Cyamus*), see our remarks on the 11th, 54th, and 27th, of the Linnæan orders. *Trapa*, *Proserpinaca* and *Pistia* close the list. Linnæus has the two last in his *Inundatæ*, ord. 15.

Class 5.

23. *Aristolochiæ* compose the end of the Linnæan *Sarmentaceæ*, but were afterwards removed to the *Rhoeadeæ*, ord. 27. They are surely best by themselves, and constitute a very natural order, not detected by Linnæus.

Class 6.

24. *Elæagni* consist of Linnæan *Calycifloræ*, ord. 16, with various genera besides, referred to almost as many different orders by Linnæus, so that here the two systems exhibit but little analogy, nor is this one of Jussieu's best orders.

25. *Thymelææ*, *Vepreculæ* of Linnæus, ord. 31, (the *Daphne* tribe,) are very clearly defined.

26. *Proteæ*, an order scarcely known to Linnæus, though an extremely natural one. It makes a part of his *Aggregatæ*, ord. 48, in the establishing of which, a sort of artificial character, expressed in the name, has led him into unnatural combinations; a fault which Linnæus, more than any other writer in this department, has generally avoided.

27. *Lauri*, a very good order, not perceived by Linnæus. We cannot say much for the genera of *Myristica* and *Hernandia* annexed to it.

28. *Polygoneæ* make a part of the Linnæan *Holeraceæ*, ord. 12.

29. *Atriplices*, another portion of the same

Class 7.

30. *Amaranthi*, these, originally a part of the *Miscellaneæ*, ord. 54, were also referred subsequently to the *Holeraceæ*. They are supposed to differ from Jussieu's two preceding orders, in having the stamens inserted into the receptacle, not into the calyx, hence forming a separate class. But there is no instance perhaps in which his system proves more artificial, and at the same time more uncertain in character. Mr Brown has anticipated the latter part of our remark in his *Prodromus*, 413, nor could it fail to strike any one who ever considered the subject.

31. *Plantagines*.
32. *Nyctagines*.
33. *Plumbagines*.
Linnæus has no order analogous to these. Yet he has left manuscript indications of his perceiving the affinity of some of the genera.

Class 8.

34. *Lysimachiæ* embrace many of the *Rotaceæ*, ord. 20, and *Preciæ*, ord. 21. *Globularia*, *Tozzia*, *Samolus*, *Utricularia*, *Pinguicula*, and *Menyanthes*, subjoined as allies, not indeed without many doubts, appear to us greatly misplaced. The first of these is allowed to indicate an order not yet defined.

35. *Pediculares*, an important order, which Jussieu has well selected out of the Linnæan *Personatæ*, ord. 40; though we are somewhat startled at finding *Polygala* at the head of the list, which Linnæus, not more happily perhaps, ranges with his *Lomentaceæ*, ord. 33.

36. *Acanthi* are a few more of the *Personatæ*.

37. *Jasmineæ* are precisely the Linnæan *Sepiariæ*, ord. 44.

38. *Vitices* consist of more *Personatæ*, separated with judgment from the rest; Linnæus having, in the contemplation of his 40th order, been again seduced by artificial principles, and by the usage perhaps of considering his *Didynamia Angiospermia* as of itself a natural order.

39. *Labiatæ* are precisely the *Verticillatæ*, ord. 42, of Linnæus, a tribe about which no two systematics could differ, and which it is one of the greatest evils of the artificial sexual system to be obliged to disjoin.

40. *Scrophulariæ* are more of the *Personatæ*, ranged here, after the *Labiatæ*, on account of the close affinity of several of them to the next order. But it must be confessed that the *Labiatæ* thus come awkwardly between what are strictly akin, and that this intrusion is a great flaw in the natural character of the system; insomuch that we should gladly remove them to another place, between the *Solaneæ* and *Borragineæ* hereafter mentioned.

41. *Solaneæ* consist principally of *Luridæ*, ord. 28, to which a few more of the *Personatæ* are subjoined as allies. It is remarkable that, in his characters of the seven last mentioned orders, Jussieu admits those marks, derived from the stamens, on which the classes of the Linnæan artificial system depend. The intelligent reader will easily observe, that the distinctions thence deduced, form a leading principle in the respective positions of these orders and the following. This is the more curious, as the French school is entirely obliged to Linnæus for bringing the organs in question into notice, for the purposes of arrangement, Tournefort and his pupils having never adverted to them.

42. *Borragineæ*, these are the *Asperifoliæ*, ord. 41, of Linnæus, surely better placed by him between his *Personatæ* and *Verticillatæ*. The order is very natural, and Jussieu's criticism upon it excellent.

43. *Convolvuli*
44. *Polemonia*
45. *Bignoniæ*

To these Linnæus has no analogous order, most of the genera in the two first being referred to his *Campanaceæ*, order 29, and of the last to *Personatæ*.

In this instance we cannot but admit the superiority of Jussieu's arrangement.

46. *Gentianæ*—a very natural and distinct order, confounded by Linnæus with his *Rotaceæ*, ord. 20, to which it has but little relationship.

47. *Apocineæ*—precisely the Linnæan *Contortæ*, ord. 30, a most distinct and curious tribe, though both the great authors, of whom we are treating, have been mistaken in referring hither a genus or two, which do not at all belong to it. See our remarks on this 30th order of Linnæus.

48. *Sapotæ*—an order of which Linnæus had no perception. Some of its genera find a place among his *Dumosæ*, ord. 43, an assemblage which, he ingenuously confesses, did not satisfy himself.

Class 9.

49. *Guaiacanæ*. Of this also Linnæus had no distinct ideas. Some of the genera he places with his *Bicornes*, ord. 18. Yet some pupils of Jussieu have refined upon this and the last, and he himself has founded an order of *Ebenaceæ*, upon the first section of his *Guaiacanæ*; see Brown's *Prodromus*, 524.

50. *Rhododendra*.

51. *Ericæ*.

These two collectively answer to the *Bicornes*, ord. 18, of Linnæus, an error or two, on either part, excepted.

52. *Campanulaceæ* nearly correspond with the genuine *Campanaceæ*, ord. 29, of Linnæus, from whence, as we have before hinted, *Convolvulus* and its allies are well separated in the system of Jussieu.

Class 10.

53. *Cichoraceæ*, a most natural order, the *Compositæ semiflosculosæ*, ord. 49. sect. 2. of Linnæus. The essential character of this 10th class is adopted from the artificial system of Linnæus, the united anthers, *antheræ connatæ*; a circumstance never adverted to by any systematic writer before him. Yet it is not absolutely without exception; witness the genera of *Kuhnia*, *Sigesbeckia* and *Tussilago*.

54. *Cinarocephalæ* answer nearly, at least in principle, to the *Compositæ capitatæ*, ord. 49. sect. 1.

55. *Corymbiferæ* embrace all the remaining *Compositæ*, including the last section of that order, *nucamentaceæ*, some of which Jussieu terms *Corymbiferæ anomalæ*; such as *Iva*, *Parthenium*, *Ambrosia*, *Xanthium*, and even *Nephelium*.

Class 11. Distinguished from the last Class, only by having separate anthers.

56. *Dipsaceæ* consist of some of the Linnæan *Aggregatæ*, ord. 48. See our remark under Jussieu's 26th order. There is ample room for speculation on the affinities and distinctions between these *Dipsaceæ*, the *Proteæ*, ord. 26th, and the whole of Jussieu's 10th class last mentioned. Their contemplation involves questions at any time sufficient to excite a botanical war—such as, what belongs to the inflorescence, and what to the flower? what is a calyx, and what the crown of the seed? what is superior and what inferior insertion? what a simple and what a compound flower?

57. *Rubiaceæ*, a vast and important order, composed, not only of the Linnæan *Stellatæ*, ord. 47, but also of numerous tribes of shrubby plants, very few of which had been referred to the *Stellatæ*, and many of them had not fallen under the notice of Linnæus at all. Jussieu shines in the elucidation of this order, and has well indicated certain characters in the habit, especially that of the intrafoliaceous sheathing stipulas.

58. *Caprifolia* are nearly equivalent to the 4th, or last, section of Linnæus's *Aggregatæ*, ord. 48, except *Viburnum* and its allies, with *Cornus* and *Hedera*; the former placed, without much reason, in the Linnæan *Dumosæ*; *Cornus* with the *Stellatæ*; and *Hedera* in *Hederaceæ*, ord. 46, nearly agreeing with Jussieu's 59th next mentioned. *Cornus* and *Hedera*, being both allowed to be polypetalous, really belong to the next class, as the author could not but perceive. Indeed Jussieu's 11th and 12th classes, however distinct in theory, naturally slide into each other.

Class 12.

59. *Araliæ* answer to the Linnæan *Hederaceæ*, ord. 46, *Hedera*, *Vitis* and *Cissus* excepted, which Linnæus himself appears to have had some idea of removing from *Panax*, *Aralia*, &c.

60. *Umbelliferæ* of course correspond with the *Umbellatæ*, ord. 45, of Linnæus, one of the most natural of the whole.

Class 13.

61. *Ranunculaceæ* answer to the Linnæan *Multisiliquæ*, ord. 26. The authors differ in the denomination of the parts of the flower, Jussieu's *calyx* being sometimes the *corolla*, and his *petals* the *nectaries*, of Linnæus.

62. *Papaveraceæ* are, except *Hypecoum* and *Fumaria*, Linnæan *Rhoeadeæ*, ord. 27.

63. *Cruciferæ* the Linnæan *Siliquosæ*, ord. 39, so natural an order, that we can scarcely say to which it is next akin.

64. *Capparides* mostly Linnæan *Putamineæ*, ord. 25, with some very anomalous genera subjoined as related thereto, *Reseda*, *Drosera* and *Parnassia*, not without great and well-founded doubts of the author.

65. *Sapindi*
66. *Acera*
67. *Malpighiæ*

These are comprehended in two of the sections of the *Trihilatæ*, ord. 23. of Linnæus.

68. *Hyperica*. *Ascyrum* and *Hypericum*, the only real genera of this order, are, with *Cistus*, subjoined to the Linnæan *Rotaceæ*, ord. 20; certainly with no very evident reason.

69. *Guttiferæ* constitute a well-marked order, to which Linnæus has nothing analogous. Most of the genera that compose it, are either left by him unarranged, or considered as of dubious affinity to any others. Indeed they are generally tropical trees, respecting which he had but slight information.

70. *Aurantia*. Of this likewise Linnæus seems to have formed no idea, since he refers *Citrus* to his *Bicornes*, and leaves *Limonia* undetermined. *Camellia* and *Thea*, subjoined by Jussieu, with some

other genera, to this order, as connecting it with the next, appear to us of very dubious affinity to the *Aurantia*; nor are they much better annexed by Linnæus to his *Columniferæ*, ord. 37.

71. *Meliæ* constitute a good order, comprehended, not very judiciously, under the Linnæan *Trihilatæ*, ord. 23, above mentioned.

72. *Vites*, consisting only of *Cissus* and *Vitis*, we have already mentioned, ord. 59, as included amongst the *Hederaceæ*, ord. 46, of Linnæus.

73. *Gerania* make a part of the Linnæan *Gruinales*, ord. 14, but *Tropæolum*, a puzzling genus, which Jussieu labours to prove in many respects related to them, is referred by Linnæus, as reasonably perhaps, to his *Trihilatæ*.

74. *Malvaceæ* are almost exactly analogous to the *Columniferæ*, ord. 37.

75. *Magnoliæ* form an order certainly as little connected with the preceding as any two could be in the most artificial system. See the following.

76. *Anonæ*. The leading genera of this and the *Magnoliæ* compose the Linnæan *Coadunatæ*, ord. 52.

77. *Menisperma* are referred by Linnæus to his *Sarmentaceæ*, ord. 11, by their habit more than any just character.

78. *Berberides* constitute a curious order, though liable to some exceptions, of which its author was aware. It entirely escaped the penetration of Linnæus.

79. *Tiliaceæ* a good order, likewise overlooked by him, or partly confounded with his *Columniferæ*, to which it betrays some affinity.

80. *Cisti*. *Cistus*, which makes this order, is placed by Linnæus, after *Hypericum*, at the end of his *Rotaceæ*, ord. 20. The reader may wonder to find *Viola* considered as related to *Cistus*, or at least to those species which Jussieu separates therefrom, by an incorrect character, and a faulty name, *Helianthemum*. He attributes to these a capsule of one cell; but one of them at least, *Cistus thymifolius*, has three cells. *Viola*, an anomalous genus, is ranged by Linnæus at the end of his *Campanaceæ*, ord. 29, with which it seems to have more points of agreement.

81. *Rutaceæ*. This is a very natural, and now become a very extensive order, of which the genuine idea is confined to Jussieu's second section, and likewise to the second section of Linnæus's *Multisiliquæ*, ord. 26. The plants which compose it have alternate leaves, without stipulas; their herbage abounding with aromatic acrid essential oil, lodged in pellucid cells, as in Jussieu's *Aurantia*, ord. 70. Calyx four or five-cleft. Petals four or five, alternate therewith. Stamens usually twice as many as the petals, distinguished by something elaborate or peculiar in their structure, by which the genera are often well defined. Germen lobed. Capsule mostly of four or five cells, each lined with a bivalve elastic tunic, containing one or two polished seeds. *Diosma* and *Empleurum*, subjoined as akin to *Rutaceæ*, are genuine specimens of the order, though the latter has a capsule deprived of three or four of its lobes or cells, and wants petals. *Melianthus* has no business here. It ranks with the Linnæan *Corydales*, ord. 24, much more properly, though a very puzzling genus. The students at Paris, in our time, used to amuse themselves with the idea, that the Professor would not allow this fine plant a place in the garden, because he knew not where to class it in his system.

82. *Caryophylleæ* are exactly analogous, except a few rather doubtful genera at the end, to the similarly named 22d order of Linnæus. But between this very natural tribe and the last, *Rutaceæ*, there is a *hiatus valdé deflendus*, as to any natural affinity; the present order being much more related, as Jussieu candidly indicates, to the *Amaranthi*, ord. 30, and proving that the presence or absence of a corolla, is no more infallible than any other character, for a general principle of arrangement.

Class 14.

83. *Sempervivæ* are the second section of Linnæus's *Succulentæ*, ord. 13.

84. *Saxifragæ* are chiefly the fourth section of the same.

85. *Cacti* consist merely of *Ribes* and *Cactus*, as artificial a combination as most in the sexual system itself. The former Linnæus ranks with his *Pomaceæ*, ord. 36; the latter is the first genus of his *Succulentæ*.

86. *Portulaceæ* are selected out of the first and third sections of the *Succulentæ*.

87. *Ficoideæ* consist of more of the same.

In this part of their respective systems, we find it more difficult than usual to follow the ideas of the learned authors. Habit seems to have guided Linnæus; but Jussieu tracing, in his last five orders, nearly the same affinities, has somewhat strained his technical characters to confirm them.

88. *Onagræ* accord, in the main, with the Linnæan *Calycanthemæ*, ord. 17. They well connect the five preceding orders with the following. *Bæckea* belongs to the *Myrti*.

89. *Myrti* are the Linnæan *Hesperideæ*, a very natural family, much amplified by Jussieu from recent discoveries.

90. *Melastomæ* are not distinguished by Linnæus from his *Calycanthemæ*.

91. *Salicariæ* are in the same predicament. Jussieu has considerably the advantage here.

92. *Rosaceæ* embrace the *Senticosæ*, ord. 35, and *Pomaceæ*, ord. 36, of Linnæus, nor can there be a more natural assemblage.

93. *Leguminosæ* comprehend, in like manner, two Linnæan orders, *Papilionaceæ*, the 32d, and *Lomentaceæ*, the 33d, which we should be disposed to keep distinct, however nearly they must be considered as akin. The Linnæan characters, though often termed artificial, serve Jussieu for the distinctions of his sections.

94. *Terebintaceæ*, an order learnedly sketched out, rather than completed, by Jussieu, which seems entirely to have escaped the perception of Linnæus. It brings together many things which he either did not pretend to arrange, or which clogged some of his orders.

95. *Rhamni* constitute a very natural order, of which the Linnæan *Dumosæ*, ord. 43, are but a sketch, confessedly imperfect.

Botany.

CLASS 15.

96. *Euphorbiæ* are Linnæan *Tricoccæ*, ord. 38.

97. *Cucurbitaceæ* agree, in name as well as idea, with the 34th of the Linnæan orders.

98. *Urticæ* are nearly analogous to *Scabridæ*, ord. 53, except that *Piper* is mentioned as related to them, instead of being referred to a monocotyledonous order with *Arum*, *Pothos*, *Acorus*, &c. Yet its germination is rather hinted at than determined, nor does any thing positive seem to be known on that subject.

99. *Amentaceæ* are mostly what Linnæus has, under the same appellation, in his 50th order.

100. *Coniferæ* are his 51st, bearing the same name.

Conclusion.

As Linnæus enumerates, at the end of his Natural Orders, 116 genera, which he could not then satisfactorily refer to any one of them; so Jussieu, at the conclusion of his System, reckons up 137, which, as we have already observed, he denominates *Plantæ incertæ sedis.* These are disposed synoptically, by their petals, germens and styles. It is remarkable how nearly, allowing for new discoveries, Jussieu accords with Linnæus in the number of such genera. These lists have both been greatly diminished by subsequent consideration, or more complete information.

The attention of botanists, first directed by Gærtner, to the minute and curious diversities of structure in the parts of the seed, has greatly assisted Jussieu and his followers in correcting and improving the details of his system. Hence he has been led to favour the world with several essays on particular families, or orders, in the *Annales du Museum d'Hist. Nat.*, some of which have appeared in the very valuable *Annals of Botany*, published by Dr Sims and Mr Konig. In these, several of the difficulties, which originally embarrassed their author, are lessened or removed, but on these it is not our purpose to enter. A new edition of Jussieu's *Genera Plantarum*, which has long been preparing, cannot fail to prove almost a new work; more valuable perhaps for the abundant information which it must afford, concerning the characters and affinities of particular genera, than for any thing concerning a general natural system, to perfect which the scientific world has not, as yet, sufficient materials.

As we cannot here undertake to detail Jussieu's own corrections or improvements of his system, neither can we explain what has been attempted, with the same design, by the late ingenious M. Ventenat, or by those excellent living botanists, M. De Candolle, or Mr Brown. We shall only observe, that Ventenat, too servile to Jussieu, explicitly contends for the natural method of classification, as superseding the artificial one, and that he aims at proving this to have been the intention of Linnæus. Yet nothing can be more positive to the contrary than the remarks of the latter, in the preface to his *Ordines Naturales* at the end of his *Genera Plantarum.* He there declares that his "artificial method is alone of use to ascertain plants, it being scarcely possible to find a key to the natural one." "Natural orders," he continues, "serve to teach the nature of plants, artificial ones to distinguish one plant from another." If it be said that Jussieu, having invented a key, or a set of distinctive characters, to his orders, has removed this objection, we would ask, What becomes of his doubtful genera, as numerous as those of Linnæus? or moreover, How is any student, using his system analytically, to make out a single unknown plant? That the pupils of Jussieu have ever been aware of this, the writer of the present essay very well knows. He has always found them, in conversation, aiming compliments at their illustrious master, by contending for the great difficulty and uncertainty of the Linnæan artificial system; by which palpable absurdity they betrayed their secret opinion of Jussieu's. On the other hand, the intelligent and candid De Candolle, adopting the just opinion of Linnæus, that plants are allied to each other rather in the form of a table, or map, than in a linear series, actually proposes such a series as *necessarily artificial*, in his *Theorie Elementaire de Botanique*, 213. Concerning the precise disposition of the genera in this series, we believe scarcely two botanists would agree; nor might their contentions be unprofitable; but they would never teach, either a tyro or an adept, to ascertain an unknown plant. We will venture to go further, and to declare our opinion, founded on long observation, that botanists who are thus perpetually intent on the abstract theory of classification, scarcely attain any excellence in the technical discrimination, or definition, of what are really founded in nature, the species or genera of the vegetable kingdom. Those err greatly who seek to improve the system of Jussieu, or any other, by refining too much on his distinctions, and subdividing his orders; than which nothing is more easy. Judgment and extensive knowledge are displayed in tracing out the most essential points of agreement in natural objects; not in exalting into unmerited importance the most minute differences. Hence the very conciseness of Linnæus, gives perspicuity to his descriptions and definitions. These afford the most instructive study, whatever mode of classification we may think most convenient.

The French school has been much flattered, by our able countryman Mr Brown, having classed his *Prodromus* of the New Holland plants after the method of Jussieu; and many a botanist enjoys this national triumph who is certainly not competent to appreciate the merit of that work. The plants of so novel a country could not, at this time of day, have been presented, with so much advantage, to a philosophical botanist, as in some natural arrangement, however imperfect; nor will many students travel thither, to make them out by methodical investigation. The touchstone of our learned friend's book however will be the *Plantæ incertæ sedis*, nor can it be judged, as to the merit of the system employed, till it arrives at that conclusion. He himself will surely not reckon it complete without a Linnæan index,

"To give the precious metal sterling weight."

(J. J.)

BOTANY BAY, the name of a British settlement in New Holland, for the history of which, see HOLLAND, NEW, in the *Encyclopædia*, and the same head in this Supplement, for an account of its present state.

BOUGAINVILLE (LOUIS ANTOINE DE), a celebrated Circumnavigator, was born in Paris in 1729. His father was a Notary, and one of the Sheriffs of the city of Paris. The parents of young Bougainville wished him to practise as a Lawyer, and, for this purpose, he was received Advocate in the Parliament of Paris; but his own inclination was averse to the profession, and he entered into the army in the corps of musketeers.

He associated much with Clairaut and D'Alembert, who happened to live in his neighbourhood, and from this intercourse he derived his knowledge of Algebra and Fluxions. At the age of twenty-five he published his treatise on the *Integral Calculus*, intended as a supplement and continuation of L'Hopital's treatise *Des infiniment petits*. Bougainville, in his preface, declares, that all he has done in this work, is to place, in a systematic order, the formulæ of different mathematicians.

He was raised to the rank of Major in the Picardy regiment. He went to London as secretary to the French embassy, and was chosen a Member of the Royal Society. In 1756, he went to Canada as Captain of dragoons, and having distinguished himself in the war against England, was rewarded by the cross of the order of St Louis.

After the peace, the French government having conceived the project of planting a colony on the Falkland Islands, Bougainville undertook to begin this establishment at his own expence. The Falkland Islands, to which Bougainville gave the name of Malouines (that is, St Malo Islands), are in 51^0 south latitude, and 10^0 of longitude to the east of the meridian of Cape Horn. Fish is abundant on their shores, and there is peat or turf for fuel, but no wood. Bougainville began the settlement by landing some families of French Canadians. The number of settlers was increased afterwards to 150.

This colony excited the jealousy of the Spanish government; and the government of France agreed that it should be given up to the Spaniards, the Spanish government undertaking to indemnify Bougainville for the expence he had been at in forming the establishment.

As a consolation to Bougainville for the loss of his colony, he was appointed to command the Frigate *La Boudeuse* of 26 eight pounders, and the transport *L'Etoile*, to go on a voyage of discovery round the world. He took with him Commerçon as Naturalist, and Verron as Astronomer.

This was the first voyage round the world performed by the French. Since the first circumnavigation by Magellan under the Spanish Government in 1519, and that of Drake under Queen Elizabeth in 1577, eleven other circumnavigations of the world had been performed, part of them by the Dutch, and part by the English, and also several voyages of discovery had been made in the Pacific Ocean, without circumnavigation.

The expedition commanded by Bougainville was at Buenos Ayres at the time of the seizure of the Jesuits of Paraguay. The missions on the river Araguay, in the province of Paraguay, contained a population of 300,000 Indians, divided into parishes, and governed solely by the Jesuit parish priests. No other Europeans but the Jesuits were admitted into the country, in order that the work of conversion might not be frustrated by bad example. The produce of the labour of the Indians was delivered into the hands of the Jesuits, who furnished them with food and clothing. For this purpose the Jesuits had warehouses filled with European and American merchandise, and also a number of slaves. They had schools for instructing the Indians in music, painting, and other arts. The Spanish government having determined on the suppression of the Jesuits, took every precaution to prevent their being informed of the intended measure; and they were arrested and sent to Europe without any attempt at resistance on their part.

Bougainville passed the Straits of Magellan, and anchored for a week at Otaheite, where the English navigator Wallis had touched eight months before. A young man of Otaheite joined the expedition, and was taken to Paris, where he staid thirteen months. On his way back to his native country he died of the small-pox.

The numerous rocks and other dangers made Bougainville turn off to the north-east, and prevented him from continuing a westerly course, so as to pass through the channel which separates New Holland from New Guinea. These two Islands, in his general chart, are laid down as forming one, although he possessed some information of the existence of the channel. Two years after, namely in 1770, Captain Cook sailed through this channel, so dangerous by its coral reefs.

The expedition having now crossed all the meridians of the Pacific Ocean, and suffering from the scurvy in consequence of scarcity of food, came to anchor in the Gulf of Cajeli, a settlement of the Dutch East India Company in the agreeable Island of Borou, one of the Moluccas. The Governor liberally supplied the wants of the expedition. He lived splendidly in a house built in the Chinese style, and judiciously adapted to the warmth of the climate; his wife and daughters wore the Chinese dress. "Sa maison étoit la notre," says Bougainville; "à toute heure on y trouvoit à boire et à manger, et ce genre de politesse en vaut bien un autre pour qui surtout se ressentoit encore de la famine." It was the beginning of September, and the expedition shortened their stay at Borou, in order to take advantage of the latter part of the easterly monsoon, which carried them to Batavia; from thence they proceeded to the Isle of France. Commerçon remained at the Isle of France, that he might from thence proceed to examine the botany of Madagascar, as did Verron, for the purpose of observing the transit of Venus.

In 1769, the expedition arrived at St Malo, after a voyage of two years and four months, with the loss of only seven men out of upwards of 200.

Bougainville's account of the voyage is written with simplicity, and in a temper which inclined him

Bougainville || Bouguer.

to view objects on the humorous side. His courage, the good humour with which he maintained subordination, and his attention to the health and comforts of the crew, are everywhere conspicuous.

The art of making astronomical observations at sea was not so much improved as it is now, and especially the methods for ascertaining the longitude were very defective. In consequence of this, Bougainville's charts are erroneous, and particularly in the longitudes. Neither did he remain long enough in any place to make particular surveys.

Bougainville's life was an active one, so that little of it could be devoted to study. On his return to France, his time was passed in the company of the highest circles in Paris. He had the command of a ship under De Grasse and D'Estaing; and, in April 1781, when the French fleet was beaten, he rallied some of the beaten ships, and brought them into St Eustachio. After the peace, by which the independence of the United States of America was secured, Bougainville returned to Paris. The Academy of Sciences was at that time composed of pensioned members, and of associates who had no salary; Bougainville solicited and obtained the place of Associate of the Academy.

He had a project of making a voyage of discovery towards the north pole. As this did not meet with support from the French Government, he sent his plan to Admiral Phipps; Phipps, however, followed a different course from that proposed by Bougainville, but he only got to the 80th degree of north latitude.

Recourse was had to Bougainville in order to repress the mutinous disposition of the sailors in the French Navy, before the breaking out of the Revolution; but his efforts were ineffectual. He had the rank of Vice-Admiral in 1791. In 1792, he escaped almost miraculously from the massacres of Paris, and went to live on his estate in Normandy. He was much attached to the Government, which was then falling. He lived on his estate for some time; it was the only part of his fortune that the Revolution had left him. He was chosen a Member of the Institute at its first formation, and, in consequence, returned to reside in Paris. He succeeded Borda as Member of the Board of Longitude. In his old age, under the government of Bonaparte, he enjoyed the dignity of Senator, was created a Count, and Member of the Legion of Honour.

He retained his good-humoured liveliness and his mental faculties to the last, and died in 1811, aged 82.

He was married, and had three sons who served in the French army. He was always eager to promote science; and he conducted himself during the Revolution, in such a manner as to obtain the respect of all parties. His eloge is written by Delambre in the *Memoirs of the Institute*. (Y.)

BOUGUER (PETER), an eminent French Mathematician, was born in 1698. His father was King's Professor of Hydrography at Croisic in Lower Britany, one of the best Hydrographers of his time, and author of an excellent Treatise on Navigation. Young Bouguer was bred to Mathematics from his infancy, and made rapid progress in that science. At an early age he was appointed to succeed his father in the chair of Professor of Hydrography, after having undergone a strict examination in Mathematics, so as completely to satisfy his examiners. In 1727, he gained the prize given by the Academy of Sciences of Paris, for his paper *On the best Manner of forming and distributing the Masts of Ships*. He got two other prizes from the Academy in the course of four years; the one was bestowed on him for his Dissertation *On the best Method of observing the Altitude of Stars at Sea*; the other, for his paper *On the best Method of observing the Variation of the Compass at Sea*. These papers are published in the *Prix de l'Academie des Sciences*. In 1729, he published a work entitled *Essai d'Optique sur la Gradation de la Lumière*; the object of which is to define the quantity of light which is lost by passing through a given extent of the atmosphere. He finds the light of the sun to be 300 times more intense than that of the moon.

Bouguer.

He was soon after made Professor of Hydrography at Havre, whereby he had the advantage of being nearer Paris than before; and he was chosen associate Geometer of the Academy of Sciences, a place which did not require residence in Paris. In this place he was the successor of Maupertius. Afterwards, he was promoted in the Academy to the place of pensioned Astronomer, and came to reside in Paris.

It was resolved in France to send an expedition to South America for the purpose of measuring a degree of the meridian near the equator. From that measurement, compared with the length of a degree of the meridian in other latitudes, the deviation from sphericity in the figure of the earth might be known. The Academy made choice of four of its members to proceed on this voyage; they were Godin, Bouguer, and de la Condamine, for the geodetical operation, and the younger Jussieu for observations in Natural History. Bouguer and his fellow-travellers sailed from La Rochelle in 1735, and it was ten years before he returned to France. The account of his operations during the expedition is given by him in the *Memoirs of the Academy of Sciences*, 1744, and in a separate work, entitled *La Figure de la Terre determinée par les observations de MM. Bouguer et de la Condamine*. There is likewise an account of this expedition published by Don George Juan and Don Antonio de Ulloa, two scientific naval officers, who accompanied the expedition by order of the Spanish Government. The length of a portion of the meridian was measured on the ground by means of a base and a set of triangles. Then by observing the altitude of the ε of Orion which passed near the zenith, simultaneously at the two ends of the meridian line that had been measured, that line was found to contain 3° 7′ of latitude. A star near the zenith was employed, to the end that the observation might not be affected by refraction; ε of Orion passed the meridian in the zenith near the middle of the line measured, so that the distance of that star *south* of the zenith of the northern extremity of the line was 1° 25′ 46″; and its distance

Bouguer.

north of the zenith of the southern extremity of the line was 1° 41′ 13″; the sum of these two numbers making 3° 7′. The altitude was taken by zenith sectors of a long radius. The ground on which these operations were performed was elevated 12,000 feet above the level of the sea, and 4200 feet above the neighbouring city of Quito, and situate in a plain extending from north to south, between the two ridges of the Cordillera. The northern extremity of the arc was on the equator. The length of the degree resulting was 56,767 toises; but this was the degree of a curve circumscribed round the earth at the height of 12,000 feet above the level of the sea; and the length of the degree at the level of the sea deduced from this, with some other corrections, is 56,753 toises. This length of the degree of the meridian at the equator was compared with the degree of the meridian measured in France, with the degree measured in Lapland, and with the degree of longitude deduced in the south of France. From this comparison it was concluded, that the equatorial diameter of the earth is to the polar diameter as 179 to 178, and that the equatorial radius of the earth was about eight leagues longer than the polar. Since the time of Bouguer, degrees have been measured in different climates, with more accurate instruments than he possessed; but the precise proportion of the equatorial and polar diameters of the earth is not yet finally ascertained. Bouguer makes the excess of the equatorial diameter above the polar to be $\frac{1}{179}$; Sir Isaac Newton made it $\frac{1}{129}$; Laplace, calculating from the lunar motion, $\frac{1}{314}$; Melanderhielm and Svanberg, from a degree measured anew in Lapland in 1783, compared with the degree measured in the province of Quito, $\frac{1}{313}$. Bouguer found the seconds pendulum $\frac{36}{100}$ of a line shorter at the summit of Pichincha than at the level of the sea; that is, the force of gravity was less by one 1200th part at that elevation.

He made some observations on the limit of perpetual snow, a subject which has been elucidated, since his time, by the researches of Humboldt, Von Buch, Wahlenberg, and others. At the equator, the limit of perpetual snow is at 14,760 feet above the sea; a height equal to that of Mont Blanc. In Mexico, in the latitude of 19° 20′, it is at 13,800 feet, according to Humboldt. In latitude 28° 15′, where the Peak of Teneriffe is situate, it is supposed to be 11,700 feet: the Peak is only 11,454 feet, and has no perennial snow. On Etna, in latitude 37° 30′, the edge of the perennial snow is at the height of 9000 feet. On Mount Caucasus, in latitude 42° 30′, the limit is at 9900 feet; whilst on the Pyrenees, in latitude 42° 45′, it descends to 8400 above the sea; and on the Swiss Alps, in latitude 46°, to 8220 feet. In Iceland, in latitude 65°, the edge of the perennial snow is at the perpendicular height of 2892 feet from the sea. In Lapland, in latitude 67°, where the summers are warmer than in Iceland, though the winters are colder, the perennial snow does not descend so low, attaining only to 3300 French feet from the sea, as Von Buch and Wahlenberg ascertained by barometrical observations. When the latitudes are the same, a solitary mountain will have the edge of the perennial snow higher than a mountain surrounded by others, on account of the warm winds from the neighbouring plains. A mountain in an inland situation will have the border of the perennial snow higher than a mountain in the same latitude, and situated in an island; the summers which reduce the limits of the snow being warmer in the inland situation. When the mass of perennial snow is large, glaciers are formed, which descend below the limit of perennial snow. Chimboraço has 5400 feet of its height covered with perpetual snow, according to Humboldt. Bouguer thought he could perceive that the clouds do not ascend higher than 2400 feet above the summit of Chimboraço. If there were mountains whose height reached beyond the greatest height to which the clouds attain, all the part of the mountain above the region of the clouds would be free from snow, although exposed to intense cold. On Bouguer's supposition of the height to which the clouds ascend, the upper limit of snow at Chimboraço would be at the height of 22,200 feet above the sea; and the distance between the upper limit of snow and the lower limit would be there about 7800 feet.

Bouguer, whilst he was at the equator, made observations to ascertain the obliquity of the ecliptic, which he found to be 23° 28′ 28″. He also made some experiments on the deviation of the plumb-line from the vertical, occasioned by the attraction of a neighbouring mountain, a phenomenon afterwards investigated by Dr Maskelyne, on the mountain Schehallien.

The number of Bouguer's papers contained in the printed Memoirs of the Academy of Sciences, is a proof of the assiduity with which he performed his duty in the Academy. His *Heliometer* is described in the Memoirs of the Academy for 1748. It is an object-glass Micrometer, and its essential parts consist of an astronomical dioptric Telescope, with two object-glasses of the same focal length, placed side by side. When this instrument is directed to the sun, each object-glass gives an image of that luminary; and the object-glasses are so placed that the limbs of the two images touch when the diameter of the sun is greatest, and when the diameter is less, there is an interval between the limbs of the two images.

Some experimenters maintained that the plumb-line had a diurnal oscillation; Bouguer showed that it remains at rest. He employed, for this purpose, a Telescope attached to the end of a chain 187 feet long, suspended within the dome of the church of the Hospital of Invalids at Paris; the Telescope was directed to a distant mark, so that any motion in this long pendulous system might be seen by the deviation of the wires of the Telescope from the mark. The particulars of this experiment are to be found in the *Mém. de l'Academie des Sciences*, 1754.

In the volume for 1739 and 1749, there are papers of his on the astronomical refraction in the torrid zone, particularly in cases where the star is seen at more than 90° from the zenith, in consequence of the observer being in a high situation. In the volume for 1747, he proposed a log of a new construction for measuring a ship's way.

In the same collection, there are papers of his on

the length of the pendulum, on the form of the prow which suffers least resistance in passing through the water, and on a variety of other subjects. He bestowed great pains on his works, and his health at length became impaired by a sedentary life, and too constant application to scientific pursuits. He died in 1758, aged sixty. His disposition was naturally mild, and the dissensions that arose between him and his fellow traveller de la Condamine caused him great vexation. He was impressed, from his earliest years, with a conviction of the truths of Christianity. By economy he had acquired a moderate fortune, a part of which he bequeathed to the poor. The following is a list of his principal works:

Traité d'Optique sur la Gradation de la lumière, 1729 and 1760.

Entretiens sur la cause de l'Inclinaison des orbites des Planetes, 1734; another edition in 1749.

Traité de navire, de sa construction, et de ses mouvemens, 1746, 4to.

La Figure de la terre determinée, par les Observations de Mess. Bouguer, et de la Condamine, envoyés par ordre du roy au Perou; Par M. Bouguer, 1749, 4to.

Nouveau Traité de Navigation, coutenant la Theorie et la Pratique du Pilotage, 1753. A new edition by de la Caille. 1761.

Solution des Principaux Problemes sur la Manœuvre des Vaisseaux, 1757.

Operations faites pour la Verification du degrè du meridien entre Paris et Amiens; Par Mess. Bouguer, Camus, Cassini, et Pingré, 1757.

After his return from South America, he was Editor of the *Journal des Savans*. Some of his papers in the *Memoirs of the Academy of Sciences* have been mentioned in this article; his *Eloge* is contained in the volume for 1758. (Y.)

BOULTON (Matthew), a Manufacturer and practical Engineer of great celebrity; son of Matthew Boulton, by his wife Christian, daughter of Mr Peers of Chester; was born at Birmingham the 14th of September 1728, and died in August 1809.

He was educated at a neighbouring grammar school, kept by Mr Ansted of Deritend, and was called early into active life upon the death of his father in 1745. The various processes by which the powers of the human mind have given facility to the artist in rendering the different forms of matter obedient to his command, afforded ample scope for the exercise of his inventive faculties, in improving the manufactures of his native place. His first attempt was a new mode of inlaying steel; and he succeeded in obtaining a considerable demand for the products of his manufactory, which were principally exported to the Continent, and not uncommonly reimported for domestic use, as of foreign manufacture.

In 1762, his fortune being already considerable, he purchased a tract of barren heath in the neighbourhood of Birmingham, with a single house on it, and there founded, at the expence of L. 9000, the manufactory which has been so flourishing, and so well known under the name of Soho. His workmen were at first principally employed in the imitation of or moulu, and in copying oil paintings with great accuracy, by means of a mechanical process which was invented by a Mr Egginton, who afterwards distinguished himself by various works in stained glass. Mr Boulton, finding the force of horses inadequate to the various purposes of his machinery, erected, in 1767, a steam-engine, upon the original construction of Savery, which, notwithstanding the inconvenience of a great loss of steam from condensation, by its immediate contact with the water raised, has still some advantages from the simplicity of the apparatus which it requires, and has even lately been found to succeed well upon a small scale. But Mr Boulton's objects required a still more powerful machine, and he had the discernment to perceive that they might be very completely attained by the adoption of the various improvements lately made in the steam-engine by Mr Watt of Glasgow, who had obtained a patent for them in 1769, the privileges of which were extended, in 1775, by an act of Parliament, to a term of 25 years. Mr Boulton induced this ingenious and scientific inventor to remove to Birmingham. They commenced a partnership in business, and established a manufactory of steam-engines, in which accurate execution kept pace so well with judicious design, that its productions continued to be equally in request with the public after the expiration of the term of that legal privilege, which at first gave the proprietors the exclusive right of supplying them; and which had been confirmed in 1792 by a decision of the Court of King's Bench against some encroachments on the right of the patentee. It was principally for the purpose of carrying on this manufactory with greater convenience, that the proprietors established an iron-foundry of their own at Smethwick, in the neighbourhood of Soho.

In 1785, Mr Boulton was made a Fellow of the Royal Society, about the same time with Dr Withering, and several others of his scientific neighbours. In 1788, he turned his attention to the subject of coining, and erected machinery for the purpose, so extensive and so complete, that the operation was performed with equal economy and precision; and the coins could not be imitated by any single artist for their nominal value; each of the stamps coining, with the attendance of a little boy only, about eighty pieces in a minute. The preparatory operation of laminating and cutting out the metal, is performed in an adjoining room; and all personal communication between the workmen employed is rendered unnecessary, by the mechanical conveyance of the work from one part of the machinery to another. A coinage of silver was executed at this mint for the Sierra Leone Company, and another of copper for the East Indies, besides the pence and halfpence at present in circulation throughout England, and a large quantity of money of all kinds for Russia. In acknowledgment of Mr Boulton's services, and in return for some specimens of his different manufactures, the Emperor Paul made him a present of a valuable collection of medals and of minerals.

Mr Boulton obtained, in 1797, a patent for a mode of raising water by impulse, the specification of

which is published in the ninth volume of the *Repertory of Arts*, p. 145. It had been demonstrated by Daniel Bernoulli, in the beginning of the last century, that water flowing through a pipe, and arriving at a part in which the pipe is suddenly contracted, would have its velocity at first very greatly increased; but no practical application of the principle appears to have been attempted, until an apparatus was set up, in 1792, by Mr Whitehurst, for Mr Egerton of Oulton, in Cheshire; consisting of an air-vessel, communicating with a waterpipe by a valve, which was forced open by the pressure or rather impulse of the water, when its passage through the pipe was suddenly stopped by turning the cock, in the ordinary course of domestic economy; and although the pipe, through which the water was forced up, was of moderate height, the air-vessel, which was at first made of lead, was soon burst by the "momentous force," as Mr Whitehurst very properly terms it. The apparatus had excited much attention in France, under the name of Montgolfier's hydraulic ram, and Mr Boulton added to it a number of ingenious modifications; some of which, however, are more calculated to display the vivid imagination of a projector, than the sound judgment of a practical Engineer, which had in general so strongly characterized all his productions.

He died, after a long illness, in possession of considerable affluence, and of universal esteem, leaving a son and a daughter to profit by the wealth and respectability which he had acquired. He was buried on the 24th of August at Handsworth, near Soho, attended by a procession of 600 workmen, and by a numerous train of his friends and acquaintance. (*Monthly Magazine*, *Oct.* 1809, p. 368.) (I. J.)

BOURBON, Isle of. In the *Encyclopædia* will be found a pretty full account of the discovery and settlement of this Island. There has since appeared the work of M. Bory de St Vincent, which, though intitled *A Voyage to the four principal Isles of Africa*, is, in fact, almost entirely occupied by a very detailed account of Bourbon. In 1811, also, an officer attached to the British expedition against that Island, published an *Account of its Conquest*, with an Appendix on its Present State. From these materials we are enabled to make some important additions to the information formerly communicated.

Structure and Aspect.

The physical structure of this Isle being the point on which most new light has been thrown, seems to merit our first attention. Bourbon does not, like the Isle of France, consist of a level plain, from which conical hills arise in detached masses. The whole Island is as it were one mountain, having its most elevated points in the centre, and thence sloping gradually down to the sea. This great mountain, however, is split into two portions, of which the loftiest, situate in the northern part, is called the *Gros Morne*, and its summit, the *Piton des Neiges* (Snowy Peak). There is here no present action of volcanic fire; but the frequent occurrence of deep valleys or basins, rapid rivers bordered by perpendicular walls of rock, hillocks precipitated into these valleys and torrents, basaltic prisms often disposed in regular colonnades, strata thrown into the most irregular positions,—all these, in M. Bory de St Vincent's opinion, indicate terrible physical revolutions in former times. The northern mountain is entirely volcanic, and the phenomena present themselves in an extraordinary state of frequency and activity. This writer not only conceives both these mountains to be originally volcanic, but the whole Island to have been thrown up by the action of subterraneous fire. The two mountains appear to him also to have formerly composed only one, having an intermediate summit higher than that of either now is. The volcanic agitations, however, having hollowed the internal part of this great mass, the exterior crust fell in, and reduced the Island to the shattered state which it now exhibits. To a great extent, indeed, it is divided into two portions by an immense hollow, bordered with perpendicular walls of rock, which, after running parallel for seven or eight miles, form an arch and unite. At the foot of the volcano is found an immense tract of what the inhabitants call *Brulé* "burnt country;" supposed to have been formed by the lava spreading into a species of fiery lake, and then consolidating into the present surface. It is destitute of all vegetation whatever; its colour is of the gloomiest black, the surface broken by holes, crevices, and innumerable asperities of every description. These, joined to its hard and brittle consistence, render it impossible to be trod without the severest injury to the feet. Those of our traveller's attendant negroes were almost torn to pieces; and his own, though defended by strong shoes, were wounded in several places.

The streams of Bourbon are mere mountain torrents, which descend from steep to steep, and throw themselves into the sea. In their descent, they dig for themselves deep ravines, bordered by lofty, almost perpendicular walls. The largest river, however, that of St Denis, has not a longer course than seven or eight miles. These deep and foaming torrents, the rude surface of the ground, and the perpendicular rents by which it is everywhere broken, render travelling through Bourbon a most arduous undertaking. M. Bory de St Vincent was assured, that his plan of reaching the two principal peaks was altogether impracticable; but his enterprise, and love of science, enabled him to surmount all the intervening difficulties.

In the ascent to the summit of the volcanic mountain, the obstacles encountered were truly formidable. Sometimes the sides of nearly perpendicular rocks were to be climbed; at other times, a road was to be made by cutting down the bushes and filling up the crevices; while a mist, which rises every day from the sea, rendered it impossible to distinguish his companions at the smallest distance. At length they reached the summit of the *Mamelon central*. The crater here, to which the name of Dolomieu was given, consists of a cavity forty fathoms in diameter, and about eighty feet deep, the bottom filled with confused piles of greyish coloured lava. The sides showed none of that soft lava which forms a species of varnish over the interior of other craters; they consisted of irregular fragments of hard and com-

Bourbon. pact substances. Our author here notices the error of those who expect, when they reach the summit of a crater, to look down into an unfathomable abyss. The fact is, from whatever depth the liquified substances may have ascended, that, when the conflagration ceases, they harden and fill up the opening, so that only a very small void remains. Being led, however, by a sulphureous smell, to the left side of the present crater, they discovered a deep hollow like a tunnel, the walls of which were composed of burning lava; while, beneath, two columns of fiery matter, rising to the height of 120 feet, threw up a bloody light, which shone brightly, even amid the blaze of a tropical noon. This spectacle, accompanied with a sound similar to that of an enormous cascade, filled their minds with terror and admiration.

Our traveller, in ascending, had supposed the *Mamelon central* the highest peak of the volcanic mountain; but he now discovered, at the distance of about 200 fathoms, a still more elevated point, which, after himself, he named *Bory*. It is a vast elliptic basin, the largest diameter of which is 120, and the smallest 100 fathoms. The sides rise perpendicularly like walls, and are 200 feet high at their greatest elevation. There were some broken parts, however, by which the travellers could descend into the abyss. They found it tolerably level; but the volcanic ashes with which it was bestrewed, hid the scoriæ and other substances which filled it. In the centre was a crevice the depth of which they could not discover. This crater was entirely silent.

The travellers spent the night on the crater Dolomieu; but the tremendous sounds, the blaze of light, and the singularity of their situation, scarcely allowed them to close their eyes. At about 1200 feet beneath, they perceived a stream of lava issuing from the mountain, the outlet, probably, of those liquified substances which they saw fermenting at the bottom of the crater.

The crater is said to have been formed during a violent eruption of the volcano in 1791. In the beginning of June, a burning vapour appeared rising from the summit; then the side of the mountain opened, and a vast torrent of lava rushed into the sea. On the 17th of July, a subterranean noise, like the discharge of cannon, was heard throughout the Island; after which, there rose from the top of the mountain an enormous column of smoke, of a deep black, with white spots interspersed. The inhabitants, who had never before witnessed such a phenomenon, were struck with consternation. Soon, however, the column fell down, and formed a species of arch over the volcano. The falling in of the interior, undermined by the previous discharge, is supposed to have been the cause of the tremendous sound, and of the ultimate opening of the crater.

This is, perhaps, the most active volcano in nature. Since the Christian era, Etna has counted only twenty-seven eruptions; and Vesuvius twenty-four. But a resident at Bourbon assured our author, that, from 1785 to 1802, the mountain had vomited flames at least twice every year, and eight of the streams had entered the sea. The lava, however, scarcely ever issues from the summit of a crater, but generally from openings far down the mountain, and sometimes almost on a level with the sea. It is remarkable, also, that earthquakes, which so generally desolate volcanic countries, are here unknown, or, at least, so slight, as to occasion no serious inconvenience. The constant escape of the subterraneous fire through the channel of the volcano, may, probably, be the chief cause which prevents it from shaking the surrounding regions. Another usual accompaniment, that of warm springs, is also wanting; and none of the waters are impregnated with any species of gas. No petroleum has been found, nor any metal, except iron.

Bourbon. Our traveller made next an excursion to the *Piton des Neiges*, which forms the summit of the *Gros Morne*, the highest mountain in the Island. This undertaking proved still more arduous. The season was favourable; yet, when they were about half-way up, a prodigious rain came on; and the road lay through wet and swampy grounds, which were soon entirely covered with water. The mists became so thick, that nothing could be distinguished. The negroes, accustomed to a milder air, were benumbed; and, refusing to proceed, would have perished with cold, had not the Frenchmen driven them forcibly on, till they came to a spot where they found shelter and refreshment. They spent here two nights; and, on the third day, were able to reach their destination. The view from the summit appeared to our traveller to equal the most majestic scenes of the Alps and the Pyrenees. In the Island beneath, every object was visible as on a map; while, on every side, the immeasurable extent of ocean mingling with the skies, made them feel as if insulated on this spot from the rest of the universe. The thermometer was so low as 8°. Here considerable masses of rock were observed, undermined to such a degree, that a very slight effort was sufficient to throw them down the precipices, where, displacing others, they rolled to a great depth, and caused prodigious havock. Every part of the mountain, indeed, appears furrowed and shattered by the violent action of the rains, which have already sensibly diminished its magnitude, and are likely more and more to produce that effect.

M. Bory does not appear to have instituted any investigation into the height of these mountains. Professor Jameson, in his *Geognosy*, estimates that of the *Gros Morne* at 9600, and that of the volcano at 7680 feet above the level of the sea. The French traveller gives a copious, but not very precise, account of its geological features. The lower part of the *Gros Morne* is composed of basalt, a substance which abounds in every part of the Island, and which, from the manner in which it is connected with and surrounded by lava, is conceived by our author to have been universally crystallized from a state of fusion. He notices, also, the frequent occurrence of what he calls *Trappean lava;* though this, as well as much of the basalt, would probably, by the disciple of Werner, be referred to some of the newer formations of Trap. On some of the precipices at the summit of the *Gros Morne*, there appeared an immense depth of horizontal strata, which

Bourbon. might have rendered an igneous origin improbable, had it not been so clearly proved by other phenomena. Large blocks of granite are found in the rivers which flow at the foot of the *Gros Morne*.

Political Commercial State. It is now time to take a view of the political and commercial aspect of Bourbon. By the Revolutionists it was called Reunion; but this name, which was never fully established among us, may be now supposed to have again given place to its ancient appellation. The Island is divided into eleven parishes, St Denis, containing the capital of that name, St Marie, St Susanne, St André, St Benoit, St Rose, St Joseph, St Pierre de la Riviere d'Abord, St Louis du Gaul, St Leu, and St Paul. St Denis can scarcely be called a city; the streets resemble roads in the country, being covered with grass and sand, under which are often concealed sharp pointed stones, which inflict severe wounds on the feet. The houses are built of wood, and are agreeable; they are constructed entirely with a view to coolness. The furniture is slender, and many of the rooms not even carpeted; a deficiency not arising from absolute poverty, but from the difficulty, in this remote situation, of procuring the artificial conveniences of life. The houses in the country are of a peculiar construction, very long, very narrow, and tapering to a point.

The Island is distinguished into the windward and leeward sides; of which the former, descending by a gentle slope, and refreshed by continual breezes, is fertile and smiling; while the latter is comparatively rude, dry, and barren. The torrents, continually washing away the soil, are supposed to augment the sterility. Only a narrow slope, about a league and a half inward from the sea, is under regular cultivation. The interior consists of immense forests, inhabited by a species of fugitive Mulattoes, who live almost in a state of nature. The reports as to the amount of the population are very various. M. Bory understood it, in 1763, to contain 4000 whites, and 15,000 slaves, and supposes that they have not much increased since that time; but the narrator of the expedition in 1811 gives the numbers then at 16,400 Europeans, 3496 free negroes, and 60,450 slaves. The precision of the numbers seems to indicate an actual enumeration.

The staple production of this Island is coffee. The first plants were early brought from Arabia, and soon flourished to such a degree, that the coffee of Bourbon was only second to that produced in the parent district. During the Revolution, the want of a regular market, by diminishing the encouragement to careful cultivation, sensibly lowered the quality. It is still, however, produced in large quantity. Next to it ranks the article of cloves. The clove-tree is of very easy cultivation; the chief disadvantage is the precariousness of the produce. It has been known in one year to yield only 1000 lbs., and in the next 500,000 lbs. Cotton, likewise, has been long a staple of the Island; but a violent hurricane in 1801, and a disease which afterwards made its appearance among the plants, discouraged a number of the planters, who accordingly began to employ their lands in the culture of coffee.

Bourbon ‖ Bourgoing.

The following is stated to be the total produce of the Island on an average of several years:

Coffee	73,200 Cwt.	Value 732,000 piastres.
Cloves	180,000 lbs.	540,000
Cotton	240,000	60,000
Grain	185,000	57,000
Maize	2,500,000	21,000
Pease	200,000	4,000
Potatoes	280,000	2,800
		1,488,800 piastres.

The imports consist of a great variety of European goods, the regular amount of which is stated at 230,000 piastres, besides a large contraband. Bourbon labours under the serious disadvantage of not possessing a single harbour, nor any roadstead in which vessels can ride with safety. The trade, therefore, can be conducted only through the medium of Mauritius, and is entirely in the hands of the merchants of that Island. (B.)

BOURGOING (John Francis de), was born of an ancient family at Nevers, on the 20th November 1748. He was educated at the Military School of Paris, and devoted himself particularly to the study of the languages. At the age of seventeen he was sent by the government to Strasburgh, where he studied Public Law under the celebrated Professor Kugler. Having spent three years there, he received a commission in the regiment of Auvergne. When scarcely twenty, he was appointed Secretary of Legation at the Diet of Ratisbon; and after having been employed, during four years, in the discharge of various diplomatic functions, he returned to his regiment; where he continued to occupy himself with the study of Public Law. In 1777, he went as first Secretary to M. de Montmorin, who was appointed Ambassador to the Court of Madrid. Eight years afterwards, Montmorin having been recalled, Bourgoing remained eighteen months at Madrid in the character of Chargé d'Affaires. It was during this long residence in Spain that he collected the materials for his *Tableau de l'Espagne moderne.* On his return to France, in 1787, he was sent as Minister Plenipotentiary to Hamburgh; and, in 1791, he went in a similar capacity to Madrid, where he remained until the month of March 1793. Having again returned to France, during the most troublesome period of the Revolution, he retired to his native town, where for some time he filled the first municipal office. The revolution of the 18th *Brumaire* (10th November 1799) drew him at length from the bosom of privacy. In 1801, the First Consul appointed him Minister Plenipotentiary at the Court of Denmark, and afterwards at that of Sweden. In 1808, he was sent as Minister Plenipotentiary to Saxony. At Dresden he was attacked by the complaint which terminated his life; and he died at Carlsbad, whither he had repaired for the benefit of the waters, on the 20th of July 1811, at the age of sixty-three.

Bourgoing was a man of the most disinterested integrity; and he died poor, although he had been employed in various situations in which he might have

found opportunities of acquiring wealth. He left a family of five children, three sons and two daughters. The following is a list of his publications: 1. *Nouveau Voyage in Espagne, ou Tableau de l'etat actual de cette Monarchie;* first published in 1789, 3 vols. 8vo. The fourth edition augmented, was published under the title of *Tableau de l'Espagne moderne*, in 1807, in 3 vols. 8vo, with an atlas. This is the best known and most esteemed of his works, and has been translated into various languages. 2. *Mémoires, Historiques, et Philosophiques, sur Pié VI. et sur son Pontificat*, 2 vols. 8vo, 1798; second edition, 1800. Some prefer the first edition of this work, although the second is continued to the death of Pius VI. 3. *Histoire des Flibustiers, traduite de l'Allemand de M. d'Archenholtz*, Paris 1804, 8vo. 4. *Histoire de l'Empereur Charlemagne, traduction libre de l'Allemand du Prof. Hegewisch*, 1805, 8vo. 5. *Correspondence d'un jeune Militaire*, ou *Mémoires du Marquis de Lusigny et d'Hortense de S. Just*, 1778, 2 vols. 12mo. Bourgoing translated some other works from the German, and published several tracts of little importance. In 1808, he published an edition of the *Travels of the Duc du Chatelet in Portugal;* and he was the Editor of the *Correspondence of Voltaire with Bernis*. (H.)

BRAMAH (Joseph), a practical Engineer and Machinist, was born at Stainborough in Yorkshire, on the 13th of April 1749. His father rented a farm on the estate of Lord Strafford, and, being the eldest of five children, he was intended for the same employment. He exhibited, at a very early age, an unusual talent for the mechanical arts, and succeeded, when he was quite a boy, in making two violoncellos, which were found to be very tolerable instruments, and in cutting a single block of wood into a violin, chiefly by means of tools which were forged for him by a neighbouring smith, whom, at a subsequent period of his life, he induced to assist him in London as one of his principal workmen. Notwithstanding the ingenuity which he had thus displayed, his destination in life might have precluded its further cultivation, had he not, fortunately for himself and for the public, been incapacitated, when he was about sixteen, by an accidental lameness in his ancle, for the pursuit of agricultural labour. He was then apprenticed to a Carpenter and Joiner, who seems, however, to have contributed but little to his improvement in mechanical knowledge.

When the term of his engagement was expired, he obtained employment for some time in the workshops of a Cabinetmaker in London, and soon after established himself as a principal in that business. Another accidental confinement left his mind at liberty for a time to occupy itself with reflection and invention; and he employed his involuntary leisure in the improvement of some of the most humble, but not the least useful, of domestic conveniences. He obtained a patent for his inventions, and established a manufacture of these and other similar articles in Denmark Street, Soho; where he continued to simplify and improve the arrangement of the pumps and pipes subservient to his principal purpose. He procured, in 1783, a patent for a watercock, intended to allow the fluid a more uninterrupted passage through it, than was practicable in the ordinary construction. He afterwards removed to Piccadilly, and established the various branches of his manufactory in some extensive premises at Pimlico.

In 1784, Mr Bramah took out a patent for his improvement in locks, which certainly appear to be of very material importance: their peculiar character depends on the arrangement of a number of levers or sliders in such a manner, as to preserve, when at rest, a uniform situation, and to be only pressed down by the key to certain unequal depths, which nothing but the key can ascertain; the levers not having any stop to retain them in their required situation, except that which forms a part of the key. The construction is more particularly detailed in the specification of the patent (*Repertory of Arts*, V. 217.), as well as in the inventor's *Dissertation on Locks*, 8vo; and some additional modifications, allowing the key to be varied at pleasure, are described in a patent, dated in 1798. It is not easy to say why the application for an act of Parliament to prolong the privilege was unsuccessful, unless it was supposed that the inventor had been already sufficiently repaid for the share of ingenuity which his contrivance exhibited; but the report, that one of these locks had been readily opened, before a committee of the House of Commons, by means of a common quill, was a gross misrepresentation of the fact; the quill having in reality been previously cut into the required shape from the true key; and the experiment only served to show the perfection of the workmanship, so little force being required to overcome the resistance, when properly applied.

For different modifications of pumps and fire-engines, Mr Bramah took out three successive patents, the two last dated in 1790 and 1793. (*Repertory*, II. III.) His "rotative principle" consists in making the part, which acts immediately on the water, in the form of a slider, sweeping round a cylindrical cavity, and kept in its place by means of an eccentric groove; a construction which was very possibly suggested by his own inventive mind, but which had been before described, in a form nearly similar, by Ramelli, Cavalleri, Amontons, Prince Rupert, and Dr Hooke. The third patent related chiefly to the attachment of a considerable reservoir of water to the fire-engine, in a cylindrical form, and to the furnishing it with wheels of its own, of a proper size and strength to allow it to be conveniently worked.

There was somewhat more of originality in the idea of applying practically, to the purpose of a press, the well-known principle of the hydrostatic paradox; by which, as by a lever with arms capable of infinite variation, the smallest imaginable weight is made capable of holding in equilibrium a force incomparably greater. Mr Bramah's patent for the invention is dated in 1796 (*Repertory*, VI. 289.), and it has been one of the most successful of his numerous speculations. He added to it in a subsequent patent the contrivance of a "retainer," for keeping goods in a constant state of pressure, for an unlimited time after their removal from the press. The apparatus has certainly a considerable advantage in the great steadiness with which the force can be applied, in the facility with which it can be regulated, and the convenience with which it can be continued without

Bramah.

alteration; and it has been extensively applied both on a small and on a large scale; for copying writings, for pressing gunpowder, for proving cables and chains, for raising weights of various kinds, and for drawing piles, and pulling up trees by the roots.

A simple but a very convenient arrangement of little pumps and pipes has been very generally employed in public-houses under the name of the Beer-machine: For this Mr Bramah took out a patent in 1797, describing it as part of an apparatus for retaining, drawing, and clarifying liquors (*Repertory*, IX. 361). He prefaces his specification with some general observations on the right of an inventor to a property both in the objects which he selects for his improvements, and in the means which he employs for the attainment of them; and demands of the public justice an ample security for both these rights; grounding this claim on his resolution to make a clear and unreserved disclosure of all his inventions. Besides the method of pumping up the liquors from the various casks through flexible pipes, without the necessity of entering the cellar, he describes a mode of converting every cask into a forcing pump, excluding the air, and raising the liquor to any part of the house, by a load on its head, which is to be converted into a piston. He mentions also a filtering machine,—a vent peg,—a method of making pipes,—and a new form of stopcocks.

In 1801 he obtained a patent for some improvements in the construction of steam-engines, particularly relating to the boilers; and in 1802, for a very elaborate and accurate machine for producing smooth and parallel surfaces on wood and other materials. The tools of different kinds employed in this machine, such as gouges, spokeshaves, and planes, are carried with a considerable velocity by a rotatory motion, and come successively in contact with the wood, which is placed on a moveable carriage gradually advancing: the centre or gudgeon of the axis or shaft, instead of a common step, is supported by a barrel of oil, to which it is fitted by a collar; and this arrangement not only diminishes the friction very considerably, but allows the height of the shaft also to be very easily and accurately regulated, by means of a small forcing pump. The inventor thinks this liquid support likely to be as permanent as it is advantageous; but it may be apprehended, that the constant friction of such a collar would cause it to require frequent repairs, in order to prevent the escape of the oil so powerfully compressed. The machine has been erected on a large scale in the Arsenal at Woolwich, and is employed with perfect success. The specification includes the description of a mode of turning spherical surfaces, either convex or concave, by the simple contrivance of a tool moveable on an axis precisely perpendicular to that of the lathe; and of cutting out concentric shells, by fixing, in the same manner, a curved tool, nearly of the same form as that which is employed by the common turners for making wooden bowls.

An improvement in the processes for making paper, with the assistance of new machinery, in large sheets, was secured to the inventor, by a patent, in 1805 (*Repertory*, 2 *Ser*. VIII. 1). The description is accompanied by that of a mode of drying the paper on sliding frames, hung on lines like sashes, and of keeping it in a state of compression by retainers adapted to the hydrostatic press; but Mr Bramah had not leisure to introduce these arrangements into actual practice, although he had been at a considerable expence in preparing the apparatus.

His next invention was, however, very effectually carried into execution in a particular department, notwithstanding its unpromising appearance, as generally stated in the specification of the patent, which he obtained in 1806 (*Repertory*, 2 *Ser*. X. 329). He proposes to facilitate the process of printing, by means of a roller, composed of a number of circular plates, closely fitted together, and turning on the same axis, each bearing twenty-six letters, with figures, spaces, and various marks, either engraved or projecting, and capable of being shifted at pleasure, so as to express any single line by a proper combination of the plates. This is described as a substitute for common printing, copperplate engraving, and calico printing; and the ink is intended to be supplied by a trough fixed above and in contact with the cylinder. Now, it is obvious, that such a machine would be insufferably tedious and inconvenient for every purpose of common printing, which it would be scarcely possible to perform by its means; but when we discover that the inventor had probably in view the apparatus which he constructed the next year for the Bank of England, for numbering and dating their notes, we shall be aware that the means were admirably adapted to the end; a single line only being here wanted at once, in which a single figure was to be changed at each step, and that in a regular order. In fact, during the immense temporary circulation of one and two pound-notes, the Bank has been able, by this machinery, under the management of about 20 clerks, to perform the labour of 120, who were before required for the purpose.

Mr Bramah procured a patent, in 1809, for a mode of making and holding pens for writing, calculated to save the substance of the quill, by cutting a number of pens out of it, instead of a single one; and those, who are not in the habit of making their own pens, may often find a convenience in the portable form, in which this and other similar "pterophori" are arranged. In 1812, he brought forward his patent for the construction of main pipes, to be carried through the principal streets of a metropolis, of sufficient thickness to withstand a great force, to which the water within them is intended to be subjected, by proper pumps, furnished with air vessels; so that the water may not only be ready for the immediate extinction of fires, without the necessity of bringing an engine to the spot, but may also furnish a convenient moving power for various mechanical purposes, such as raising weights, by means of tubes sliding out of each other, like those of a telescope. He observes that he has frequently had occasion to employ a hydrostatic pressure, in many of his operations, equivalent to that of a column of water 20,000 feet high, which is about 4 tons for every

Bramah. square inch. He also asserts that he can form 500 tubes, each 5 feet long, capable of sliding within each other, and of being extended in a few seconds, by the pressure of air forced into them, to a length of 2500 feet; and, with a power of this kind, he seems to have imagined that he could raise wrecks, and regulate the descent of weights of various descriptions.

His improvements in wheel-carriages, for which he obtained a patent in 1814, consisted in fixing each wheel to a separate moveable axis, having its bearings at two distinct points of its length, but loosely inclosed between these points, in a cylinder filled with oil; and, in some cases, he proposes to fix the opposite wheels to the same axis, though with a power of turning very stiffly round it, in order to lessen the lateral motion of the shafts in very rough roads. He also suggests the use of pneumatic springs, formed by pistons, sliding in cylinders, as a substitute for common springs of metal.

The purpose of Mr Bramah's last patent was the prevention of the dry rot, by laying on the timber, meant to be preserved from it, a thin coat of Parker's Roman cement, much diluted with water; but he does not appear to have pursued this experiment, having transferred his right in the invention to other hands.

In addition to the seventeen patents which have been mentioned, he took out two or three others of less importance, at different times, besides a variety of contrivances, which he did not think necessary to appropriate to himself by a legal privilege. Mr Nicholson has mentioned a double plunger for a forcing pump, as described to him by Mr Bramah (*Nich. Jour.* VII. 50); which, in the form he has delineated, is certainly possessed of no particular advantage, producing only with a large apparatus the effect of a much smaller. Mr Bramah had erected, in the latter years of his life, some large machines at the Thames Bank, for sawing stones and timber; he had begun to devise some improvements in bridges and in locks for canals; and he had at one time been actually employed in the execution of some water-works belonging to the department of the civil engineer, which he had completed with ability and with success. His great and various exertions appear in some measure to have exhausted the strength of his constitution; and his last illness was immediately occasioned by a severe cold, taken in the prosecution of his experiments on the tearing up of trees, made in Holt Forest. He died in his sixty-sixth year, on the 9th of December 1814.

Mr Bramah was a sincere believer in the doctrines of the Christian religion; and, notwithstanding his diversified avocations, he left several manuscript essays on religious subjects. In his moral character, he was cheerful, benevolent, and affectionate; in his habits he was neat and methodical; and he knew well how to temper liberality with economy. He often kept his workmen employed more for their sake than his own, when the stagnation of trade deprived him of the means of disposing of the products of their labour. It is surely on the characters of such individuals that the wealth and prosperity of the British empire most essentially depend; an inventive imagination, controlled by a sound judgment, an incessant activity of mind and body, a head that can direct, and a heart that can feel, are the genuine sources of that practical superiority which is well known to distinguish the productions of our national industry. (*Life of Mr Bramah, by Dr Brown*, in the *New Monthly Magazine for April* 1815.) (S. F.)

Brasil. BRASIL. In the *Encyclopædia* will be found an account of the discovery of Brasil, with such particulars relative to its subsequent history, and circumstances, as could be collected from the most approved publications on the subject. We shall here add such further information as has been communicated to the public in the works of more recent travellers.

Bounda[ries]. The name of Brasil, which was at first understood to apply to a small portion of the American coast from the mouth of the Amazons southward, now comprehends the whole Portuguese territories in South America. On the east, this region is bounded by the Atlantic Ocean, and on the west by Peru. To the north and south, its natural boundaries seem to be the two great rivers, the Amazons and the Plata; but its actual frontiers have been fixed by treaties, and have either receded from those natural boundaries, or been enlarged beyond them, according to the political interests and views of the different powers interested in the possession of those territories. This vast country, from the mouth of the river Amazons, almost under the equator, to the 35th degree of south latitude, extends in length about 2000 miles, and its greatest breadth, from east to west, is nearly the same; but, towards the south, it is contracted, by the mutual approach of its eastern and western boundaries, within much narrower limits. The mouths of its navigable rivers, and the windings of the shore, give it about 1200 leagues of sea-coast.

General aspect. Viewed from the sea, Brasil appears on its first aspect mountainous, rough, and unequal; but, on a nearer approach, no prospect can be more picturesque and agreeable than that which it presents,—its eminences covered with magnificent woods, and its valleys with eternal green. The interior of the country, generally speaking, is one vast forest. But in the centre is the vast plain of Campos Parexis, which extends east and west for several hundred miles, and is covered with a light earth, and with heaps of sand, resembling from a distance, by its continual shifting and undulation, the agitated waves of the ocean. The soil is so loose and sandy, that the convoys of mules which have to pass this way, frequently sink into it, and make their way forward with great difficulty. The vegetation with which it is covered consists of a stunted species of herbage, with small leaves, round and pointed like a lancet. This immense sandy plain rises up towards the centre into chains of mountains, which are generally considered the highest in Brasil, and are extended over a space of more than 200 leagues. It is from this mountainous country that all those rivers proceed, which finally pour their tributary waters into the Amazons, the Paraguay, and the southern Atlantic. Those rivers, and the river Madera, which flows northward into the Amazons, together with their

Brasil. tributary streams, run along the interior frontier of Brasil for a space of nearly 1500 miles, and form the boundary by which this country is separated from the Spanish provinces.

Mountains. The principal mass of mountains is to the northward of Rio Janeiro, towards the sources of those three great rivers in the interior, the St Francis, the Parana, and the Toccantins. These mountains not only abound in mines of copper and of iron, but they conceal besides rich mines of gold, diamonds, and other precious stones. From this elevated group, different chains are prolonged towards the south, in a direction parallel with the coast, under the name of *Cerro des Emeraldas*, and *Cerro do Frio*. Another branch, proceeding from the same centre, follows a similar direction to the south, while a third chain, under the name of Matto-Grosso, bends to the north-west towards the central plain, and forms the dividing ridge between the waters which flow southward into the Paraguay and the Parana on one side, and those which flow northward into the Toccantins and the Chingu, and finally into the Amazons, on the other. Between the Parana and the Paraguay, an extensive chain of mountains, running in a direction from north to south, intervenes, which, at its termination, diverges into other ranges, running from east to west. Divers other groups of mountains skirt, for a great distance, the banks of the river Toccantins, while another range, which is one of the most considerable in Brasil, extends towards the northern coasts, and forms a natural division between the provinces of Maranham and Pernambuco.

Rivers. Brasil is watered with a profusion of great rivers. The longest is the Amazons, which, rising in Peru, enters the Brasilian territory by the south-west, is increased by the accession of the Rio Negro, which, from its great inundations, has been compared to a sea of fresh water; by the Rio Madera, or the River of Forests, which rises in the central mountains of Brasil, and has a course of more than 2000 miles, before it joins the Amazons; by the Topayos, which rises in the heights of the Campos Parexis, and has a course of 900 miles; and, finally, by the Chingu, which descends from the ridges of Matto-Grosso. This last river rises at the distance of 1200 miles from its mouth, and its course is interrupted by several cataracts. Its banks are covered with impenetrable forests, inhabited by tribes of warlike and independent savages. Farther to the east, the great river Toccantins falls into the sea near the mouth of the Amazons, and, being connected by a branch with the main stream, those two immense rivers mixing their waters, rush with one common current into the ocean. The land and sea seem to dispute the dominion of the extensive regions where this junction takes place, which are accordingly either parched by a burning sun, or deluged with periodical rains. About 300 miles before it falls into the ocean, the Toccantins is joined by the Aragua, which is nearly equal to itself in size, and from this point the united streams of these two rivers are navigable to the ocean. Their banks are skirted by mountains and forests, and towards their source they make their way across deep valleys and precipices, where the navigation is interrupted by numerous cataracts.

To the southward of the tributary streams of the Amazons, Brasil is chiefly drained of its waters by means of the great river La Plata. This river, for a considerable part of its course, skirts its interior frontier, running from north to south. For the space of nearly 1600 miles, it receives all the streams which flow down the eastern declivity of the Andes, while, for the same space, it receives all the waters of the Brasilian Andes, which take a westerly course into the interior. The land which divides the waters of the Amazons from those of the Plata, rises to its height between the 13th and 14th parallels of south latitude. Here it is that the Paraguay or the Plata has its rise, and its sources approach within a few miles of those of the Topayos, Chingu, and Toccantins, which are tributary to the Amazons. In many parts, indeed, owing to the configuration of the ground, the tributary rivers of the Amazons and the Plata appear as if they were blended together, and as if their respective streams were in a manner interlocked. From the sources of these rivers, the dividing ridge runs south-west, and afterwards, turning towards the north-east, makes a sort of circle round the head waters of the Araguay, a branch of the Toccantins, which are to be found, in consequence of this bend in the ridge, as far south as the 18th degree. In its course towards the north-east, the ridge confines the waters of the Toccantins within the 16th parallel of south latitude, and, running in a northerly direction parallel to the course of this last-mentioned river, it divides its waters from those of the Rio Francisco, which has its rise about the 20th degree of south latitude, and, after running to the north for a considerable space in the bottom of a longitudinal valley, turns round at length towards the east, and falls into the Atlantic about the 11th degree of south latitude. The Rio Francisco is the only considerable river of Brasil, which is unconnected either with the Amazons or the Plata. Along the Francisco, parallel to its course, runs a ridge of mountains distant from the Atlantic Ocean about 250 miles. This ridge divides the waters of the Francisco from those flowing directly to the ocean, which consist of a variety of insulated streams, such as the Rio Grande, the Rio Doce, and several others of inferior note.

To the south of the dividing ridge between the waters of the Plata and those of the Toccantins, the great river Parana, which flows into the Plata, on the eastern bank, about 700 miles from its mouth, is formed by the accumulated waters of several extensive valleys. From the east, it receives all the waters of the western declivity of that mountainous ridge which runs along the shores of the Atlantic, and rising to its height at the distance, generally, of some hundred miles from the coast, pours all its great streams into the interior, to make their way into the ocean by the channel of the Plata. The head waters of the Parana approach within less than 100 miles of the eastern shore, from which their course is westerly into the interior, until they turn towards the

Brasil.

south. To the southward of the Parana rises the river Uruguay. Its head waters, like those of the Parana, flow from the mountainous ridge which runs along the Atlantic shore, and they pursue a course somewhat similar, flowing down the western declivity into the interior, and afterwards turning in a circular direction to the south. The Uruguay falls into the Plata near its mouth, after a course of 1000 miles.

Soil and Climate.

In consequence of the immense extent of Brasil, from north to south, it possesses great variety both of soil and climate. The country in the vicinity of the Amazons is exposed to the tropical heats, which, however, are in some measure tempered by the natural humidity of the climate. In those regions, there is little distinction of seasons. The ground is continually covered with flowers and with trees, always green, while the abundant dews, the shade of the forests, and the delicious coolness of the nights, present the image of perpetual spring. In ascending towards the sources of the great rivers, the temperature is modified by the height of the ground; and within the elevated plains which spread out into the interior, fertile valleys are found, which possess a salubrious and temperate climate, and in which all the fruits of Europe grow to maturity, along with the native productions of America. Of this nature is the climate of Brasil towards Minas Geraes, Villa Rica and Saint Paul. In some of the more elevated mountainous situations, which are raised to the height of 5000 and 6000 feet above the level of the sea, and towards the southern extremity of Brasil, the air is still colder, and the soil produces, in great perfection, both European fruit and grain.

The west wind, passing over vast marshy forests, is frequently found to be unhealthy in the interior parts, while the excessive heat which follows the course of the sun, fills the atmosphere with igneous particles, which produce occasionally fatal consequences. But those unhealthy blasts are corrected by the influence of the aromatic plants which abound in the woods, and which fill the air with their fragrance, so that it can be plainly perceived at several leagues from the shore, when the wind blows in that direction.

From the month of March to August, the rainy season prevails upon the coast. During the rest of the year, there is almost constant drought, the wind blowing from the north, with little interruption. Under the influence of these dry and parching blasts, vegetation languishes, and all the higher and more exposed parts appear to be burnt up and withered. The sea breeze, which ushers in the rainy season, refreshes the atmosphere and reanimates vegetation.

The interior of Brasil consists in many parts of one continued forest, in which the trees are covered with brushwood and twigs, twining round them even to their summits, after which they frequently make their way again to the earth, where they take root, and, mounting anew, they grow from one tree to another, until the whole forest is laced together by this vegetable cordage, and rendered completely impracticable. It sometimes grows to the thickness of a man's leg, and is so closely interwoven that neither animals nor birds can pass across it. When young, these twigs are flexible, and frequently serve for ordinary purposes instead of cords. Mr Mawe mentions that he had often seen negroes convert them into bridles, and ride with them for days together. In some species of this underwood, if an incision is made, a considerable quantity of cool and excellent water is procured. The shrubs which yield this precious resource are found in marshy countries, or in sandy plains, where, without this assistance, the traveller would die of thirst. The wild recesses of those impenetrable forests are inhabited by great numbers of apes, which multiply undisturbed in these inaccessible abodes.

Productions.

At a little distance from the coast, the country is covered with numerous varieties of the palm-tree, among which we meet with that celebrated species, whose long, serrated, lancet-formed leaves are composed of innumerable fibres, which rival silk both in fineness and strength. These are frequently used for fishing-lines. Here also is to be found the Brasilian cocoa tree, which is thicker and more elevated than that of the Indies,—also the tree called the *pekia*, which bears a fruit large and hard, something similar both in shape and size to a common ball, so that it is dangerous to be near it when the fruit falls to the ground,—and the Brasilian myrtle, distinguished by the shining of its silver bark. No country in the world furnishes so many precious woods for dyeing, for cabinet work, or for ship-building. The cedar, the wild cinnamon tree, and the rosewood trees, are improved by being worked, and resist for a long time the action both of the water and of the air. There is, besides, an immense variety of other species of trees, adapted for every purpose, either of utility or ornament; and it is in Brasil, also, that those gigantic trees are to be found which rise to the height of 80 feet, and which are so well adapted by their size for the construction of the largest ships.

The woods of Brasil are full of rapacious animals, such as the tiger-cat, the hyena, the saratu, which is the size of a fox, but much more ferocious and brave. The jaguar, from its strength and ferocity, the terror of the Brasilian peasantry, is frequently met with; also the porcupine, which, when it is irritated, darts its quills with such force as to occasion serious wounds. This animal must not be confounded with the armadillo, or with the common porcupine, which rolls itself up like the hedge-hog, and presents to its pursuers an impenetrable coat of mail. The farmers in Brasil are much infested by ounces, which are of various colours, some black and brown red, and are exceedingly ravenous and ferocious. This animal is hunted with dogs, and when it is run down, a contest ensues, which is seldom terminated without the loss of some of the dogs. Wild hogs are common, and all sorts of monkeys; some of which, when asleep, snore so loud as to astonish the traveller. The tapir is the largest quadruped found in the country; in its form it resembles a hog, but is nearly the size of a calf. The most formidable rep-

tiles are the corral-snake, the sorrocuco, and the jarraraca, all of them venomous, and generally dreaded by the inhabitants. The corral-snake is between two and three feet in length, and about two inches in circumference, with a pointed tail and white belly; the head is covered with white cubical scales, edged with black, and the back is adorned with red, black, and white spots, in alternate order. In the marshy countries of the south is found the boa-serpent, which grows to the length of 30 feet, and in thickness equals the body of a man. As some sort of compensation for the production of these monstrous reptiles, the forests of Brasil abound in an infinite variety of the most beautiful birds, which are distinguished not more by the brilliancy of their plumage than by the melody of their notes.

The great extent of Brasil, and the general aspect of the country, diversified as it is by hill and valley, gives it such a variety of soil and climate, that it is well adapted to produce all that is necessary either for luxury or use; and the fruits and productions of the tropical climates, as well as all sorts of European grain, are accordingly found to flourish in its congenial soil. In no country would agriculture yield larger returns to the industrious farmer, and in no country is it more generally neglected. A propensity to seek after gold and diamonds, with which the country abounds, is fatally prevalent among the people; and to such a length is this carried, that they have lost all relish for sober industry. They will not be turned away from this, as they fancy, short road to wealth; and their whole time being wasted in a fruitless search after these precious productions, they entail upon themselves and their families wretchedness and want. It is a general remark, that those who devote themselves wholly to mining, are badly clothed and worse fed, while those who have attended to agriculture are well provided with every necessary of life. But though there are not wanting many examples of the superior advantages of agriculture, it is extraordinary that, throughout all Brasil, the husbandmen have ever been considered an inferior class to the miners; and it is probable that this prejudice will continue until the country being in a great measure exhausted of its gold and diamonds, its inhabitants shall be compelled to seek, in the cultivation of the soil, a sure and permanent source of wealth. Most of the towns in the southern provinces of Brasil were first settled by bands of adventurers, who penetrated into the interior in quest of the precious metals; and when they had gradually exhausted the country of its mineral treasures, they were then compelled to employ themselves in husbandry. The town of St Paul's, in the province of Minas Geraes, which contains about 15,000 inhabitants, was settled in this manner. The town of Villa Rica owed its origin to the same cause. The country around both these places has been in a great measure drained of its gold by the rapacious industry of successive adventurers. The inhabitants of St Paul's, the vicinity of which has been long exhausted, have betaken themselves to industry. But in Villa Rica, where the precious metal has not entirely disappeared, they still retain their blind passion for mining, and totally neglect the fine country around them, of which the produce would amply compensate them for the loss of its former wealth. The descendants of the original settlers in the interior of Brasil, have generally sunk into a deplorable degeneracy of manners. They are unfitted for active life by their education, their habits, and still more by their hereditary prejudices. Perpetually indulging in prospects of fancied wealth, they neglect the means by which alone their hopes can be realized. They are listless and indolent, passing whole days in perfect inactivity, and leaving every trade to be occupied by mulattoes or negroes.

Every where throughout Brasil there are large tracts of unoccupied land, which may be obtained by making proper application to government, and may be afterwards held as freehold property. Other excellent lands are possessed by many indolent persons, who are either unwilling or incapable of turning them to any advantage. These may be bought at very low prices, and they afford every possible encouragement to enterprising settlers. Many districts abound with iron ore and limestone; there is excellent clay for making bricks,—wood in abundance for every purpose, and water at command. As an example of the profits which may be gained by farming in Brasil, Mr Mawe mentions having met with an industrious Priest, who, having obtained possession of a farm, which he diligently cultivated, had in the course of four years rendered it worth L. 400,—although he possessed only L. 8—*per annum*, his salary as a clergyman, with which to hire negroes for the cultivation of his property.

Maize, beans, cassava root, which is generally eaten as bread by all ranks, are very generally cultivated. In many parts wheat and other European grain is reared; and where the farmer has planted a sufficient supply of food for the consumption of the farm, he grows coffee, and, if he has the means, he prepares for growing and manufacturing sugar. The farm-houses are generally miserable hovels of one story; the floor is neither paved nor boarded, and the walls and partitions are formed of wicker-work plastered with mud. The kitchen is a filthy room with an uneven muddy floor, interspersed with pools of water; the fire-places are formed by the rude contrivance of three round stones; and as there is no proper chimney, the place is always filled with smoke, which vents itself through the door and other apertures, leaving all within black and dirty. In more remote parts of the country, the same habits of indolence prevail. "The people," says Mr Mawe, to whose researches we are indebted for much valuable information respecting this interesting country, "seemed to act as if the tenure by which they held their lands was about to be abolished; all around them had the appearance of make-shift; their old houses fast hastening to decay, bore no marks of repair about them; wherever a bit of garden ground was inclosed, it appeared overrun with weeds; where coffee-trees, planted in former years, still existed, the present occupiers were too indolent to

Brasil.

gather the fruit; no inclosures were made for pasturage; a few goats supplied the little milk that was consumed, and cow's milk was rarely to be procured."

Gold and Diamonds.

Brasil has long been celebrated for the gold and diamonds with which it abounds; but so watchfully was this precious produce formerly guarded by the jealousy of the Portuguese Government, that no foreigner was ever permitted to penetrate into the interior; and, in consequence, no satisfactory information could ever be procured respecting those valuable productions. Lately, however, and more especially since the emigration of the Portuguese Royal Family to the Brasils, this policy has been relaxed; and we are indebted to Mr Mawe, who was freely permitted to visit both the gold and the diamond mines of the interior, and to examine every part of the works connected with them, for many curious details respecting this branch of domestic industry, by which the inhabitants are drawn from every other pursuit.

In the beds of almost all the rivers which have their rise in the interior of Brasil, gold is found in abundance, and the nearer the source of the river, the soil always proves to be the richer in mineral wealth. It is known that the head waters of all those streams which have their source in the provinces of Minas Geraes or of Goias, and which, running south-west, fall into the Parana, a branch of the great river Plata, or turning to the north-east, are carried by the Rio Francisco to the Atlantic, are rich both in gold and diamonds. Almost all the towns in the interior of Brasil, were established by adventurers in pursuit of gold, and they will be found, accordingly, to be situated near the sources of the great rivers. The town of St Paul is situated on the western declivity of the chain of mountains which run along the coast near the source of the river Tiete, which, running west, falls into the Parana. Villa Rica is, in like manner, situated near the source of the Paraiba, which falls into the Atlantic, and on the sources of all the other rivers, towns have been established by adventurers drawn to these remote and unfrequented regions by their eager searches after gold. The village of Paracatu is established on the sources of the Rio Francisco, between 300 and 400 miles north-west from Rio Janeiro; its population is estimated at 1000 souls; and it will soon be more numerous, as the rumoured discovery of some rich mines lately found in its vicinity, has already tempted many families to remove to it. Farther to the west, we meet with the head waters of the rivers Toccantins, and with those of the river Aragua, as we advance into the province of Matto-Grosso. There is every reason to believe that those unexplored regions abound in untouched treasures both of gold and diamonds. The town of Villa Boa is situated on the eastern waters of the river Aragua, in the province of Goias, and is 80 leagues to the west of Paracatu, from whence there is a good road. Several other villages have also been established, at no great distance, for the purpose of collecting the gold which is found in the channels of those mountain streams. In various other parts of the Capitania, gold washings are established, at some of which gold is found of a very fine quality. Diamonds have been collected in some parts, which are more brilliant in their appearance than those found in the diamond districts of Cerro do Frio, but are not generally of so pure a water. It is known that the river Das Mortes, which belongs to the Capitania of Matto-Grosso, and flows in a large stream into the Aragua from the west, is auriferous; and, according to the experience of those most skilled in the nature of the country, the smaller streams which descend from the higher grounds, must be still more productive of gold. Some mining works were at one time established in these remote districts, which were abandoned, not from any scarcity of gold, but because the few inhabitants who had settled in the country, being far removed from the road, and in the midst of a swamp inhabited by savages, could neither be conveniently supplied with arms for their defence, nor with implements for their trade. Farther to the west is found the river Cuiaba, and the other head waters of the river Paraguay, all of which produce gold. The mines of Cuiaba are established on the river of this name, and near the town of Cuiaba, which is large, and is estimated to contain 30,000 inhabitants. They were discovered in the year 1718, and were long celebrated for the quantity of gold which they produced, which has been calculated at 20 arrobas (500 lbs.) annually. The metal is also said to be of an extremely fine quality. The head waters of all the other great rivers, such as the Chingu, the Topayos, and the Madera, which rise in this Capitania, and flow into the Amazons, are found to produce gold. On the river Arinos, which is a western branch of the Topayos, some establishments for collecting gold were begun in 1747. But they were afterwards abandoned, chiefly in consequence of the dangers to which the adventurers were exposed from the tribes of warlike Indians by which this country is infested. The inveterate hostility of the native tribes to the Portuguese, tends greatly to obstruct the progress of new settlements; as a body of adventurers must be collected sufficiently numerous to protect themselves against their savage enemies, before any settlement can be begun; and, even in this case, being in a state of perpetual watchfulness and alarm, their attention is continually distracted from agriculture or mining, to the more necessary business of war. But where the country is known to abound in gold or diamonds, adventurers soon crowd from all quarters to gather the rich harvest; the barbarous inhabitants are driven back into the desert; towns and villages arise; roads are opened; and the country around quickly assumes the appearance of cultivation and improvement.

The gold which is collected in Brasil, is found either in deep valleys or in the channels of rivers. It is generally contained in a loose marl-like stratum of rounded quartose pebbles and adventitious matter, called *cascalhão*, which rests upon granite, and is covered by earthy matter of variable thickness. Sometimes the gold is found covered by the soil at

Brasil.

the depth of 20 feet, while at other times, on many of the hills where water can be collected for washing, particles of gold appear in the soil at little greater depth than the roots of the grass.

At the gold washings of Villa Rica, the bed of *cascalhão* was on the margin of the river; and Mr Mawe found the workmen engaged in cutting away the bank to the depth of, at least, 10 feet, before they could reach the vein containing the gold which was incumbent on the rock. The substance they had to cut through was clay, so strong that, though falls of water were precipitated upon it, and negroes were constantly working it with hoes of various kinds, it was with difficulty removed. Nor was this the only impediment; for, by the continual washing down of mud from the higher grounds, the *cascalhão* was five feet lower than the bed of the river, so that when the pits were sunk to its depth, they were soon filled with water, which had to be drawn off by means of machinery.

Gold Washings.

When the stratum which contains the gold is found at a distance from the rivers, it is dug up and carried to a convenient place, where it is washed, for the purpose of separating the earth and other materials from the gold. The method of washing it is simple, and the following account of it is given by Mr Mawe, who was freely permitted to visit the different gold-washings established in the country.

"Where water" (he observes) "of sufficiently high level can be commanded, the ground is cut in steps, each twenty or thirty feet wide, two or three broad, and about one deep. Near the bottom a trench is cut to the depth of two or three feet. On each step stand six or eight negroes, who, as the water flows gently from above, keep the earth continually in motion with shovels, until the whole is reduced to liquid mud, and washed below. The particles of gold contained in this earth descend to the trench, where, by reason of their specific gravity, they quickly precipitate. Workmen are continually employed at the trench to remove the stones and and clear away the surface,—which operation is much assisted by the current of water which falls into it. After five days washing, the precipitation in the trench is carried to some convenient stream, to undergo a second clearance. For this purpose wooden bowls are provided, of a funnel shape, about two feet wide at the mouth, and five or six inches deep, called *gamellas*. Each workman, standing in the stream, takes into his bowl five or six pounds weight of the sediment, which generally consists of heavy matter, such as oxide of iron, pyrites, ferruginous quartz, &c. of a dark carbonaceous hue. They admit certain quantities of water into the bowls, which they move about so dexterously, that the precious metal, separating from the inferior and lighter substances, settles to the bottom and sides of the vessel. They then rinse their bowls in a larger vessel of clean water, leaving the gold in it, and begin again. The washing of each bowlful occupies from five to eight or nine minutes; the gold produced is extremely variable in quantity, and in the size of its particles; some of which are so minute that they float, while others are found as large as peas, and not unfrequently much larger. This operation is superintended by overseers, as the result is of considerable importance."

Brasil.

There is another mode of separating the gold from the *cascalhão*, which is described in the following manner: "Two planks about ten or twelve inches broad and about twelve or fifteen feet in length, are laid in the ground, forming an inclined plane, sloping one inch in twelve; two other planks, of similar dimensions, are fixed in the same direction at the lower end, forming a second inclined plane, with a fall of six inches from the former. On their sides are boards placed edgewise, and staked down to the ground, so as to form long shallow troughs, the bottoms of which are covered with hides tanned with the hair on, having the hairy side outwards, or, in defect of these, with rough baize. Down these troughs is conveyed the water containing the oxide of iron and the lighter particles of gold; the latter substance precipitating in its course is entangled by the hair. Every half hour the hides are taken up, and carried to a tank near at hand, formed of four walls, say five feet long four broad and four deep, and containing about two feet depth of water. The hides are stretched over this tank and well beaten, then dipped, and beaten repeatedly, until all the gold is disentangled, after which they are carried back and replaced in the troughs. The tanks are locked up at night, and well secured. The sediment taken from them being light, is easily washed away by the hand, in the manner before described, leaving only the black oxide of iron, called *esmeril*, and the gold, which is so fine that mercury is used to separate it."

In all those various operations of digging up the *cascalhão*, of removing it to a convenient place, and, finally, of washing away the earth from the gold, a great deal of time and labour is wasted which might be saved by adopting some very simple contrivances. In removing the earth, for example, to the place where it is to be washed, not a cart or a wheelbarrow is used. The whole is transported in bowls, which are carried on the heads of poor negroes, who have frequently, with these heavy burdens, to climb up steep ascents, where various methods might be adopted with little trouble or contrivance, to abridge this unnecessary labour. The hydraulical apparatus, in use for draining off the water, is cumbersome and expensive. In many cases, ordinary pumps would answer the purpose better, as they can be made at little trouble and expence, are easily repaired, and can always be ready to work at an hour's notice. It is singular, that this very common and simple machine should be utterly unknown in those parts. The method practised in washing the *cascalhão* in bowls, is extremely tedious, and might be easily shortened. Great advantages would also be derived from the use of properly constructed mills for breaking down the hard substances which contain gold, and which might then be washed in the same manner as the softer matter. We are informed by Humboldt, that, in the silver mines of Mexico, this operation is executed with admirable skill,

Brasil.

and with great advantages.* The hardest substances, previous to their amalgamation, are reduced to a fine powder; by which process every particle of the precious metal which they contain is carefully extracted. Those who are employed in washing for gold in Brasil, are exposed to various disadvantages from the scarcity and high price of iron; and owing to this circumstance they are frequently in want of the most ordinary tools. This fact strikingly illustrates the indolence and want of enterprise which generally prevails in this country. A blind pursuit after gold seems to be the exclusive occupation of all classes, in favour of which the most valuable resources of the country are neglected. In many parts iron-ore is produced in abundance, and there is little doubt that, if any spirited individual were to devote his attention to this branch of industry, he would not only facilitate the acquisition of the precious metals, but he would more rapidly acquire wealth, than if he were directly seeking after it by establishing gold-washings.

The particles of gold being separated, by washing, from the stratum in which they are found, are brought to the nearest mint, where a fifth part is taken for the crown. The remainder undergoes a process of amalgamation with mercury, and is afterwards poured into an ingot, which being sent to the assay master, he ascertains its weight and fineness, and puts upon it the public stamp, when it is delivered to the owner for circulation. The operation of melting seldom occupies more than ten minutes; and those who deliver into the mint any quantity of gold dust, may reckon on having it returned to them for circulation in less than an hour. The gold is of different qualities. Some of the bars which are in circulation are so low as 16 carats, while others are as fine as $23\frac{1}{2}$ carats, which is within one-half carat of what is denominated pure gold. The standard is 22 carats fine, and gold exceeding this standard receives a premium in proportion to its fineness. Gold of a low standard is generally of a pale colour, which is ascribed to the mixture which it contains of silver, platina, or some other metals.

Diamond Washings.

The washing for diamonds is another favourite employment in Brasil, and, being esteemed too lucrative a branch of business for individuals to enjoy, is now prosecuted by the state as a royal monopoly. The district of Cerro do Frio, or of the cold mountains, in which the diamond works are established, is situated on the highest ridge of those mountains; which, running nearly parallel with the coast of Brasil, rise to their height at the distance of about 300 miles in the interior, and divide the streams which fall into the Atlantic by the Rio Doce and the Rio Grande, from those which, running westward into the Rio Francisco, are carried to the north by that river, and fall into the Atlantic about the 11th degree of south latitude. It is at the sources of these streams that the diamond works are situated. This district consists of a range of rugged mountains that run north and south, and are generally considered to be the highest in Brasil. The tract of country termed the diamond ground, extends about 16 leagues from north to south, and about 8 leagues from east and west. Nearly in the middle of it stands the town of Tejuco, 400 miles north of Rio Janeiro, in a straight line, but nearly double that distance by the winding roads of the mountains. It contains about 6000 inhabitants, and is chiefly supported by the diamond works in its neighbourhood. The most considerable of these is situated on the head waters of the river Jijitonhonha, a branch of the Rio Grande, while others are established on the Rio Velho, a branch of the Francisco, and on the other numerous small streams which have their rise in this mountainous region. The river Jijitonhonha, where the diamond works are established, is about as wide as the Thames at Windsor, and is in general from three to nine feet deep. The *cascalhao* consists of nearly the same materials as that which contains the gold, and it has to be dug from the bottom of the river, which, for this purpose, is diverted into a new channel. When Mr Mawe visited these works, they were working at a bend of the river, from which the water was diverted by means of a canal cut across the tongue of land round which it held its course; an embankment formed of several bags of sand, being carried quite across the old channel, just below the head of the canal. After this operation, the deeper parts of the river are laid dry by means of pumps, and, the earth being removed, the *cascalhao* is dug up and removed to a convenient place for washing. This fatiguing work was until lately performed by the unassisted labour of the negroes, who carried the *cascalhao* in bowls on their heads, and in many establishments this mode of working still prevails. Two inclined planes have been since contrived, along which, by means of a water-wheel, two carts are set in motion, one of which descends empty by one inclined plane, while the other, loaded with *cascalhao*, is drawn to the top of the other. At some of the diamond works, on the same river, the *cascalhao* is conveyed to the place for washing by different and more improved machinery, and railways are even constructed on some parts of the uneven ground. The *cascalhao*, when it is carried from the bed of the river whence it is dug, is laid down in heaps, containing apparently from five to fifteen tons each; and they calculate in digging as much during the rainy season, as will give full employment to all their hands during the months which are not subject to rain. Into all the various parts of the works erected for washing the *cascalhao*, water is distributed by means of aqueducts, constructed with great ingenuity and skill. The following is an account of the mode of washing for diamonds, as it was observed by Mr Mawe, which appears to be highly curious and interesting.

"A shed is erected in the form of a parallelogram, 25 or 30 yards long, and about 15 wide, consisting of upright posts, which support a roof

* *Political Essay on the Kingdom of New Spain,* Vol. III. p. 256.

Brasil.

thatched with long grass. Down the middle of the area of this shed, a current of water is conveyed through a canal, covered with strong planks, on which the *cascalhão* is laid two or three feet thick. On the other side of the area is a flooring of planks, from four to five yards long, imbedded in clay, extending the whole length of the shed, and having a slope from the canal, of three or four inches to a yard. This flooring is divided into about twenty compartments or troughs, each about three feet wide, by means of planks placed upon their edge. The upper ends of all these troughs (here called canoes) communicate with the canal, and are so formed that water is admitted into them between two planks that are about an inch separate. Through this opening, the current falls about six inches into the trough, and may be directed to any part of it, or stopped at pleasure by means of a small quantity of clay. For instance, sometimes water is required only from one corner of the aperture, then the remaining part is stopped; sometimes it is wanted from the centre, then the extremes are stopped; and sometimes only a gentle rill is wanted, then the clay is applied accordingly. Along the lower ends of the troughs, a small channel is dug to carry off the water.

"On the heap of *cascalhão*, at equal distances, are placed three high chairs for the officers or overseers. After they are seated, the negroes enter the troughs, each provided with a rake of a peculiar form and short handle, with which he rakes into the trough about 50 or 80 lbs. weight of *cascalhão*. The water being then let in upon it, the *cascalhão* is spread abroad, and continually raked up to the head of the trough, so as to be kept in constant motion. This operation is performed for the space of a quarter of an hour; the water then begins to run clearer, having washed the earthy particles away, the gravel-like matter is raked up to the end of the trough: after the current flows away quite clear, the largest stones are thrown out, and afterwards those of inferior size, then the whole is examined with great care for diamonds. When a negro finds one, he immediately stands upright and claps his hands, then extends them, holding the gem between his fore-finger and thumb; an overseer receives it from him, and deposits it in a gamella or bowl, suspended from the centre of the structure, half full of water. In this vessel all the diamonds found in the course of the day are placed, and at the close of work are taken out and delivered to the principal officer, who, after they have been weighed, registers the particulars in a book kept for that purpose.

"When a negro is so fortunate as to find a diamond of the weight of an octavo ($17\frac{1}{2}$ carats), much ceremony takes place; he is crowned with a wreath of flowers, and carried in procession to the administrator, who gives him his freedom, by paying his owner for it. He also receives a present of new clothes, and is permitted to work on his own account. When a stone of eight or ten carats is found, the negro receives two new shirts, a complete new suit, with a hat and a handsome knife. For smaller stones of trivial amount, proportionate premiums are given. During my stay at Tejuco, a stone of $16\frac{1}{2}$ carats was found; it was pleasing to see the anxious desire manifested by the officers that it might prove heavy enough to entitle the poor negro to his freedom, and when, on being delivered and weighed, it proved only a carat short of the requisite weight, all seemed to sympathize in his disappointment."

The flat pieces of ground which lie on each side of the river, are generally equally rich throughout their whole extent, and the officers employed in the works are enabled to calculate the value of the places unworked from the parts adjoining. The substances which are considered the best indications of diamonds are bright, bean-like, iron-ore; a slaty flint-like substance, resembling Lydian stone, of fine texture; black oxide of iron in great quantities; rounded bits of blue quartz; yellow crystal, and various other materials, entirely different from any substance found in the adjacent mountains. Diamond washings have been established on the river Jijitonhonha, and the neighbouring streams for many years, and great quantities of the finest stones have been collected. These vary extremely in size, some being so small that four or five are required to weigh one grain, and consequently there are sixteen or twenty to the carat. It is calculated that only two or three stones of from 17 to 20 carats are found in the course of a-year, and not once in two years is there found throughout all the diamond washings a stone weighing 30 carats. Mr Mawe mentions, that during the five days in which he was employed visiting these works, the number of diamonds found amounted only to forty, the largest of which weighed only four carats, and was of a light green colour.

Royal Monopoly of Diamonds.

The diamond district was first explored by some enterprising miners from Villa do Principe, which is about 60 miles south-east from Tejuco. Their search was after gold, which they sought for on the banks of the rivulets in the neighbourhood of Tejuco, and not suspecting that they contained diamonds, they were not aware of the value of these stones when they were first discovered. Nor was it until they were sent to Europe that their worth was accurately ascertained. Immediately on this discovery, the Portuguese Government erected Cerro do Frio into a distinct district, which was placed under its own peculiar laws and regulations; and the lucrative trade of searching for diamonds being prohibited to all individuals under the severest penalties, was constituted a strict monopoly for the benefit of the crown. But in this, as in most other cases, the power of the Government was counteracted by the fraud and cunning of its subjects. By means of the intrigues and misrepresentations of interested individuals, government was prevailed on to farm these territories to a company, who were bound only to employ a certain number of negroes, or to pay a certain sum for each negro employed over the quantity agreed for. Under cover of this lease, every species of fraud and corruption was practised. About double the stipulated number of negroes was employed, and the agents of Government were bribed to connive at this fraud. Seasonable presents were also made in order

to secure influence at court; and, by such arts, the farmers of these valuable works were continued in their lease until about the year 1772, when Government resolved to appoint its own officers to superintend this valuable branch of its revenue. Under this new system of management, abuses, however, still continued; and the establishment was run in debt to foreigners, who advanced a considerable sum to carry it on, on condition of receiving, as security, all the diamonds which it produced. This debt still remains unpaid, and there are other incumbrances from which it is not likely that the establishment will ever be freed while it continues under the management of the state. According to the information of Mr Mawe, "the expences of these works amounted, during a period of five years, from 1801 to 1806 inclusive, to L.204,000; and the diamonds sent to the treasury, at Rio Janeiro, during the same period, weighed 115,675 carats. The value of the gold found in the same period, amounted to L. 17,300 Sterling, from which it appears that the diamonds actually cost Government 33s. 9d. *per* carat. These years were esteemed singularly productive; the mines in general do not yield to Government more than 20,000 carats annually."

Consequences of the Royal Monopoly.

All the gold collected in Brasil being liable to pay a fifth share to the crown, the temptation to evade so heavy a tax has given rise to a contraband trade in this precious commodity, and various precautions have been adopted to prevent the injury thence arising to the revenue. But the temptation is even greater to carry on an illicit trade in diamonds than in gold, because, in the one case, it is only the royal fifth which the smuggler gains by evading the regulations of the state, while, in the case of diamonds, he gains the whole value of the article which he succeeds in conveying clandestinely away. The irresistible temptation which this monopoly holds out to illicit trade, is met by regulations of corresponding strictness and severity. For the security of the revenue, the country has been subjected to a most vexatious system of military police, and the unhappy offender, who is detected in the heinous crime of illicit trade, is doomed to experience, in a cruel and hopeless captivity, or in transportation to the African colonies, the utmost vengeance of his rapacious rulers. The more effectually to counteract the projects of the smugglers, the diamond district is placed under peculiar regulations. On all the various roads leading to it, registers or military posts are established, in which is stationed an officer with twenty horse soldiers under him. These are continually patrolling the roads. Whenever they observe a stray passenger they instantly ride up to him, questioning him as to his business and the purposes of his journey, and he must satisfy them as to all these particulars before he is allowed to pass. They are authorized to stop all travellers without distinction, and to search, with the utmost rigour, those whom they suspect of concealing gold dust or diamonds. All persons passing with mules are ordered to stop at these registers, and to deliver their passports to a soldier for the inspection of his commanding-officer, who, if he is satisfied that there are no grounds of suspicion, allows them to proceed. But if he judges otherwise, the mules are unloaded, and all the baggage subjected to the strictest scrutiny. If, in the course of these examinations, a negro is suspected of having swallowed a diamond, he is confined to a bare room until the truth can be ascertained. These buildings are all provided with strong cells for the confinement of suspected persons. In the management of the works many precautions are adopted to prevent the negroes from embezzling diamonds. They work immediately under the eye of their overseers, who sit on a seat raised above them for the purpose of watching them, and, at the word of command from the overseers, they instantly move into each other's troughs, so that no collusion can possibly take place.

Notwithstanding the strictness of the police, however, and the severity of the criminal law, there is no doubt that a contraband trade, both in gold and diamonds, is carried on in Brasil to a great extent; and the present plan upon which the diamond works are managed, is calculated to give every facility to this forbidden traffic. Owing to the pecuniary embarrassments of the establishment, the Intendant has never been able to purchase a stock of negroes to carry on the work, and he is, in consequence, obliged to engage the negroes of others. The hiring out of negroes to the diamond works has long been the favourite occupation in Tejuco, in which rich and poor engage with equal eagerness to the full extent of their capital; and numbers of persons are supposed to reside in Tejuco with no other view than to place their negroes in this profitable employment. There is no apparent reason for this anxiety among all classes to hire out the industry of their negroes, seeing that the pay is small, the labour hard, the maintenance poor, and the treatment not always the most gentle. It is conjectured, therefore, with great probability, that the real object is to gain access to these works for the purpose of purloining some portion of their precious produce; and it is certain, that by whatever means they are procured, the market is supplied with large quantities both of contraband gold and diamonds. The great value and small bulk of these articles, hold out such temptations, and, at the same time, such facilities for secreting them, that no laws, however strict, can possibly counteract those strong inducements to illicit trade.

In this view, the policy of imposing so heavy a tax on gold may well be questioned; and, in regard to the monopoly of diamonds, there can be no doubt that it is both impolitic and tyrannical. There is something mean and rapacious in the principle of those measures, of which the object is to seize upon all the most valuable produce of the country; and Government, having set the example, can hardly expect that its subjects will be outdone in the practice of avarice and fraud. In this, as in all other cases, the sagacity and address of individuals will prove an overmatch for the violence of power. Harsh and cruel laws may be passed; but, while the inducement to violate them continues, adventurers will be found to run all risks; and though individuals may occasionally incur the penalties of the law, the contraband trade will flou-

Brasil.

rish in proportion to the bounty held out by the regulations of the state. The colonial policy of Europe seems generally to have been founded on the most false calculations. Even in respect to revenue, a moderate tax on several articles of general consumption would, in a flourishing community, be far more productive than this monopoly established in Brasil. The authors of these devices for cramping industry seem to imagine, that, for the diamonds which are exported by private adventurers, no valuable equivalent is received in return. They make no calculation of the additional capital which they bring into the country; of the increase thus made to the fund for maintaining productive industry; and of the general vigour diffused by a free trade over every department of an industrious community. They do not reflect, that an improving commerce, cherished and protected by an enlightened government, would soon pour into the treasury, as the cheerful gift of a free and a flourishing people, a far ampler revenue than can ever be extorted from them by all the miserable devices of tyranny.

Oppressive system of taxation.

There are various other duties imposed on the transit of commodities into the interior, which are both oppressive and impolitic. They generally take place at the crossing of ferries, and are laid on according to the weight of the goods passing, without any regard to their bulk or value. All heavy articles, in consequence, pay high, while woollens, cottons, and other light goods, pay only about 8 or 10 *per cent.* Iron, which is in great request in the interior, pays an enormous duty, of nearly 100 *per cent.* This is the case also with salt, which, being absolutely necessary in this country for the subsistence of the cattle, the effect of the tax is to discourage breeding, and is, in this view, most injurious to the interests of agriculture. A duty of 2d. *per* lb. is also imposed on all commodities which pass into the mining districts, and a new tax has lately been laid on the rents of houses. We are informed, that the weight of the taxes presses most severely upon the poorer classes, and the same remark seems applicable to other parts of the country. A tenth in kind is raised upon cattle, poultry, and agriculture, and even upon salt. This belonged, in former times, to the clergy; but as, in the infancy of Brasil, it was inadequate to their support, they petitioned Government to have it commuted into a fixed stipend. This petition was acceded to. In the meantime, by the improvement of the country, the tithes begun greatly to increase in value to the profit of the Government, and to the loss of the church, and the clergy now complain grievously of this agreement, by which, for a temporary advantage, such a valuable revenue was surrendered. For the due collection of the public revenue, the country is parcelled out into extensive districts, and the taxes of each district are farmed out to the highest bidder. These again dispose of their farm in small shares to under farmers, who oppress and plunder the people for their own private emolument. Besides a tithe of all the cattle, which is levied on estates in the interior, meat in the shambles pays a duty of about 25 *per cent.* Fish pays a 10th, and afterwards a 15th. A duty of 10 *per cent.* is imposed on every transfer of immoveable property, and of 5 *per cent.* upon the sale of all moveable. Rum, whether for exportation or home consumption, pays a duty of from 15 to 20 *per cent.* Cotton pays a 10th, and, on its exportation, pays an additional duty of 1¼d. *per* lb.; and all goods imported are liable at the custom-house to an *ad valorem* duty of 15 *per cent.* There is also a tax imposed at Pernambuco for lighting the streets of Rio Janeiro, while its own streets are in total darkness. The produce of these duties is expended in the support of the civil Government, in which, owing to the excessive multiplication of offices with inadequate salaries, peculation and bribery prevail to such an extent, as not only to escape punishment, but even any great degree of public reproach.

Interior Commerce.

The roads in the interior are generally indifferent. The common mode of travelling is by mules, by which means are transported to the towns on the coast cotton, sugar, coffee, grain, and the other produce of the country. In return are procured iron, steel, salt, woollens, cottons, common and finer earthenware, and glass. In the towns of the interior Mr Mawe saw all sorts of English goods, which were by no means dear.

Settlement of the Court of Portugal in Brasil.

The most remarkable incident in the recent history of Brasil is the emigration to its capital of the royal family of Portugal from Europe. In the long wars which have been recently concluded between France and Britain, it was obviously the interest of the minor powers, such as Portugal, to preserve a strict neutrality. But this was rendered difficult, as well as by the inveterate hostility of the two nations at war, as by the preponderating power which both had acquired on their respective elements of land and sea. Portugal, from her situation, was entirely exposed to the vast military power of France; and it was well understood, when France had gained the undisputed ascendancy in Europe, that the inferior states could only hope to purchase a nominal independence by acceding to, and rigorously executing within their territories, the system devised by Bonaparte, for the proscription of the British trade. The Court of Portugal, terrified by the menaces of so powerful a state, agreed, about the end of the year 1807, though with reluctance, to adopt that harsh system; but delaying, under various pretences, to seize the property and persons of British merchants, which was prescribed as an indispensable condition of her alliance with France, the French ambassador quitted Lisbon, which was the prelude to more decisive measures. A French army was directed to march against Portugal, and there being no resistance, it was rapidly advancing to the capital. In the meantime, war had been declared against England by the Court of Lisbon, a fleet had been fitted out, and all the severe measures dictated by France against Britain had been agreed to; but the secret connections of Portugal with this country were but imperfectly disguised by this affected hostility; and it had accordingly no effect in retarding the march of the invading army. In this emergency, it was resolved by the Court to escape the danger by embarking for Brasil, under the protection of Sir Sidney Smith, whose squadron was at that time blockading the mouth of the Tagus,

Brasil.

This revolution was announced to the people by a royal decree. A council of regency was established, the public archives and treasure were embarked, the royal family followed, and on the 19th November 1806, the Portuguese fleet, joined by the English squadron, finally departed from Europe, and arrived at Bahia on the 19th January following. The royal family were received with every demonstration of attachment and respect; and the inhabitants of Bahia even offered to contribute a large sum of money in order to build a suitable palace for their reception, provided they would agree to reside in that place. Rio Janeiro, however, was thought more suitable for the residence of the Prince, and this capital, to which the court of Portugal soon afterwards removed, now became the seat of the Portuguese monarchy.

Effects of the Emigration of the Court of Portugal.

In considering the emigration of the royal family of Portugal to Brasil, some speculative writers have indulged in the most fanciful anticipations of improvement from this event. They seem to have imagined, that the presence of the Supreme Government of Portugal in its colonies would revive the languishing industry of these countries; that it would remove the corruptions and abuses of their domestic administration; and that, by opening to them a free trade, it would enable them, in some degree, to rival the North American States in their rapid advances to wealth and improvement. But in order to realize those pleasing expectations, it would have been necessary that the Portuguese government, which was feeble and corrupt in Europe, should have totally changed its character in removing to Brasil, and this unhappily does not appear to have been the case. Abuses and corruptions still prevail in that country; the administration of justice is not amended;—the royal monopolies for the sale of ivory, Brazil wood, diamonds, gold dust, gunpowder, tobacco, and snuff, are upheld in all their rigour; and, in general, the government is regulated upon the same principles as before. All the advantages of this translation of the government from the mother country to the colonies, seem therefore to be comprised in the commercial treaty connected with the measure; the effect of which is to open all the ports of Brasil to the vessels and produce of Great Britain, on payment of a duty of 15 *per cent*. The former system of restraint being removed by this treaty, there will thus be a greater stimulus to improvement of every sort; and industry, freed from the pernicious restrictions under which it formerly laboured, will be excited to new and active exertions by a higher price for its produce. These effects have accordingly, to a certain degree, taken place. We are informed by Mr Koster, who quitted Pernambuco in April 1811, and returned in the end of December in the same year, that, during this short interval, he observed a remarkable change for the better in the aspect of the place, and of the adjacent country. The houses had been greatly improved,—the ladies, in imitation of some families who had arrived from England and Portugal, began to walk abroad during the day,—the English fashions in clothes had become general among both sexes,—the equipages had assumed a gayer appearance,—a greater number of country residences had been built,—lands had risen in price,—labour was in request,—and the adjacent grounds, which had been covered with brushwood, were now cleared, and were laid out for building and for gardens. Before Mr Koster quitted the country, in 1815, various other local improvements had been carried into effect; all which clearly indicate, that the free trade and the unrestrained intercourse with strangers, had diffused a general spirit of amelioration throughout this hitherto languishing community.

Owing to particular circumstances, the opening of the trade to the Brasils was not attended with the same beneficial consequences to Great Britain. At the period when this took place, all British goods were excluded from the Continent of Europe, by the edicts of France; the home-market was, in consequence, overstocked, and the British merchant was naturally anxious to find an outlet for his unsaleable produce. In these circumstances, the market of Brasil was suddenly thrown open, and such immense quantities of British goods were immediately poured into it, that it was completely overstocked. Prices fell proportionably; the goods were sold cheaper than they could have been bought or even manufactured at home; and, at last, they were accumulated in such excess, that the warehouses were not adequate to contain them. In many cases they were exposed on the quays to waste and peculation, or they were left to rot in warehouses ill-adapted for their reception. The loss and ruin consequent on these rash speculations, gave rise to numerous bankruptcies at home; and thus the commercial embarrassments of the country were rather aggravated than relieved by the opening of this new market for its produce. There can be no doubt, however, that a free intercourse with this extensive country, must ultimately create an increased demand for the manufactures of Britain, and must, in this view, be of permanent benefit to her commerce.

Military Force.

The military force of Brasil is composed of regular troops and militia. The regular army, which generally amounts to about 8000 men, is extremely ill regulated. It is badly clothed and poorly paid, and, owing to the disadvantages of the service, has to be recruited by impressment, a power which, under this despotic government, is exercised with the grossest partiality. The cavalry regiments which patrole the mining districts, are, however, highly respectable, both in point of discipline and equipment. The militia amount to upwards of 30,000 men; and to this service all are liable, with the exception of the first rate nobility.

Populat[ion].

The population of Brasil has been differently estimated. According to M. Beauchamp, it amounted in 1806 to 800,000 Europeans, 1,500,000 negroes, and to from 800,000 to 900,000 civilized Indians. This, however, appears to be an exaggeration. Sir George Staunton computes the number of whites at 200,000, and the blacks at 600,000; and some authors make the whole amount only to 420,000.

Histoire du Brasil, par M. Alphonse de Beauchamp. 3 tomes 8vo. 1815. Mawe's *Travels into the Interior of Brasil*, 4to. 1812. Koster's *Travels in Brasil*, 4to. 1816. (o.)

Brass.

BRASS, in Chemistry and Manufactures, an alloy of copper and zinc. This name, however, has not been exclusively applied to the alloy of these metals; for the gun-metal, which has been also called brass, is an alloy of copper with tin. The same alloy, with more tin, is used in machinery, and is preferred to the alloy of copper and zinc, on account of its greater hardness.

Different brass.

It appears from the analysis of the brass of the ancients, that it was an alloy of copper and tin. A small portion of tin gives to copper great hardness, and renders it capable of bearing much greater resistance. A larger portion of tin gives increased hardness, but is less fitted to bear a straining resistance, on account of its brittleness. Its elasticity is very great, which fits it for bells. In this state it is called bell-metal; with a still greater proportion of tin, it forms an alloy employed for the mirrors of reflecting telescopes. The alloy of copper with tin is easily distinguished from that with zinc from the agreeable colour of the latter, which varies with the proportions of the metals. Pinchbeck has the least proportion of zinc. Common brass has more zinc, and the gold-coloured alloy called Prince's metal, contains a still greater proportion of zinc. An alloy of copper with a very large proportion of zinc is used for the common white metal buttons.

Proportions of alloys.

These various alloys of copper with tin and zinc forming the different kinds of brass, are to be considered as chemical compounds, and, of course, governed by the same laws of definite proportions which belong to the more conspicuous compounds.

On these principles, which cannot be doubted, we have an unerring rule for uniting these and other metals in the best proportions, the weights of their atoms being previously known. See the article Atomic Theory in this Supplement.

The weight of the atom of copper being 8, tin 7.35, and zinc 4; the following table will exhibit the proportions of the various alloys, expressed in atoms, and their proportions by weight, the third column pointing out the colour and character of the resulting compound. CZ and T are to represent the atoms of the metals respectively.

COMPOUNDS OF ZINC WITH COPPER.

Atoms.	Proportions by Weight.	Character and Colour of the Compounds.
C+Z	1 to 2	The best proportions for common brass.
C+2Z	1 to 1	The alloy called Prince's Metal, of a beautiful gold colour.
C+3Z	2 to 3	Of a paler yellow, very little malleable.
C+4Z	1 to 2	Still of a lighter colour, and not malleable.
C+5Z	2 to 5	Yellowish white and brittle.
C+6Z	1 to 3	Very brittle, nearly white.
2C+Z	4 to 1	A very malleable brass used in watch-work.
3C+Z	6 to 1	An alloy much harder than copper and inclining to its colour.

COMPOUNDS OF TIN WITH COPPER.

Atoms.	Proportions by Weight.	Character and Colour of the Compounds.
T+C	11 to 12	A very brittle and rather white alloy.
2T+C	11 to 6	Still more brittle and more white.
3T+C	11 to 4	Very white, used for speculums.
4T+C	11 to 3	Coarse-grained and too brittle for any purpose.
T+2C	11 to 24	A yellowish alloy, very hard and sonorous.
T+3C	11 to 36	Bell metal.
T+4C	11 to 48	A very hard alloy used for some culinary vessels.
T+5C	11 to 60	Softer but not malleable.
T+6C	11 to 72	Still increases in softness and of a yellower colour.
T+7C	11 to 84	Used for some purposes in machinery.
T+8C	11 to 96	An alloy used for cannon.
T+9C	11 to 108	More common for cannon and machinery, and used for bronze statues.

Hitherto the proportions of these alloys have depended upon the caprice of workmen, obtained by numerous trials; and what confirms the law of definite proportions, is proved by the necessity of adhering to such fixed proportions, ascertained by trials. By attending to the stages of composition pointed out in the above table, the most striking and proper compounds will be produced, without the trouble of trying. Any proportions intermediate will, doubtless, be marked by defective colour, irregular crystallization, or imperfect malleability, in such as are expected to be so.

Although the most direct way of forming these different kinds of brass is by immediately combining the metals together, one of them, which is most properly called brass, was manufactured long before zinc, one of its component parts, was known in its metallic form. The ore of the latter metal was cemented with sheets of copper, charcoal being present. The zinc was formed and united with the copper, without becoming visible in a distinct form. The same method is still practised for making brass, which we are about to describe.

Brass-making.

The materials used in making brass are, copper in small rounded masses produced by passing the melted metal through an appropriate vessel into water, in which state it is called shot copper, and calamine, an ore of zinc. This latter substance is a carbonate of zinc, often containing some oxyd of iron, which gives it a reddish appearance. As it is chiefly found with lead, the lumps frequently contain more or less gallena, which requires to be separated by the same means employed for purifying lead ore. The calamine is first reduced to powder, and the lead is then separated by washing. When the calamine is separated, reduced to powder, and sifted, it is heated upon the hearth of a reverberatory furnace. This expels the volatile matter, which is principally water

Brass.

and carbonic acid. What remains is principally oxyd of zinc, abounding with some earthy matter, and probably much carbonic acid, which is not all expelled by the heat. The calamine thus prepared, charcoal powder, and copper, are the materials to be operated upon. The proportion in which they are mixed together, are equal weights of copper and prepared calamine, and $\frac{1}{10}$ their weight of powdered charcoal.

This mixture, intimately blended, is compressed into a crucible of the form of fig. 3. Plate XXXVI.* One of these crucibles holds about 100 lbs. of brass, when the process is finished; but as this consists of the pure copper and zinc, the pot, when charged, will contain of copper 66.3 lbs., of calamine 63. lbs., and of charcoal powder 13 lbs. When the crucible is filled, the contents should be covered with a mixture of clay sand and horse-dung, in order to defend the metals and charcoal from the action of the air. When this covering is strictly attended to, less charcoal powder might be employed, and a larger dose of the other ingredients might be put in its place, but it is generally the most defective part of the process. Having charged the pots, we will now describe the furnace which has to receive them.

Fig. 1. Plate XXXVI.* is a plan of the furnace. The part AB is taken at the level EF, showing the opening into the furnace on the ground floor at *a* and *b*: *c* and *d* are horizontal flues leading to the chimney *f*, and can be cut off from the same by the dampers seen in the dark part of the flue. CD, in the same figure, is a plan on the level GH, where the pots rest upon the cast iron plate on bottom *x*, *y*.

Fig. 2, is an elevation and section of the same furnace. AB shows a front view of the pyramidal chimney, and the archway opening into it. CD is a section of the same, through the middle of the fire-place II. R,P,Q, is a vaulted passage going across the building, and open at both ends, for the admission of air, which passes through the openings in the arch, through the fires. The bottom of the furnace is not a common grate, but a thick plate of cast metal, perforated with holes for the air to pass through; one hole being between each pot, as they are seen arranged in fig. 1. at I, I, and also in the section at *x*, *y*. When the pots are placed upon the plate, the fire is not placed immediately upon them, as it would not only derange them, but it would displace the covering. To prevent this, the pots are first covered by some dried heath, or common brambles. This lying on the pots, defends them for a time, when the fuel is thrown in. By the time the brambles are consumed, the coal will have coked upon the pots, and will act as a defence for the rest of the process. The fire is kept up from twelve to twenty hours at the Cheudle Brass Works in Staffordshire, where these drawings were taken from. They cast twice in the twenty-four hours.

The melted brass, after the refuse is skimmed off, is cast into ingots, if sold for melting over again, and into plates, if intended to be rolled into sheets, or made into wire. The plates are cast between large blocks of Cornwall stone. The lower stone is fixed, and the face made even and smooth, by filling up the recesses of the ruff stone with fine sand. The upper stone is similarly prepared, and is suspended over the fixed one. The height and breadth of the place to receive the metal is limited by iron bars laid on the lower stone. The upper stone is then let down upon the bars. The lower stone is a little longer than the upper one, and projects to the front. Being a little higher in that part, it forms a lip, or mouth-piece, to pour the metal into. The flat sides of the cast plate are therefore bounded by the surface of the stones, and the edges of the same by the bars above-mentioned. The ingot moulds are recesses in blocks of cast-iron, open on one side.

Brass || Bread-fruit.

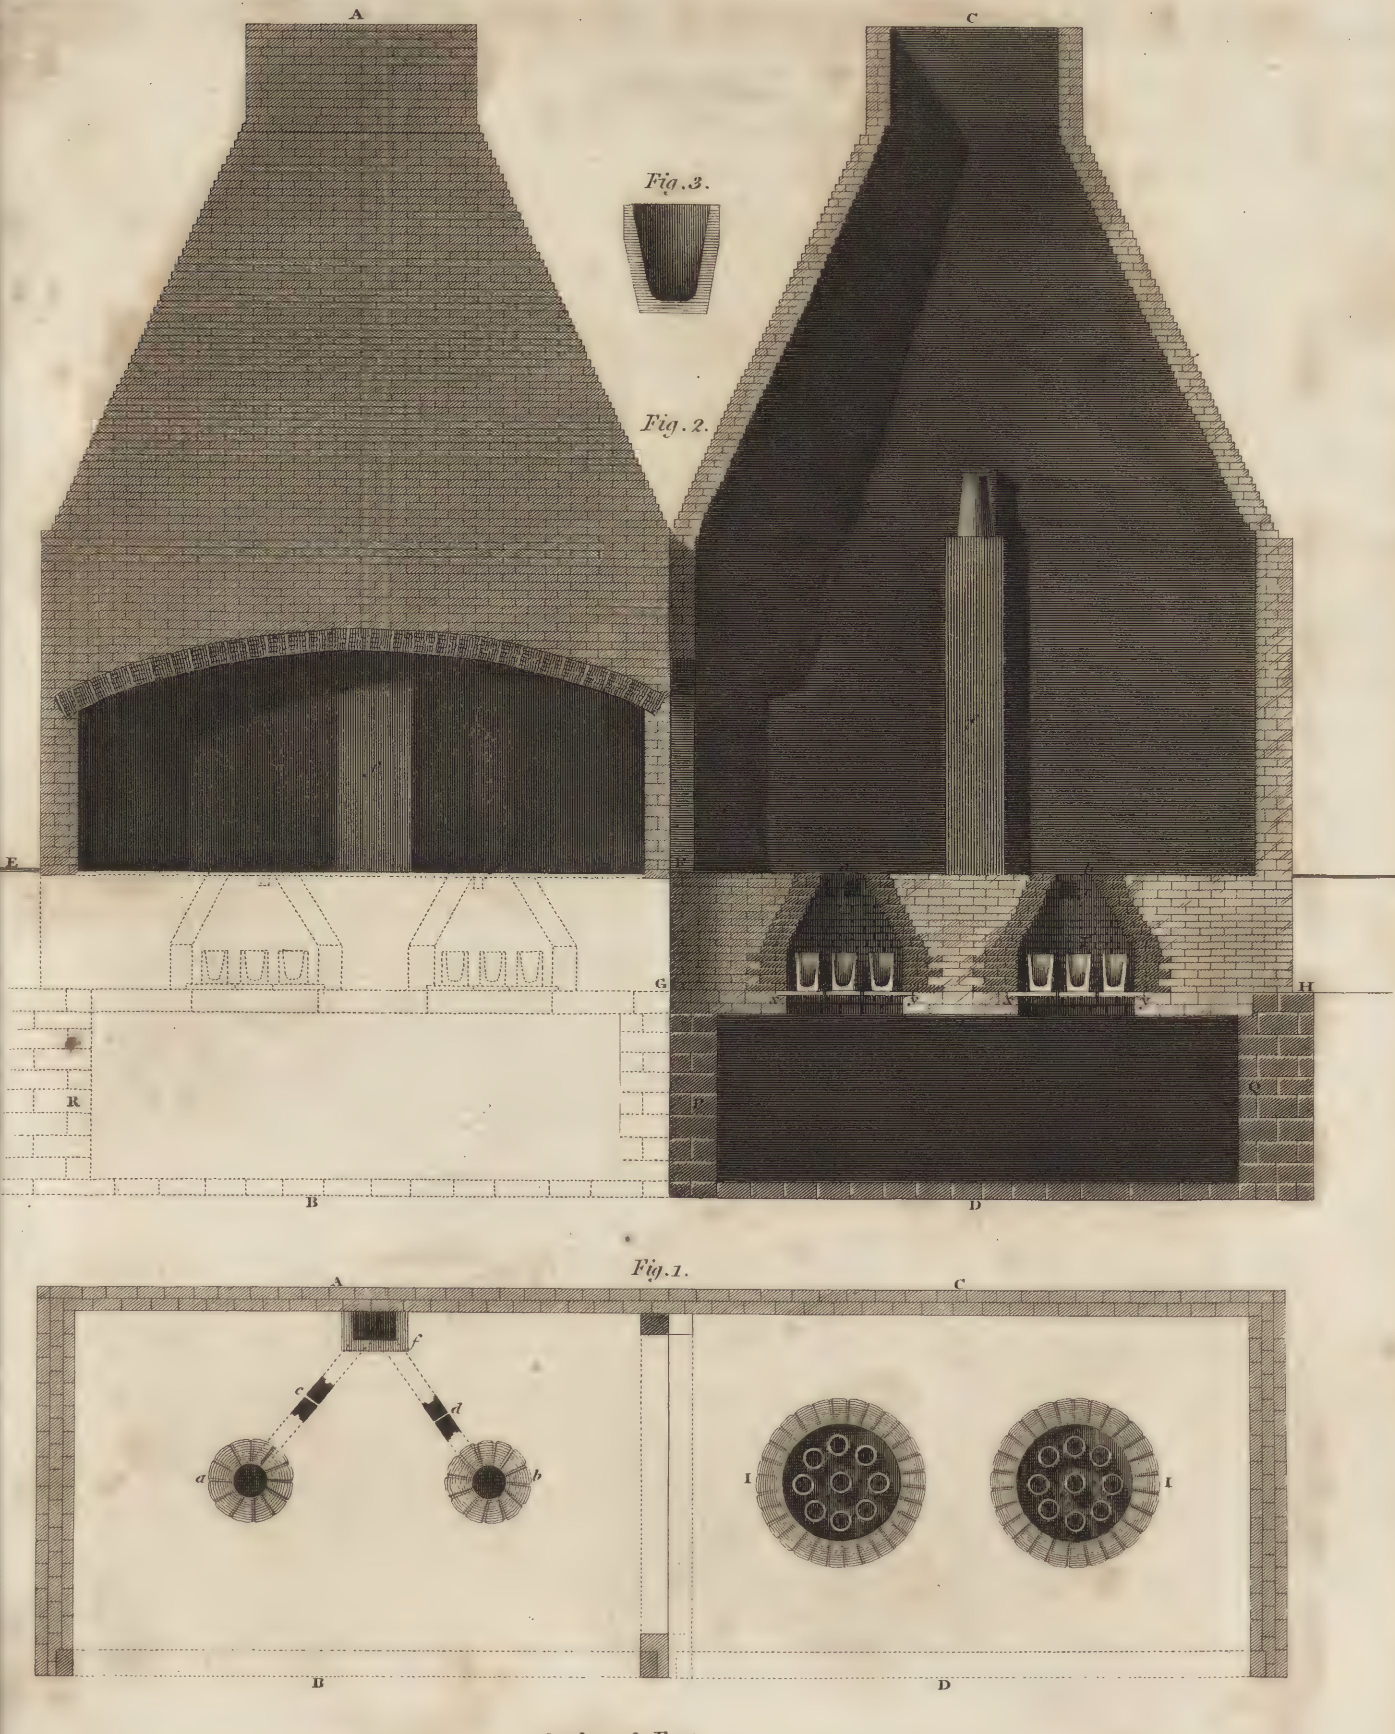
The most certain and correct method of forming brass and the other compounds expressed in the table above-given, is by immediately uniting the metals in given weights. It should, however, be observed, that it will be found difficult to introduce zinc into melted copper. The best way of uniting it with copper, in the first instance, will be to introduce the copper in thin slips to the melted zinc, till the alloy requires a tolerable heat to fuse it, and then to unite this alloy with the melted copper. (T.)

BREAD-FRUIT. Among the more valuable products of the warmer climates and the fertile islands of the southern Pacific Ocean, is to be ranked the bread-fruit, or *Artocarpus incisa* of botanists. Nature has favoured the tropical regions, and those countries in their vicinity, with inexhaustible quantities of the choicest vegetables, while the inhabitants of the north are restricted to shrivelled berries and meagre roots; and, if they have obtained a supply, always precarious, of some of the finer fruits, it is the result of patience, skill, and industry.

History of its discovery.

Ever since Europeans frequented the Eastern world in commercial enterprise, it is probable that they were acquainted with the bread-fruit. How, indeed, could its properties be unknown to Quiros, who visited Otaheite so long ago as the year 1606? Yet the English navigator Dampier seems the first of the Europeans whose notice was particularly directed towards it, during his circumnavigation in the year 1688; and he expresses himself in these words: "The bread-fruit, as we call it, grows on a large tree, as big and high as our largest apple trees. It hath a spreading head, full of branches, and dark leaves. The fruit grows on the boughs like apples; it is as big as a penny-loaf, when the wheat is at five shillings the bushel. It is of a round shape, and hath a thick tough rind. When the fruit is ripe, it is yellow and soft, and the taste is sweet and pleasant. The natives of Guam use it for bread. They gather it, when full grown, while it is green and hard; then they bake it in an oven, which scorcheth the rind, and makes it black; but they scrape off the outside black crust, and there remains a tender thin crust; and the inside is soft, tender, and white, like the crumbs of a penny-loaf. There is neither seed nor stone in the inside, but all of a firm substance like bread. It must be eaten new, for if it be kept above twenty-four hours, it becomes dry and eats harsh and choaky; but it is very pleasant before it is too stale. This fruit lasts in season eight months in the year, during which time the natives eat no other sort of food of bread kind. I did never see of this fruit any where but here (Guam). The natives told us that

BRASS. PLATE XXXVI.*



Published by A. Constable & Co. Edin.r 1817.

Eng.d by W. Archibald, Edin.r

ad-fruit. there is plenty of this fruit growing on the rest of the Ladrone Islands, and I did never hear of it anywhere else." The bread-fruit, however, is found in still greater profusion, and in equal perfection, on many of the groups of islands scattered throughout the South Pacific Ocean; nor is it confined to them exclusively, but their soil and climate seem to correspond more intimately with the conditions of its vegetation.

ferent cies. There are two leading species of this plant, which are characterized by the presence or absence of seeds; the latter being the preferable kind, and that which is cultivated more carefully for its produce. The natives of the South Sea Islands maintain, however, that eight different species, or rather varieties, may be distinguished, and for which they have the following names: Patteah, Eroroo, Awanna, Mi-re, Oree, Powerro, Appeere, Rowdeah. The leaf of the first, fourth, and eighth, differs from that of the rest; the fourth being more sinuated, and the eighth having a large broad leaf, not at all sinuated. In the first, also, the fruit is rather larger, and of a more oblong form, while in the last it is round, and not above half the size of the others. European observers, however, do not seem, in general, disposed to recognise these as essential distinctions, although they admit other varieties.

As Dampier observes, the bread-fruit is a large tree, growing to the height of forty feet or more. It is thick in the stem, and has a luxuriant foliage. The trunk is upright, the wood soft, smooth, and yellowish; and wherever the tree is wounded, a glutinous fluid exudes. The branches form an ample head, almost globular; the leaves are eighteen inches long, and eleven broad, resembling those of the oak, or the fig tree, from their deep sinuosities. The younger leaves, like all the more tender plants of the tree, are glutinous to the touch. The male-flowers are among the upper leaves, and the female flowers at the ends of the twigs. But it is the fruit which constitutes the value of the plant, and this is a very large berry, according to botanists, with a reticulated surface, resembling a cocoa-nut or melon in size and form, nine inches in length. It is filled with a white farinaceous fibrous pulp, which becomes juicy and yellow when the fruit is ripe; and the edible portion lies between the skin, which is green, and a core in the centre, which is about an inch in diameter.

d as l to a it ex- During a considerable portion of the year, the bread-fruit affords the chief sustenance of the Society Islanders. It is prepared after different fashions, and its taste depends in a great measure on the mode of preparation. It is insipid, slightly sweet, somewhat resembling wheaten bread mixed with Jerusalem artichokes, and some compare it to a cake made of flour, egg, sugar, milk, and butter. In general, it is cut into several pieces, and roasted or baked in a hole made in the ground, which is paved round with large smooth stones; and then it resembles a boiled potatoe, not being so farinaceous as a good one, but more so than those of ordinary quality. The stones are previously heated by a fire, kindled in the excavation, and the bread-fruit, being wrapped in a banana leaf, is laid upon them, and covered with leaves and hot stones. In Otaheite, and in the West Indian Islands, several dishes are made of it; either by thus baking it in an oven entire, when it is considered to equal or surpass any kind of bread; by adding water, or the milk of the cocoa nut, by boiling it, or forming it into a paste. This last is accomplished by taking the fruit before attaining complete maturity, and laying it in heaps, closely covered up with leaves, where it undergoes fermentation, and becomes disagreeably sweet. The core being then drawn out, the fruit or pulp is thrown into a paved excavation, and the whole covered up with leaves, whereon heavy stones are laid: it undergoes a second fermentation, and becomes sour, after which it will suffer no change for a long time. A leaven may be thus formed of it, which is baked as occasion requires. In the Island of Nukahiwa, an agreeable beverage can be obtained from it, and in the West Indies it can be baked like biscuit, and will keep nearly as long. The fruit is in greatest perfection about a week before beginning to ripen, which is easily recognised by the skin changing to a brownish cast, and from small granulations of the juice. In the West Indies, it is soft and yellow when ripe, and is in taste and smell like a very ripe melon. Hogs, dogs, and poultry then feed on it readily.

Besides this, the bread-fruit-tree proper, there is one that has been long known in India and the Eastern Islands, of which the fruit contains from forty to an hundred farinaceous seeds, in appearance resembling chesnuts. These when roasted or boiled are more grateful to many persons than the bread-fruit, and the negroes are very fond of them. The external characters of the tree are scarcely to be distinguished from those of the other, and the chief distinction lies in the fruit, which attains nearly the size of that we have described, and is covered with prickles like a hedgehog. It grows from the seed with rapid vegetation, and attains larger dimensions than the proper bread-fruit-tree.

The natives of those islands producing this useful vegetable, collect it without the smallest trouble; they have only to climb the tree to gather the fruit. Nor is this the sole purpose to which it is converted, for they have a method of fabricating cloth from the bark; the leaves are substituted for towels, and the wood is employed in the construction of their boats and houses. A kind of cement and birdlime is also prepared by boiling the juice exuding from the bark in cocoa-nut oil. Its other uses.

It appears that there are other vegetables of this class, producing fruit of inferior quality, but on that account receiving less attention. The bread-fruit proper is of easy cultivation in its native soil. In some of the Islands it seems an indigenous product, and springs from the root of old trees, without any care; in others, it requires simply to be put into the earth. The trees flourish with greatest luxuriance on rising grounds; and it has been remarked, that where the hills of the Sandwich Islands rise almost perpendicularly in a great variety of peaks, their steep declivities, and the deep valleys intervening, are covered with trees, among which the bread-fruit is particularly abundant. It has also been observed, that although we are accustomed to consider Otaheite as of the greatest fertility in this plant, the trees of Its cultivation.

Bread-fruit. the Sandwich Islands produce double the quantity of fruit. Though nearly of the same height, the branches begin to shoot out much lower from the trunk, and with greater luxuriance. In Otaheite, they are propagated by suckers from the root, which are best transplanted in wet weather, when the earth forms balls around them; then they are not liable to suffer from removal. This valuable plant is widely diffused in the Southern and Eastern Isles, and it is generally found throughout the great Pacific Ocean. It grows on Amboyna, the Banda Islands, Timor, and the Ladrones; but it is more specially the object of care and cultivation in the Marquesas, and the Friendly and Society Islands, where it vegetates in uncommon luxuriance and profusion.

Attempts to transplant it to the West Indies.

The great utility of the bread-fruit as an article of subsistence for mankind, has, at different times, led to speculations on the possibility of naturalizing it in places where it is not of spontaneous growth. M. de Poive, the philosophic Governor of the Mauritius, succeeded in introducing it there, and in the Isle of Bourbon, whither it was conveyed by M. de Sonnerat from Luçon in the Philippine Islands. Being found in the greatest luxuriance under the same latitudes as the British West India Islands, and in a climate not dissimilar, Government deemed the transmission of it thither, both as practicable without much difficulty, and as promising a future store of subsistence for the inhabitants. An expedition was therefore fitted out, with particular care, under the command of Captain, then Lieutenant Bligh, who sailed in the Bounty store ship, for the South Seas, in December 1787. This vessel was prepared so as to receive a great many bread-fruit and other plants, which would have proved a valuable acquisition to the colonists of the West Indies, and some which were expected to succeed under the culture of the curious in Great Britain. The Bounty arrived in safety at Otaheite, the principal place of her destination, and took on board 1015 bread-fruit plants, besides a great variety of different species of other plants, and after remaining twenty-three weeks, which were busily occupied, set sail on the 4th of April 1789. But it is unnecessary to say more of the expedition, which was rendered totally abortive by a mutiny ensuing three weeks subsequent to its departure; the cause of which still remains in obscurity. The Captain and eighteen adherents were barbarously turned adrift in an open boat, wherein they suffered incredible hardships, and, after a navigation of 3600 miles, reached the Island of Timor, having lost only one of their number, who was murdered by the savages of an intermediate Island. Notwithstanding the unfortunate result of this voyage, the object was still kept in view, and a new expedition planned with still greater precaution than the former; and it has been said that his present Majesty, King George III. took a lively interest in conferring so important a benefit on a distant part of his people. Captain Bligh having arrived in England, was appointed to the command of the Providence and Assistance, two vessels specially fitted out as before; and part of their complement consisted of two gardeners, to take the management of the plants collected. The vessels sailed in August 1791, reached Van Diemen's Land in February 1792, and anchored at Otaheite in February following. Here they remained above three months, and obtained even a greater store of plants than formerly; for there were now 1281 pots and tubs, whereas the first number of the bread-fruit-trees, in 1789, did not exceed 887. Captain Bligh, in returning, made a dangerous voyage through Endeavour Straits, the exploring of which was part of his former instructions, and anchored at Coupang in the Island of Timor, where he substituted many other plants for those that had died. He then sailed for the West Indies, and, touching at St Helena, landed some bread-fruit plants, and took on board those of different species. The object of his voyage was at length completed by reaching the Island of St Vincent's in January 1793, where he committed 544 plants, of which 333 were bread-fruit, to the care of Dr Anderson, Superintendent of the Botanical Garden, and substituted for them 467 of different species, designed for his Majesty's garden at Kew. In the next place, Captain Bligh landed 623 plants, of which 347 were bread-fruit, at Port Royal in the Island of Jamaica, and replaced them with a farther collection for the King, with which he arrived in England on the 2d of August 1793. Five years and eight months had thus been occupied in accomplishing the desirable purpose of these two expeditions. But it belonged especially to Britain, by whom a familiar intercourse with the southern Islanders was first opened up, to effect an object of so much importance.

Nevertheless, some have been found inclined to challenge the wisdom of so difficult and expensive an experiment; both because the expectations of those who looked for an inexhaustible source of subsistence were not speedily realized; and because the places the best adapted for its culture already possess another vegetable, the plantain, which is much more grateful to the negroes, for whom the bread-fruit was principally designed. It has been argued, that the bread-fruit-tree requires considerable care in cultivation, that its progress to maturity is slow, though in Britain it would appear extremely rapid. Three years are required to reap the fruit; the plantain demands no care, while it produces its crop in fifteen months; thus giving it a decided preference in the opinion of the Colonist, who is always impatient for a return. Further, that wherever any vegetable, already relished by the inhabitants of a district, is completely established, they will always reject what they think less agreeable. These arguments have certainly had considerable weight; probably, however, from not duly appreciating the difficulties attendant on such an experiment as the naturalization of plants. But were we to take a retrospect of all the obstacles which have opposed the cultivation of many species of grain and fruits at present not uncommon in Britain, it would be very evident that success has resulted only from the most patient and laborious attention. Positive conclusions on this subject, are perhaps as yet premature.

In the year 1777, a premium was offered by the

Bread-fruit.

Society for the Encouragement of Arts and Manufactures, to any individual who should bring the bread-fruit plant from the South Sea Islands in a state of vegetation to the West Indies, and the gold medal was awarded, in 1793, to Captain Bligh accordingly. That Society, with the laudable design of promoting its culture, continued to offer further premiums for the greatest number of plants raised in the British settlements; and in consequence a silver medal was awarded to Dr Anderson, Superintendent of the Botanical Garden at St Vincent's in 1798; and, in 1802, the gold medal to the Honourable Joseph Robley, Governor of the Island of Tobago. From the course adopted by these two Cultivators, the history of the bread-fruit has received much elucidation, and we shall comprise it in a few observations.

Result of these attempts.

Mr Robley received three plants from Dr Anderson in June 1793, which he planted in very deep rich soil, and paid them every attention, in hopes of procuring shoots. They flourished exceedingly, produced fruit in 1795, and continued to do so until autumn 1801, after which we have no notices respecting them. Being disappointed of obtaining suckers, Mr Robley applied to Dr Anderson, who advised him to lay bare some of the uppermost roots, and to wound them very deeply; and having followed these directions in October 1800, they almost immediately began to put forth shoots in abundance. In December, 120 fine plants were thus obtained, which Mr Robley placed in baskets containing about a gallon of good rich loose soil, and deposited them in the shade, in the vicinity of water. With this element also they were refreshed when the weather required it. Baskets were preferred to pots for the plants, from being lighter and more easily removed. Likewise, because when deposited in the place where they were ultimately to remain, the baskets would speedily rot, and not repress the growth of the plant, which would then extend its roots. European Cultivators would do well to attend to the beneficial use of baskets, for it too often happens that a tender plant is wounded in removing it from a pot, or that the earth surrounding it is so deranged and displaced, that no subsequent care can preserve it from destruction. Encouraged by the successful issue of these previous experiments, Mr Robley prepared a point of land of loose sandy soil, bounded by a salt lagoon and the sea, for receiving a large plantation. When the tide filled, brackish water was to be found everywhere at the depth of two feet and a half from the surface; but it had been observed in some of the South Sea Islands, that bread-fruit-trees grew in full vigour, though brackish water bathed their roots, and the point was otherwise defended from the encroachments of the sea by an artificial bank. The land being ploughed and harrowed twice, was divided into beds stretching across from the sea to the lagoon: the beds were 27 feet in breadth, and the plants put into the earth in the middle of each, and exactly at the distance of 27 feet asunder—thus leaving a large space for their vegetation. Mr Robley's expectations were not disappointed. In August 1801, he had 153 plants in a flourishing condition; and, prosecuting the object still farther, he had, in the course of the subsequent year, 371 on the point of land, of which no less than 319 plants were in a flourishing, and some of them in a productive state. He transmitted specimens of the fruit to England preserved in vinegar, as it will not keep above two days after being taken from the tree; as also of the dried leaves and blossom. Other correspondents, nearly about the same time, sent specimens of cakes made from the bread-fruit converted to flour, which were extremely well flavoured; and it seemed that a dry nutritious food, resembling Tapioca in appearance and quality, might be prepared from it. The vegetation of this plant is very rapid. Ten of those committed to the care of Dr Anderson, in 1793, were about two feet high, and half an inch in diameter; and he observed, that, in the year 1798, most of the trees in the Botanical Garden at St Vincent's were above 30 feet high, and the stem two feet above the ground was from three feet to three and a half in circumference. From the remarks he was enabled to make in this interval on the varieties of the tree in the Botanical Garden, it appeared that the fruit came out in succession during the greater part of the year, but less of it between November and March than at any other time. The number produced by a single tree was very great, being often in clusters of five and six, and bending the lower branches to the ground. According to the different varieties, the fruit was of various shapes and sizes, weighing from four to ten pounds, some smooth, others rough and tuberculated. When taken from the tree before maturity, the juice appeared of the consistence and colour of milk, and in taste somewhat similar. It issued for above ten minutes in an uninterrupted stream, and thickened into a glutinous and adhesive substance. Three months were required to bring the fruit to perfection, which, as above remarked, is about a week before it begins to ripen. Besides the Otaheitan bread-fruit, Captain Bligh left some of the East India bread-fruit in the Botanical Garden. But this proved of infinitely inferior quality, and a very indifferent substitute for it. It was ill-shaped, of a soft pulpy substance, and, like the other, wanting seeds, and propagating itself by suckers springing from the root.

Bread-fruit of the Nicobar Islands.

A species of fruit, bearing considerable analogy to those above described, is found on the Nicobar Islands, but we are unacquainted with the degree of attention it has received, either for the purpose of illustrating its natural history, or for economical uses. It is not less beneficial, however, to the natives. The tree producing this fruit vegetates promiscuously with others in the woods, but preferring a humid soil. Its trunk is straight, thirty or thirty-five feet in height, and from ten inches to two feet in circumference. The roots spring from it above the surface, and do not penetrate deep into the earth. The leaves are disposed like the large calyx of a flower; they are three feet long and four inches broad, of a dark green hue and tenacious substance. A long time elapses before the tree produces fruit, not less than about the period of human life. It then forms at the bottom of the leaves, from which it proceeds as it is enlarged, and, when nearly ripe, it changes from green to yellowish colour. This is the proper

Bread-fruit || Breakwater.

period for gathering it, when its weight is between 30 and 40 pounds. The exterior surface is cut off, and the fruit is boiled in earthen pots covered with leaves, during several hours, on a slow fire; when, becoming soft and friable, the preparation is sufficient, and the fruit is then exposed to the air, and is next formed into a mass not unlike maize, either in taste or colour. It may be preserved a long time, but exposure to the atmosphere occasions acidity. The plant producing this fruit, however, is not of the same genus as those above described, although its fruit is converted to similar uses, but is rather a kind of palm which it might be useful to naturalize in the eastern possessions of Britain. (s.)

BREAKWATER, is any obstruction of wood, stone, or other material, as a boom or raft of wood, sunken vessels, &c., placed before the entrance of a port or harbour; or, any projection from the land into the sea, as a pier, mole or jetty, so placed as to break the force of the waves, and prevent their action on ships and vessels lying at anchor within them. Thus, the piers of the ancient Piræus and of Rhodes; the moles of Naples, Genoa, and Castellamare; the piers of Ramsgate, Margate, Folkstone, Howth, and the wooden-dike de Richlieu, thrown across the port of Rochelle, may all be denominated *Breakwaters*. In French it is sometimes called *Battre d'Eau;* a name which appears to have been applied to the mole at Tangier, a work commenced in 1763, under the direction of Lord Tiviot, Sir J. Lawson, and Sir Hugh Cholmley, and finished, or rather discontinued, in 1776, after having cost this nation the sum of L. 243,897, 5s. 4½d. The term *Breakwater*, however, has, of late years, been considered as more peculiarly appropriate to large insulated dikes of stone, whether of regular masonry or sunk promiscuously in rough masses, so placed, as to form an artificial island across the mouth of an open roadstead, and thereby, from obstructing and breaking the waves of the sea, to convert a dangerous anchorage into a safe and commodious harbour for the reception of ships of war or merchantmen.

Of this description of dike, for creating an artificial harbour on a grand scale, fit for the reception of ships of war of the largest class, there are two remarkable examples in the Breakwater of Cherbourg and that of Plymouth,—the one after thirty years of almost uninterrupted labour still very far from being completed; the other, in the course of about four years, in a much more forward state, and if necessary, capable of being completed in the course of two years.

Breakwater of Cherbourg.

Breakwater of Cherbourg. In M. de Cessart's *Description des Travaux Hydrauliques*, will be found a very minute and laborious detail of all the preparatory operations, the progress and the expence of constructing the Breakwater of Cherbourg, up to the period of the Revolution. But the history of this great undertaking is summarily stated in a report made to the National Assembly in 1791, by M. de Curt, in the name of its Committee of Marine, concerning the Marine Establishment of Cherbourg.

Its History.

It had always been a source of considerable annoyance to the French (and more particularly since the demolition of the works and basin of Dunkirk, which cost them more regret than the useless and expensive projects for that port ever could be worth), that while the whole line of their coast, bordering on the English Channel, presented only sandy shores with shallow water, or an iron-bound coast bristled with rocks, Nature had lavished on their "eternal rival" of the opposite coast, the incalculable advantages of a succession of deep and commodious harbours, or of safe and extensive roadsteads, inviting their possessors to commerce and navigation, and placing in their grasp "the sceptre and the sovereignty of the seas." M. Curt observes, that "the misfortunes of La Hogue, which all the talents of Tourville could not prevent, taught Louis XIV., that, in completing the defence of his frontiers by land, he had too much neglected his frontiers on the sea; that this great prince, however, profiting by experience, soon discovered that England owed the superiority of her marine to the military establishments which she possessed in the Channel." With a view of securing to France similar advantages, the Marechal de Vauban was directed to visit the coasts of Normandy, for the purpose of adopting measures for placing in security, against hostile attacks, all such bays, harbours, and inlets, as were favourable for the disembarkation of troops; and to furnish plans of such works as he might judge to be necessary, not only for military, but for naval purposes. Among other projects, he reported that the roadstead of Cherbourg possessed the means of attack, of defence, and of protection; that it was very capable of exerting an influence on maritime war, and in their commercial relations with the northern powers; that it was the spot on which the head-quarters should be established on the coast of the Channel; and, in short, that it was a central advance post with regard to England. He moreover reported, that it might be made a port for the safe retreat of a squadron crippled by stormy weather, or beaten by an enemy, or even for the reception of a victorious fleet with its prizes. By thus converting the present exposed roadstead of Cherbourg into a safe and protected anchorage for a fleet of men of war, France, he said, would be able to watch the motions of England; to oblige her at all times to keep a corresponding fleet in the Channel; and to menace her shores with invasion of which she at all times stood so much in dread.

Opinions, however, being divided between the advantages of La Hogue and Cherbourg, Louis XVI., immediately after the conclusion of the American War, issued his directions to M. de Castries, Secretary of State for the Marine, to appoint a special commission, to consider and report which of these two roadsteads combined the most advantages, and was, in all respects, preferable for constructing a port and naval arsenal capable of receiving and equipping from 80 to 100 vessels of war of different descriptions. The Commissioners had little hesitation in deciding upon Cherbourg, because, by means of a Breakwater, it would be capable not only of admitting a fleet to ride securely at anchor when thus sheltered from the sea, but also of affording them protection against any attempt of an enemy. It was added, that Cherbourg was an admirable place for watching Portsmouth, without appearing to have

ence recollected what an excellent anchorage Spithead was for watching Cherbourg.

Directions were accordingly given to M. de Caux, Commanding Officer of Engineers at Cherbourg, to commence, as a preparatory measure, with the construction of a fort on the Island of Peleé, and another on Du Homet, according to plans given in by Vauban in 1679; by these works the roadstead would be flanked on the right and left. The interval, however, being found too great to afford sufficient protection to all the ships that might require to be anchored in the roadstead, M. de Caux presented a plan to the Minister at War for constructing an intermediate fort in the sea, which should be casemated, and sufficiently large to contain all the buildings necessary for a garrison. The surrounding walls were proposed to be sunk in caissons of 6000 feet square at the base, and 52 feet high. The top of the platform was to be 80 feet high from the bottom of the sea, and the area of its surface 1000 square toises. This plan, however, was not considered to give sufficient shelter to a fleet from the winds and waves, and new projects were called for by the Government.

In 1777, M. de la Bretonniere, Capitaine de Vaisseau, one of the commissioners who had been named to report on the comparative merits of the two roadsteads of Cherbourg and La Hogue, had addressed a memorial to the Minister of Marine, in which he expatiated, at great length, on the numerous advantages held out by the former, and particularly with regard to the security of the anchorage. He proposed to construct, at the distance of a league in the sea, a stone dike of 2000 toises in length, leaving three open passages into the roadstead it was intended to cover; one in the middle, and one at each extremity. This dike, like that which was sunk before Rochelle, was proposed to have as its nucleus a number of ships filled with masonry, floated off and sunk in proper situations, and afterwards to be cased with large sunken stones, to the height of 50 feet above the bottom of the sea. The reason assigned for sinking the stone vessels was the supposition that an under current might cause so much motion at the bottom of the sea as would derange the level, and work away the loose stones; so little appears at that time to have been known of the increasing tranquillity of the waves of the sea, in proportion to the increasing depth of water.

On this plan the commissioners observed, 1. That in order to construct a dike of 2000 toises in length, with sloping sides proportioned to its height, there would be required so great a number of old ships as could hardly be collected in all France in less than ten years; and, if purchased from foreigners, the expence would be enormous. 2. That the assembling and employing the necessary number of seamen would be next to impossible, but, if possible, highly impolitic, when, just at the close of a maritime war, commerce felt a pressing want of their services; whereas it might be practicable, and would be advantageous, to employ the military for some time before disbanding them. 3. That no comparison would hold good between the roadstead of Cherbourg with an opening to the sea of 3600 toises, and a depth of 40 to 42 feet of water at the lowest ebb, and the closing up the entrance of the port of Rochelle, which is only 740 toises in length, and the depth of water only five or six toises. 4. That the upper part of the projected dike, being exposed to the violent action of the sea, the stability of that part could not be depended on; and besides, a dike covered at high spring-tides with 18 feet water would not fulfil the two indispensable conditions—smooth water, and protection against an enemy. These arguments were deemed conclusive, and the plan of M. de la Bretonniere was abandoned.

In 1781, M. de Cessart, Inspector-General of Bridges and Embankments, received directions to prepare a plan that should cover a fleet of 80 to 100 ships of war in the roadstead of Cherbourg, from the attack of an enemy, and protect them against the elements. M. de Cessart was fully aware that, to raise a barrier in front of this roadstead, and in the middle of the sea, capable of resisting the impetuosity of the waves, and repelling the enterprises of the enemy, was no easy task. "Nothing," says he, "that I had ever performed, or that I had ever read of, in ancient or modern history, appeared to me to be worthy of being placed in comparison with the grandeur of this project." He suggested, as the preferable and only mode of answering the purpose of producing smooth water in the roadstead, that, in the place of one continued dike or mole, a number of large masses, separated from each other, of a circular form, with an elevation greatly inclined, should be substituted; in short, a series of truncated cones, which, touching each other at their bases, might present to the sea at the surface, alternate obstacles and openings, and thus interrupt and break down the waves previous to their entering the harbour. He also considered that, as these openings at the surface would not exceed 72 feet, a sufficient barrier would be formed against the passage of an enemy's vessel; and that, if necessary, in time of war, it might be rendered still more secure by placing strong chains of iron across the intervals. It was proposed to construct these conical caissons, of wood, the number of which to cover a front of 2000 toises would amount to 90, which, at 360,000 livres for each cone, would cause a total expence of 32,400,000 for the whole. The number, however, was afterwards reduced to 64, and the time estimated for completing the work 13 years. Each cone was to be 150 feet in diameter at the base, and 60 feet in diameter at the top, and from 60 to 70 feet in heighth, the depth of water at spring-tides, in the line in which they were intended to be sunk, varying from about 56 to 70 feet. They were proposed to be sunk without any bottoms in them, by which the upward resistance of the water acting on a base whose surface was equal to 17,678 square feet, would be avoided. The caissons floated off by casks, attached to their inner and outer circumference, being towed to the spot where they were destined to be sunk, were then to be filled with stones to the tops, and left for a while to settle; after which the upper part, commencing with the line of low water, was to be built with masonry laid in pozzolana, and encased with stones of granite.

This plan of a stone dike or Breakwater being

laid in detail before the Minister of Marine, it was deemed proper, on a subject so entirely novel, and of such great national importance, to consult the ablest men in France, before any steps should be taken for carrying it into execution. The details were accordingly submitted to the four commissioners, M. de Borda, a naval officer and Member of the Academy of Sciences; M. de Fleurieu, Capitaine de Vaisseau, and Director of Ports and Naval Arsenals, afterwards Minister of Marine; M. Peronnet, Member of the Academy of Sciences, Chief Engineer of Bridges and Embankments; and M. de Chezy, Inspector and Director of the School of Engineers. They recommended that, in the first instance, an experimental cone should be constructed, and floated off. Instead, however, of 60 feet in height, the cone made at Havre was only 36 feet; the circumference of its base 472 feet, and having a slope of 60 degrees; the upper circumference was 339 feet. Within the exterior cone, and at the distance of 5 feet 10 inches from it, was an interior and concentric cone, bound together by beams of wood, pointing to the common centre, each being the section of the radius. The frame of each cone was composed of 80 large upright beams, 24 feet long and 1 foot square. On these were erected 80 more, of 14 feet in length, making in the whole 320 of these large uprights; the machine was then planked, hooped, and firmly fixed together with iron bolts.

The cone at Havre being completed, the next operation was to tow it off to the particular spot where it was to be sunk. Being open at the bottom, it was found necessary to attach to the lower circumference 284 large casks, part to the exterior and part to the interior cone; besides 50 casks, attached by lines of equal lengths, from the bottom of the inner circle, to float towards the centre, and thus assist in keeping it upright and steady. It was easy enough, by these means, to float off a vessel of this kind. M. de Cessart observes, that the force of 7200 pounds produced by a capstan, was found sufficient to draw it on the water, to a distance equal to the length of its own diameter, or about 25 toises, in two minutes.

"The success of the experiment made at Havre," says M. Curt, "had inspired such veneration for the conical caissons, that those persons who had been most disposed to object to the plan, were now obliged to be silent." The result of the experiment at once decided the Government to commence operations at Cherbourg. M. de Cessart was appointed director of the works, with four Engineers to assist him. A permanent council, consisting of Commanders in Chief, Directors, Engineers, &c. was ordered to reside, for six summer months, at Cherbourg, and the other six in Paris; and a considerable body of troops were marched down to the neighbourhood, to furnish a competent number of artificers and labourers, to be employed on this great national undertaking.

In 1783, the buildings were commenced for lodging the principal officers of the civil and military departments, and their respective establishments; a naval yard marked out and inclosed,—roads of communication opened with the forts,—and at Becquet, about a league to the eastward of Cherbourg, a small harbour was dug out for the reception of about 80 vessels, which were to be employed in transporting the stones from thence by sea.

On the 6th June 1784, the first cone was floated off and sunk, and the second on the 7th July following, in presence of 10,000 spectators, assembled on the shores and quays of Cherbourg; but before the cavity of the latter could be filled with stones, a storm, in the month of August, which continued five days, entirely demolished the upper part of this cone. In the course of this summer the quantity of stones sunk within the cavities of the two cones, outside their bases, and in the intermediate space, amounted to 4600 cubic toises, or about 65,000 tons.

In 1785, three more cones were completed and sunk at irregular intervals; and, at the end of that year, the quantity sunk amounted to 17,767 cubic toises, or about 250,000 tons. In 1786, five additional cones were completed and sunk; one of them in presence of the King; and the quantity of stones thrown within them, and deposited on the dike connecting the cones, amounted, at the end of this year, to 42,862 cubic toises, or 600,000 tons. In 1787, five more cones were sunk and filled with stones, making, in the whole, fifteen; and the distance between the first and fifteenth cone was 1203 toises, and the quantity of stones deposited within these cones and the connecting dike, at the end of this year, amounted to 71,585 cubic toises, or more than 1,000,000 tons. The violent gales of wind that were frequent in November and December, carried away all the upper parts of the five cones which were sunk this year. In 1788, three more were sunk, but the upper parts of the first two were carried away as the others had been; the height of the third was, therefore, reduced, so as to be, when sunk, on a level with low water; but this cone was upset and soon went to pieces.

The enormous expence, and the delay that had been occasioned in completing and sinking these eighteen cones, exhausted the patience of the Government, so that, in the following year, 1789, it caused the three cones, then on the building slips, to be sold for whatever they would fetch.

The total quantity of stone that was sunk within the cones, and on the intermediate dike, from the year 1784 to the end of December 1790, being seven years, amounted to 373,359 cubic toises, or about 5,300,000 tons.

These 18 cones being sunk at irregular distances from each other, some being 25 toises, and others at 300 toises from centre to centre, occupied a line of 1950 toises in length. The distance of the first cone from the Island Pelée, on the east, was 510, and of the eighteenth to Fort Querqueville on the west 1200 toises; so that the whole entrance or opening of the roadstead of Cherbourg was originally 3660 toises, more than one-half of which was now imperfectly covered by the breakwater.

The expence of this great undertaking was not, we suspect, accurately known, and could not, probably, be ascertained. M. de Cessart estimates the eighteen cones alone, at 6,231,407 livres, or about L. 260,000; and the total expence incurred between the 1st April 1783 and the 1st January 1791, he states as under:

Break-water.

Making the general total	21,658,420	0	0

or L.900,000 Sterling. In this estimate the extra pay to the troops and seamen employed, would not appear to be included; for M. de Curt, in his report to the National Assembly, states the total expence to have amounted to 32,000,000 livres, or L. 1,300,000 Sterling; and that a farther sum would be required of 879,648 livres, to bring the top of the dike to an uniform height, namely, a little above the level of the surface, at low water, of ordinary tides.

The number of people employed was prodigious. To enable M. de Cessart to complete and sink five cones a-year, he found it necessary to employ 250 carpenters, 30 blacksmiths, 200 stone-hewers, and 200 masons,—in all 680 artificers. The number of quarrymen, and others, employed in transporting 174,720 cubic toises of stone for the 64 cones originally intended, or 13,650 yearly, was estimated at 400 workmen, 100 horses, 30 drivers, 24 chasses-marées, each carrying seven cubic toises, or about 98 tons, with 100 seamen; making an aggregate, for this service, of 526 men, and for the whole operation from 1200 to 1500 artificers and labourers, to which were actually superadded about 3000 soldiers.

A very considerable part of the expence might have been saved by dispensing altogether with the cones, all of which burst, as might have been expected from the superincumbent weight of a deep column of water, pressing the stones within against their sides. The 9th cone, which was sunk in 1786, went to pieces in 1800, after standing fourteen years; another reached the duration of five years; six remained on an average about four years; and all the rest went in pieces within a year from the time of their being sunk.

The failure of the cones, and the breaking out of the Revolution, put an entire stop, for some time, to all operations at Cherbourg. The attention, however, of the National Assembly was speedily called to what they considered to be an object of great national importance. In 1791 they directed their Committee for the Marine to make out a detailed report of the operations that had already been carried on. On this report being given in by M. de Curt, in the name of the Committee, it was read and approved by the Assembly, and funds to a certain extent decreed, to complete the undertaking on a new plan proposed by M. de Cessart. The principal feature of this plan was that of casing over the surface of the dike as it then stood with large blocks of stone; and to carry the height of the breakwater along the whole of its extent, so far above the high water mark of spring-tides, as to render it capable of receiving batteries on the summit, at the middle, and at the two extremities.

The slope of the side next to the roadstead was found on examination to sustain itself unaltered at an angle of 45 degrees, but the slope on the side next to the sea, whose base was three for one of height, had given way to the depth of fourteen feet below the low water mark; and the materials being composed of small stones, were washed away, and had formed themselves into a prolonged slope of one foot only in height for ten feet of base, which was therefore concluded to be the natural slope made by the sea when acting upon a shingly shore; a conclusion, however, too vague to be correct, as the slope occasioned by the action of the sea must depend on the nature of the materials against which it acts, and the force and direction of the acting power. A sandy beach, for instance, has invariably the most gradual slope, gravel the next, shingles the next, and large masses of rock or stone, the most precipitous. At the present time, the stones of the breakwater, by constant friction, have worn away the sharp angles, and it has been found that the base on the side next to the sea is on the average fully eleven for one of perpendicular height.

It was proposed, therefore, to cover the side with a coating of stone 12 feet thick, to consist of blocks of 12, 15, 20, and 30 cubic feet, or from one to two tons each, which casing was to be carried to the height of 12 feet above the high water mark of the highest spring-tides; the size of the stones to increase towards the summit, so as to be capable of resisting the percussion of the waves, which is there the strongest. It was calculated that this covering of 12 feet thick on both sides would require for each toise in length 70 cubic toises of stone, and that the whole length of the dike would consequently require 136,500 cubic toises, which, by deducting for the vacant spaces between the stones, would be reduced to 113,750 cubic toises of stone, or about one million and a half of tons. It was farther calculated, that the expence of quarrying, the transport to the quays, the loading, conveyance, discharging machinery, together with the commissioners, clerks, &c. would cost for each cubic toise deposited on the dike the sum of 55 livres, which for 113,750 cubic toises, would amount to 6,256,250 livres, and, adding for contingencies 600,000 livres, the total estimate amounted to 6,856,250 livres.

The machinery employed for thus casing the breakwater may be seen in Plate XXXVII., in which,

Fig. 1. Represents a section of a lighter on which it is erected.

AZX is an elevated deck or platform.

Y, three rollers of six inches diameter.

TK, two beams or sheers, moving on trunnions in grooves at T.

S, hooks to hold the sheers at the proper angle of inclination.

L, the axle of the windlass or wheels B, round which the rope of the pullies passes. The wheels are 12 feet in diameter.

Fig. 2. A chasse-marée laden with blocks of stone.

E, the block and its hook laying hold of an iron chain round a stone.

F, the stone hoisted to the platform AZ, (fig. 1.) when the brace is unhooked at S; the hoisting con-

tinued until the summit K of the sheers is brought to V, when they rest against the frame which supports the windlass; the stone F is then lowered upon the rollers as at M, from whence it is pushed forward by men to the inclined plane, off which it is rolled into the water upon the side of the dike.

It was calculated that, by employing a certain number of these machines, 34,090 toises might be deposited in one year, reckoning only six working months, or 5682 toises *per* month, or that 487 superficial toises of the dike might be covered in one season, and the whole completed in four years. Very little progress, however, had been made at the commencement of the war in 1803. At that period the centre of the dike only had been brought above the high water mark, in which was placed a battery and a small garrison of soldiers, the whole of which were swept away by a heavy sea, occasioned by a tremendous gale of wind in the year 1809, when all the buildings which had been erected on this part of the breakwater, the men, women, and children which composed the garrison, together with several workmen, were washed away; at the same time, two sloops of war in the roadstead were driven on shore, and dashed in pieces. This disaster was such as might have been expected. The effect of sinking large stones upon the small ones, already rounded by constant attrition, could not be otherwise; the latter acting as so many rollers, carried out the former even beyond the extremity of the base, to which the breakwater had naturally been brought by the action of the sea.

At present small spots only are visible above the surface of the sea at low water of spring-tides, and no where such spots exceed three feet in height; the intermediate spaces are from 3 to 15 feet below the surface; and, taking the average, the whole dike, from one end to the other, may be about four feet below the surface of low water at the spring-tides. Near the middle, however, there is about 100 yards where the height rises to 18 or 20 feet above high water, but it exhibits only a shapeless mass of ruins. In one spot a large heap of stones has been accumulated, as if to try how much weight might safely be trusted upon it, before the attempt be made to rebuild the fort. The largest of the stones in this mass may be about four tons, and they descend to the size of 200 or 300 pounds.

Of the remainder of the dike, very few parts are visible at low water; and, at this moment, the greater part is four feet below the surface of low water; it is sufficiently high, however, to break the force of the waves, and to make the port of Cherbourg a safe anchorage in some winds for about 40 sail of the line.

On the renewal of the war, after the rupture of the treaty of Amiens, Bonaparte began to bestow a greater share of attention on the navy of France; and though, for a time, the unparalleled victory of Trafalgar checked his efforts, it did not induce him to abandon them. His plans were vast, and, at the period of his fall, were in rapid progress towards their completion. He had determined on a fleet of 200 sail of the line, and the noble port of Antwerp gave him every facility for ship-building. For the better security in forming a junction of his two great fleets of Brest and Antwerp, Cherbourg now became more valuable, as a convenient port of retreat in case of accident; but it had no dock-yard, nor means of giving to a ship a large refit or repair. He might have thought too, as we believe most of our naval officers do, that a fleet of ships, riding at anchor behind the breakwater, are easily attackable by fire-ships, as the same wind which carries a vessel in at one entrance will carry her out at the other, and the course would lie directly through the centre of the fleet at anchor. Besides, it might be possible, in certain winds, under the lee of the centre part of the breakwater, to bombard a fleet at anchor in the roadstead within it.

He determined, therefore, to establish a large dock-yard at Cherbourg, not merely for repairing, but also for the construction of the largest class of ships of war; to dig a basin that should contain 50 or 60 sail of the line; to construct dry-docks and slips for building and repairing, and to make it a naval port of the first rank. In 1813, this basin was completed at an expence, as Bonaparte is said to have asserted when on board the Northumberland, and which has since been confirmed, of L. 3,000,000 Sterling. A wet-dock of the same magnitude, communicating with it, was then commenced, and is now in progress.

The only description that we have been able to find in print of this great work, which took ten years in carrying into execution, is contained in a short letter from M. Pierre-Aimé Lair, Secretary to the Society of Agriculture and Commerce of Caen, who was present at the ceremony of opening and consecrating the great basin, in presence of the Empress Maria Louisa, the 27th August 1813. He describes this basin to be excavated out of a rock of granite schist, or gneis, the density and hardness of which increased as the workmen descended from the surface. He compares it to an immense trough dug out of a single stone, and capable of containing many millions of cubic feet of water. We now know, however, that Mr Lair is mistaken; that it is not one mass of rock, but rock and gravel mixed; that the whole of the sides are cased with a well constructed wall of red granite; and that a noble quay, built of the same material, and extending between the two forts of Galet and Homet, separates the basin and wet-dock from the sea.

The dimensions of the new basin he states to be about 900 feet in length by 720 in width, and the average depth 55 feet from the edge of the quay; and as this edge is five feet above the high water mark of the equinoctial spring-tides, the depth of water in the basin is then 50 feet, and the mass of water, after making allowance for a slope of the solid sides inward in an angle of 45^0 from the height of about 25 feet, amounts to about 30 millions of cubic feet; and that it is calculated to contain about 30 sail of the line. We have reason to think that it is considerably larger; about 1000 feet by 770 feet, and consequently contains a surface of about 18 acres, which, at three *per* acre, will contain 54 sail of the line, and the adjoining wet-dock, when finished, an equal number. The latter is at this time about two-thirds completed, and from 300 to 400 men are employed in blasting the rock and building granite walls. The dike or breakwater seems to be abandoned; the

works having long been stopped, and the stone vessels going rapidly to decay. The French officers say, indeed, that it has occasioned the roadstead to become shallower, by the deposition of sand that has taken place.

The entrance canal leading from the outer harbour into the basin is at right angles to the latter, and its direction ENE. Its dimensions are as under:

	Feet.	In.
Width between the two moles in the direction of their axis, - - -	196	8
Width at its opening into the basin,	308	8
Length from the axis of the moles or piers to the line of wall forming the side of the basin, - - - -	274	0

The basin, having no gates, is said to be excavated to the depth of nine feet below the bottom of the canal, the former having, as before mentioned, 50 feet water, and the latter only 41 at high spring-tides, which, as they ebb 20 feet, would leave only 21 feet in the passage or canal at low water. This inequality, we presume, is intended to keep the ships afloat in the basin at low water, when the depth in the canal is not sufficient for that purpose; but after so much expence incurred in digging the basin, one would suppose a little more might have been expended in digging the canal to the same depth, so as to let ships pass into and out of the basin in all states of the tide; an advantage of the utmost importance for speedily securing their ships in the basin, when in danger of an attack from the enemy in the roadstead, or of speedily putting to sea and escaping the vigilance of a blockading squadron. No reason is assigned for leaving the basin without gates; but we suspect that Mr Lair is again mistaken, and that the passage has depth of water sufficient for ships of the largest class to run into the basin at all times of the tide. But even here they do not lie in safety; for the wide entrance facing the NE. is covered only in that direction by the Isle Pelée, so that the water in the basin partakes of the swell in the road, which is sometimes so great as to make it necessary to apply 10 or 12 cables to hold ships steady in the basin.

Another serious inconvenience is likely to arise from this particular construction of the basin. Whatever silt or mud is carried in by the tides must be deposited there, and cannot possibly escape. The quantity is probably not very great in the water of the Channel opposite to Cherbourg, but, higher up, towards Ostend, it is very considerable. When we took possession of that port, it was found that, in the course of the Revolutionary war, the harbour, by neglect, was filled up with six or seven feet of mud.

Several pieces of cannon are intended to be mounted on the two piers, to protect the entrance into the basin. On one of them is likewise placed a lighthouse, and on the other a Semaphoric telegraph. Four slips of granite, for building large ships, were at this time constructed on the southern side of the basin; and on each of them was a ship of the line in progress, L'Inflexible of 118 guns, Le Centaure of 80, Le Jupiter and Le Genereux of 74 guns each. Two other ships of the line were on the stocks without the dock-yard, nearly ready for launching, Le Zelandais of 80, the first line of battle ship laid down at Cherbourg, and the Duguay-Trouin of 74 guns; and in the roadstead were Le Polonais and Le Courageux. In the centre of the same side of the basin, with two slips on each side of it, a noble dry-dock was cut out (or built rather) of solid granite, in which ships of the largest class might be built or repaired. Its dimensions were,

	Feet.	In.
Length, - - - -	230	
Width, - - -	74	
Depth, - - -	26	6

Thus the ships built on the four slips may be launched into the basin, and at once docked out of it.

But few store-houses, or other buildings necessary for a naval establishment, are yet erected; but there is an ample space laid out for every purpose that can be required to make Cherbourg one of the first naval arsenals in Europe; and a narrow canal, between the walls of Fort du Homet and the wall of the wet-dock, leads to a most convenient space for mast-ponds and mast-houses.

The fortifications for the protection of the anchorage in the roadstead, and the new naval arsenal, are, 1. Querqueville. 2. Fort du Homet. 3. Fort du Galet. 4. Fort Royal, on Isle Peleé. Fort Royal, and Fort du Homet, have circular faces towards the sea, with each two tiers of guns, and turrets above them; the former mounts about 80 guns, the latter 65, and Querqueville about 30 guns.

The principal channel from the road to the sea is at the western end of the breakwater, which, for large ships, is not more than half a mile in width; and this want of space will always make it difficult for ships of the line to work out; but, on the other hand, a fleet may push out to the westward in southerly winds, which lock up the English ports in the Channel.

The eastern channel is a very indifferent one; and, from the position of the Isle Peleé and the main, is likely to become worse, from the accumulation of sand, which the French officers say is actually the case.

Such, as are here described, were the mighty preparations of that extraordinary man for the destruction of the naval power of Great Britain, and, with it, of the national glory, pride, and prosperity; which, whether elated with success, or depressed by reverses, he never attempted to conceal as being the object nearest to his heart; and he had sufficient cause for his hatred, well knowing that it was England, and England's navy, that opposed the only obstacle between him and the subjugation of the world to his dominion.

To give the greater eclat to this grand undertaking, he sent the ex-Empress Maria Louisa to be present at the opening of the basin. When the time arrived for the water to be let in, and the dam broken down, her approach was announced by flourishes of warlike music and numerous discharges of artillery. "Cries of joy," says M. Lair, "were mingled for a long time with the thunder of the batteries. Her Majesty took her place in the pavilion which had been prepared for her, when the Bishop of Contances, surrounded by his clergy, advancing towards

Breakwater.

her, pronounced an address suitable to the occasion. After the ceremonies and customary prayers, he turned round towards the basin, and blessed this work of man. It is delightful to see a nation consecrating by religious rites an event so memorable, and causing the divinity to intervene in all its grand undertakings." He speaks with rapture on the gratification he derived from seeing men born on the shores of the Tiber, and on the banks of the Guadalquiver, working under the direction of French engineers, at the establishment of a port in the channel, formidable to the English navy; and suffers no expression of regret to escape him at the idea of these poor Italian and Spanish prisoners of war being compelled to labour in chains at a work, for which they were neither paid, nor in which they could take the least possible interest.

Breakwater in Plymouth Sound.

Breakwater in Plymouth Sound, is a work of a similar nature to that of Cherbourg, but constructed on sounder principles, with less machinery, and fewer people. Compared in extent and dimensions with that of Cherbourg, it is only in the ratio of about one to four.

There is no port and harbour on the south-west coast of England possessing so many advantages as Plymouth,—none so well situated for assembling and equipping a fleet to watch the movements of the enemy in the harbour of Brest. Its dock-yard may be considered as the second in the kingdom in point of size, convenience, and effective strength; the margin of which stretches along the magnificent harbour of Hamoaze, a noble expanse of water, nearly land-locked, of a capacity sufficient for mooring safely a hundred sail of the line in excellent anchoring-ground, and in water that carries its depth to the very quays of the yard. On the opposite or eastern side of the Sound, and at the distance of about three miles from Hamoaze and the dock-yard, is another sheet of water, called Catwater, not quite so deep, nor so well sheltered as Hamoaze; but, since the progress made in the Breakwater, forming a safe and commodious harbour for merchant vessels of every description. These two harbours open into Plymouth Sound and Cawsand Bay, in which ships employed in the blockade of Brest, or those refitted in Hamoaze, have been accustomed to assemble and prepare for putting to sea. But the very exposed situation of Plymouth Sound, and the heavy swell that almost constantly rolled in, especially when the wind blew fresh from the south-west to the south-east, made it so inconvenient and so unsafe an anchorage for ships of the line, that, of late years, the fleet employed in blockading Brest, has been in the practice of bearing up, when driven from its station, for the more distant anchorage of Torbay, though little better with regard to security, and worse in every other respect, than Plymouth Sound. It is, for instance, a more ineligible rendezvous for the western squadron, in the chance of the fleet being caught there by an easterly wind, and unable to get out, when it is the most favourable wind for the enemy to put to sea; in the danger to which the ships are liable when so caught at an anchorage, so open and exposed; in the inconvenience, the delay, and the expence of obtaining the necessary supply of stores and provisions from the other ports, there being none at Torbay;—in short, this open and exposed bay bore so bad a character among naval officers, that Lord Howe used to say, it would one day be the grave of the British fleet.

It is, besides, an object of the first importance to the efficiency of every naval arsenal, to have a safe and commodious roadstead in its neighbourhood, like that of Spithead to the harbour and dock-yard of Portsmouth. Here those ships which may have gone through a course of repair or refitment, or those new from the stocks, may assemble and complete their final equipment for sea; and here, also, ships returning from sea may safely lie at their anchors, till the wind and tide may serve them to go into harbour. But, in Plymouth Sound, ships coming out of Hamoaze, or ships going into that harbour, had no such security: by the rolling sea that set in, they were exposed to the double danger of parting their cables, or striking against the hard and rocky bottom, either of which would be almost certain destruction.

Its History.

It was most important, therefore, to render Plymouth Sound, if possible, by any means, and almost at any expence, a safe roadstead for ships of war. To ascertain the practicability of this measure, Mr Rennie, the Civil Engineer, and Mr Whidby, the Master Attendant of Woolwich Dock-yard, were sent down by Lord Howick, at the suggestion, we believe, of Lord St Vincent (Earl Grey), in the year 1806, with directions to examine and report, whether by any, and by what means, a sufficient shelter might be given to insure a safe anchorage for a fleet of ships of the line. The report was favourable; and several plans were offered for sheltering this sound, so as to render it capable of containing in safety at their anchors, above 50 sail of the line. Nothing, however, was done or attempted, notwithstanding all the increased and mighty preparations of the enemy, till Mr Yorke presided at the Board of Admiralty; when one of his first measures was to carry into execution this grand and important national object,—the most important that, perhaps, was ever undertaken for the glory and the safety of the British navy. The delay that took place can only be explained by the frequent changes of the Board of Admiralty, which, we believe, have been fatal to many important measures for the benefit and advantage of this great bulwark of the nation.

Of the plans proposed for sheltering the sound, one was to throw a pier from Staddon point to the Panther rock, of 2650 yards in length; another, to construct a pier from Andurn point to the Panther, of 2900 yards; and a third, to carry a pier from the same point to the Shovel rock, being only 900 yards.

The objection that was urged against throwing out piers from either of these points, and abutting against the shore, was principally grounded on the certain effect they would have of changing the current of the flux and reflux of the tide to the opposite side of the sound; and of increasing its strength and velocity on that side, while it left all calm on the other; the inevitable consequence of which would be, a deposition of mud or silt in the calm part or eddy, which, in process of time, would shallow the water, already not too deep, to such a degree as to unfit it for the reception of large ships of war.

Besides, of the three passages for large ships into

Plymouth Sound from the sea, the two best are those on the two sides; the worst was that in the middle. Either of the plans, therefore, which proposed piers to be thrown from the mainland, must have destroyed one of the best passages, and left the worst open, which was nearest to the anchorage behind the proposed pier. The middle passage might, in fact, be almost considered as shut up against very large ships by the St Carlos and the Shovel rocks; whereas, if this middle passage should be shut up altogether, it would rather serve to deepen, by giving an increased velocity to the tide, which would scour out the bottom, than to shallow, the two side passages.

On these considerations, Messrs Rennie and Whidby proposed, that an insulated pier or Breakwater should be thrown across the middle of the entrance into the sound, having its eastern extremity about 60 fathoms to the eastward of St Carlos rock, and its western end about 300 fathoms west of the Shovel, the whole length being about 1700 yards, or close upon a mile; stating, with confidence, that such a Breakwater might, with every chance of success in its favour, be constructed; and that it would give shelter to ships in the sound, without any danger of lessening the depth of water.

The middle part of the Breakwater was proposed to be carried in a straight line for the length of 1000 yards; but they recommended that the length of 350 yards at each end should have an inclination towards the straight part, in an angle of about 120°. See the *figure*, Plate XXXVIII. These inclined ends would not only give shelter to a greater extent of the sound, but would, in a greater degree, prevent the rushing in of the tide from agitating the water at the anchorage, than if the two extremities were left in the same straight line, and at right angles with the direction of the current into the sound.

It was also proposed, in order to cover the sound more effectually, that a pier should be thrown from Andurn point towards the principal Breakwater, of about 800 yards in length, with the same inclined point of 120° as the head of the Breakwater. This pier, however, does not appear to have been thought necessary, and might have been in some respect injurious to the sound. It might, however, have made Bouvisand Bay a good anchorage for frigates and smaller vessels, and given them the advantage of a fine stream of fresh water, which falls into that bay.

It was recommended, as the most practicable and best mode of constructing this great work, to heap together promiscuously large blocks of stone, which were to be sunk in the line of the intended Breakwater, leaving them to find their own base, and take their own position; and it was conceived that stones of the weight of one and a half to two tons each would be sufficiently large to keep their places, without being rolled about by the tremendous swell which, in stormy weather, is thrown into Plymouth Sound, and thus avoid the inconvenience and loss of time and labour which the French experienced at Cherbourg, by throwing down small rubble stones. It was thought, that, in those places where the water was 5 fathoms or 30 feet deep, the base of the Breakwater should not be less than 70 yards broad, and the summit 10 yards, at the height of 10 feet above the low water of an ordinary spring-tide; that is, the dimensions of the Breakwater, in those places, should be 40 feet high, 30 feet across the top, and 210 feet wide at the foundation.

The surrounding shores of Plymouth Sound and Catwater were next examined, with a view to determine from what quarter materials for this great undertaking could most conveniently be obtained, as to quality, cheapness, and celerity of conveyance. On the west or Cornish side of the sound, nothing appears but hard granite; at the head of the sound and in Catwater, on the Devonshire side, all is marble and limestone. In Catwater alone, it was estimated, on a rough calculation, that 20 millions of tons might be procured in blocks fit for the work, which was about ten times the quantity that would probably be wanted. The time required for the completion of the work, would depend on a variety of circumstances. It is obvious that, if the two sides of the sound had furnished proper materials for the purpose, the time would considerably have been abridged, as, in that case, when the wind was easterly, vessels might deposit stones on the eastern end of the Breakwater, and in westerly winds, on the western extremity, and the work would thus be proceeding with an uninterrupted progress; whereas, if the stone was to be brought from one point, and that point on the shore of Catwater, a strong southerly and south-westerly wind, those most prevalent in this country in the winter months, would generally impede and frequently render it impossible for vessels to go off with their cargoes.

Catwater, however, having many advantages, and especially for the convenience of loading the vessels, and the facility of procuring blocks from the quarries of any size, was considered, on the whole, as entitled to the preference over any other place. Besides the quarries here being in the neighbourhood of villages, lodgings and conveniences would be afforded for the workmen; and, on the whole, it was calculated that the work might be completed from hence at a cheaper rate, and perhaps in less time, than from situations much nearer to it, but much more exposed to the wind and waves.

An estimate of the expence could not be made with any degree of accuracy, as no correct section of the bottom had been taken. Supposing, however, the great Breakwater to be 1700 yards in length, 30 feet in width at the top, when carried 10 feet above low water of spring-tides, with a slope on the southern or sea side, of three horizontal to one perpendicular, and, on the sound or land side of one and a half horizontal to one perpendicular, it was calculated that the whole mass of stone required, would be about two millions of tons. If then 100 sail of vessels of 50 tons burthen each were employed in carrying stone, and that each vessel was to carry only 100 tons a week, the quantity deposited in one week, would amount to 10,000 tons, or say 500,000 tons a year; and, at this rate, the Breakwater would be completed in four years; but making allowance for time lost in preparations, contingent delays and unfavourable weather, and deductions in the quantity of stone for the shallow parts over which the line of

the breakwater was carried, the completion of the work might safely be calculated within the period of six years.

Nor would the building of the pier from Andurn point, if so determined, increase the time of completion. If carried from the shelving rocks within the point, leaving a passage between them, the pier would require about 360,000 tons of stone, which, by employing about 30 vessels, might be deposited in three years.

It was recommended by the gentlemen above mentioned, that the great Breakwater should be begun on the Shovel and extended on both sides of it, as, by so doing, the effect produced on the sound would be observed as the work proceeded; and that buoys should be placed along the line, so that the whole of the vessels employed might, if necessary, deposit their cargoes at the same time without interrupting each other.

The rough estimate for completing this great national work, made on the grounds above stated, was as follows:

Estimate of the Probable Expence of a Breakwater and Pier for the Sheltering of Plymouth Sound and Bouvisand Bay.

2,000,000 tons of limestone, in blocks, from 1½ to 2 tons weight each, for the great breakwater, at 7s. 6d. *per* ton,	L.750,000	0	0
360,000 tons in the pier, proposed to be built from Andurn point, at 7s. - -	126,000	0	0
Contingencies, say at 20 *per cent.* on the whole, -	175,200	0	0
Total for the Great Breakwater,	L.1,051,200	0	0

Estimate of the Probable Expence of a Cut-Stone Pier and Two Light-houses to be built on the top of the Great Breakwater.

42,000 cubic yards of masonry, in the out and inside walls of the pier, at 27s. - -	L.44,700	0	0
62,000 cubic yards of rubble filling between the out and inside walls, at 6s. - -	18,600	0	0
Paving the top of the pier with large blocks of stone, 8500 square yards, - -	22,950	0	0
Two light-houses, with reflectors, and argand lamps, - -	5,000	0	0
Contingencies 20 *per cent.* -	28,650	0	0
	L.119,900	0	0
Breakwater,	1,051,200	0	0
Total Estimate of completing the works, - -	L.1,171,100	0	0

It was not before the opinions of the best Engineers, men of science, and naval officers eminent in their profession, had been collected, compared, and seriously considered, that Mr Yorke determined to carry into execution this great undertaking. The principal objection started against it was that it might cause the anchorage in the Sound to be destroyed in the course of time by the deposition of mud and silt along the whole eddy within it. There does not, however, appear to be any solid ground for this objection. The water brought by the tides from the sea is at all times perfectly clear and transparent, and that which proceeds from Hamoaze and supplied by the Tamar and the Tavy, is almost wholly free from any alluvial matter, these rivers holding their course through a fine granite soil. The fact is sufficiently proved by the circumstance of no deposition taking place in the recesses of Hamoaze along the dock-yard wall, which lead into the docks, nor in the numerous eddies that are caused by the projecting jetties and salient angles of that wall. Another objection started against the undertaking was, that, by the diminished quantity of water thrown in by the tide into Hamoaze and Catwater, the Sound would gradually fill up and these harbours be destroyed. No perceptible alteration, however, has as yet taken place in the height of the water in Hamoaze, or in the strength or set of the tides.

Commencement of Work.

A rock of limestone, or rather gray marble, situated at Oreston, on the eastern shore of Catwater, consisting of a surface of 25 acres, was purchased from the Duke of Bedford for the sum of L.10,000; quays for shipping the stone were erected in front of it; iron railways leading from the quarries to the quays were laid down; ships were hired by contract to carry off the stone, and others built at the dock-yard. Mr Whidby was appointed to superintend the work. The quarries were opened on the 7th August 1812; the first stone deposited on the 12th of the same month; and, on the 31st March 1813, the breakwater made its first appearance above the surface of the Sound at low water of the spring-tide. The system of quarrying the stone is conducted with admirable skill, and stones of the proper size obtained with less waste of small rubble than might be expected. In working these quarries an extraordinary phenomenon was discovered in the very body of the great mass of this old marble rock. At the depth of 65 feet from the summit of the rock, and 25 from the margin of the sea, a cavity, or rather a nodule of clay was discovered, of 25 feet long and 12 square, or thereabouts, in the midst of which were found several bones of the rhinoceros, in a more perfect state, and containing less animal matter in them, than any fossil bones that have yet been dug out of rock or earth.

Machines employed.

The vessels employed for carrying off the large blocks of stone, are of a peculiar construction, adapted to convey, with ease, masses of marble weighing from three to five tons each. These great blocks of marble are placed on trucks at the quarries, and run down from thence, on iron railways, to the quays, against which the vessels lie with their sterns. The two stern ports are made sufficiently large to receive the trucks with the stones upon them. Each truck is passed separately through the port-hole, on an inclined plane, and run to the forepart of the vessel, in the hold, on an iron railway.

The two sides of the hold of the vessel are calculated each to contain eight of these loaded trucks, which, at five tons on each truck, gives 80 tons of stone for one cargo. The stones thus placed on the trucks remain till the vessel arrives at the point in the line of the Breakwater where they are to be deposited. By means of a crane on the deck of the vessel, the two trucks nearest to the two stern ports are then drawn up the inclined plane, and run upon a frame on moveable hinges, called the *typing-frame;* by the falling of this frame, in the manner of a trapdoor, the stone or stones are discharged from the trucks on the slope of the Breakwater; but the typing-frame remains, by means of a catch, in the position in which it is left at the moment of discharging the stones, until the empty truck is pulled up by the crane to the after-part of the deck, from whence it is run forward to make room for the second pair of loaded trucks in the hold. The catch being now disengaged, the typing-frame returns to its former position, ready to receive the next pair of loaded trucks, and so on till the whole sixteen have been discharged, and the light trucks run upon the deck of the vessel, ready to be run out at the quay, and from thence to the quarries, to take in fresh loads of stone. In this manner a cargo of 80 tons may be discharged in the space of 40 or 50 minutes. The vessels are placed in the proper places for depositing the stones by means of buoys, and the exact line of the Breakwater is preserved, by observing lights or staves placed at a distance on the shore.

The following description, referring to Plate XXXIX., will convey an accurate idea of these excellent vessels for the purpose they were constructed.

Fig. 1. Shows the stern of the vessel, in the act of depositing the stones. The runner R being hooked to the fore-part of the truck, raises it up, and by that means tips the stone overboard. When the stone is in the act of being drawn up out of the hold, on the inclined plane B (fig. 3.), the runner is hooked to the fore-part of the truck, and lashed down to the after-end, over the stone, which prevents the latter from sliding off the truck, in its progress up the inclined plane. The empty trucks are, for the most part, lodged on the fore-part of the deck, and some placed on an edge against the side of the vessel.

Fig. 2. Shows the stern of the vessel when loaded, with the ports up, or closed.

Fig. 3. A longitudinal or sheer-section of the vessel, when loaded, with the trucks on one side of the hold and deck, showing the number which the vessel usually stows on each side. The stones being frequently longer than the trucks, the number carried in the hold must be proportioned accordingly. In bad weather it is unsafe to send many trucks on deck; and, in general, not more than four are sent into the Sound, in that way, at one time; the amount of the cargoes, therefore, vary according to circumstances, from 40 to 65 tons; the largest stone hitherto deposited being about eight tons.

The after-part of the deck, under the tiller, is divided into two parts, length ways, and made to move up and down; the fore-parts are secured to a beam by hinges. This moveable deck, when raised, as at X, allows the stones to come out of the hold; and, when down, as at Y, serves to convey the empty truck from the port to the deck, in order to make room for another stone.

D Is a common windlass for heaving the trucks out of the hold up the inclined plane B.

C The hinges of the typing-frame.

Ten vessels of this construction, for carrying large masses of stone, built in the King's Yards, and forty-three hired by contract, averaging about fifty tons each, are employed in conveying stones from the quarries. The contractors' vessels are not of the same construction as those in the immediate employ of government; they carry stones of less weight, which are hoisted out of the hold by a chain and windlass, and thrown overboard. A load of fifty tons is discharged from one of these vessels in about three hours. By all these vessels, the quantity of stone deposited in 1812 was 16,045 tons; in 1813 71,198 tons; in 1814, 239,480 tons; in 1815 264,207; and in 1816 up to 12th August, 206,033 tons; at which time, the total quantity of stone sunk, amounted to 896,963 tons; and at the conclusion of the year to upwards of 1,000,000 tons.

Of this quantity, the proportions of the different sizes of the blocks deposited are nearly as follows:

	Tons.
Of one ton each stone and under - -	423,904
— one to three tons each - -	309,706
— three to five tons each - -	150,593
— five tons and upwards - -	12,760

The original contract price for quarrying the stone was 2s. 9d. *per* ton, and the original contract price for conveying it to the Breakwater 2s. 10d. *per* ton, since which the former has been reduced to 2s. 5d., and the latter to 1s. 10d. *per* ton. The cost of each ton of stone sunk in the Breakwater, including the building of quays, purchase of land, salaries, and every other expence, according to the nearest calculation that can be made, amounts to about 8s. 1½d., which, upon the whole quantity deposited, gives the total sum expended up to 12th August 1816, equal to L. 364,000. And as the work may be considered as more than half completed, it will be finished considerably within the original estimate, and, if parliament had thought fit to grant the money, within the time.

The greatest quantity of stone sunk in any one week was 15,379 tons; and the part of the Breakwater, at the above mentioned date, above the level of low water spring-tides, was in length 1100 yards. The length completely finished to the height of three feet above the level of the highest spring-tides, and thirty feet wide at top, was at the same time 360 feet. The large stones of the upper part of the Breakwater are deposited to any nicety by means of a vessel constructed for the purpose, having the same sheer or slope at the bow with the side of the work, so that by a projecting beam or mast, the largest stones can be taken out of the vessel, and placed on

Breakwater.

the opposite side, or middle, or any other part of the Breakwater.

The small establishment, and the quick manner with which this great work has been carried on, form a curious contrast with the multitudes employed on the Breakwater of Cherbourg, the time occupied by that undertaking, and the parade and ostentation with which it was conducted.

The whole establishment for carrying on the Plymouth Breakwater is as follows:

	Persons.
A superintendent, with proper officers and clerks, to keep and control the accounts	10
Warrant officers and masters of the ten stone vessels in the immediate employ of the public - - -	21
Seamen and boys to navigate these vessels	90
Seamen employed in the superintendents' vessels, the light vessel, boats' crews, &c. -	45
Masons, blacksmiths, carpenters, sailmakers, and labourers, employed at Oreston	39
In the immediate pay of Government	205
Seamen employed in the contractors' vessels	170
Quarrymen, labourers, &c. employed at Oreston by the contractors - -	300
Total establishment	675

Beneficial Results of this Great Work.

The result of this great work has completely answered the expectation of its warmest advocates. The good effects of it were, indeed, very sensibly felt at the end of the second year, when about 800 yards of the central part, where the water was shallowest, were visible at low water spring-tides. The swell was then so much broken down and destroyed at the head of the Sound, that the fishermen were no longer able, as heretofore, to judge of the weather outside the Sound; and ships of all sizes, and, among others, a large French three-decker, ran in with confidence, and anchored behind the Breakwater. Since that, near 200 sail of vessels of all descriptions, driven in by tempestuous weather, have, at one time, found safe shelter within this insulated mole, where a fleet of 25 to 30 sail of the line may, at all times, find a secure and convenient anchorage, with the additional advantage of having a stream of excellent water from a reservoir constructed above Bouvisand Bay, capable of containing from ten to twelve thousand tons, or a quantity sufficient to water 50 sail of the line. This water is brought down in iron pipes to Staddon Point, opposite to the anchorage, where it is intended to build a jetty from which the water will descend through the pipes into the ships' boats. The whole expence of this most useful appendage to the Breakwater is calculated at about L. 16,000.

During the winter of 1816-7, the gales of wind were more frequent and tremendous than had been known for many years; and, on the night of the 19th January, such a hurricane came on as had not been remembered by the oldest inhabitant. The tide rose six feet higher than the usual height of spring-tides. The Jasper sloop of war, and the Telegraph schooner, being anchored without the cover of the Breakwater, were driven to the head of the Sound, and both lost; but a collier deeply laden, and under its cover, rode out the gale. No damage was sustained by any of the shipping in Catwater; but it was the general opinion, from former experience, that, if no Breakwater had existed, the whole of the ships therein must have been wrecked, and the storehouses and magazines on the victualling premises, and most of the buildings on the margin of the sea, been entirely swept away. Till this tremendous gale, the Breakwater had not sustained the slightest damage from the heavy seas that, through the winter, had broken against it with unusual violence, not a single stone having moved from the place in which it was originally deposited; but after the hurricane above-mentioned, and the high tide which accompanied it, it was found that the upper stratum of the finished part, extending about 200 yards, and 30 yards in width, had been displaced, and the whole of the huge stones, from two to five tons in weight each, carried over and deposited on the northern slope of the Breakwater. In no other part could it be discovered that a single stone had been displaced.

Propriety of a Breakwater in Portland Roads.

The want of a harbour, or any place of safety to which ships can resort in bad weather, or in distress, between the ports of Plymouth and Portsmouth, led to the suggestion of Portland Roads being converted into a secure harbour by means of a Breakwater. It was estimated that the construction of such a stone dike, extending from the north-east part of Portland Island, about two miles and a quarter in length, covering an anchorage of about four square miles, and completely sheltering the pier, harbour, and bathing place of Weymouth, would require about four million tons of stone, five years to complete it, and an expence of about six hundred thousand pounds Sterling. The capstone alone, which covers the Portland stone, and which, not being marketable, is not only useless, but a great incumbrance, would be sufficient to complete this great undertaking; and the elevation of the quarries, being 300 feet above the level of the sea, would admit of the stone being sent down on rail-ways to the water side, without the aid of either engines or horses; and, on this account, would be deposited at less than one fourth part of the expence which is incurred at the Plymouth Breakwater. Such a secure anchorage in this situation, in which the largest fleets, either naval or mercantile, would ride at anchor in all winds, and the most stormy weather, in perfect security, is not unworthy the consideration of the public; and, perhaps, in the present increased state of our population, and the difficulty of finding employment for the labouring poor, there can be no truer policy than that of carrying on great national works of public utility, were it only for the sake of encouraging industry, instead of expending an equal, or probably a far greater sum, for the support of idleness and the encouragement of vice, in those parochial buildings, too frequently miscalled *work*-houses. (K.)

BRECONSHIRE, or Brecknockshire, in South Wales, is divided from Radnorshire by the river Wye; its other boundaries are artificial. Its length is 29 miles, the breadth of its southern basis 34, and its circumference rather more than 100. It contains nearly 500,000 acres of land, not one-half of which are either in a state of cultivation, or adapted to it. Its form is irregularly triangular, narrowing towards the northern extremity. It is divided into six hundreds; and contains the county town, Brecon, and three market-towns besides, Crickhowel, Biulth, and Hay. There are in it one hundred and eleven parishes, and places paying parochial rates, according to the last returns to Parliament respecting these rates.

ce of the ntry l Soil.

Breconshire is one of the most mountainous counties in Wales; and the Van, or Brecknock Beacon, is one of the loftiest mountains. Ridges of hills which form the separation of this from most of the adjacent counties, shelter it in such a manner as to render it temperate. It appears from observations made in the year 1802, with a rain guage, that 26¼ inches of rain fell at Brecon. There is a considerable variation, not only in the surface of the country, but also in the nature of the strata. In the hundered of Biulth, the soil is remarkably argillaceous, and the water does not sink sufficiently deep; in the Vale of Usk, on the contrary, it is too porous to retain the necessary moisture. In general, the soil of the vales consists of a light loam, lying on a deep bed of gravel; the soil of the hills, for the most part, is argillaceous. The principal river, next to the boundary one of the Wye, is the Uske, which, taking its rise from the black mountain, in the western side of the county, on the border of Caermarthenshire, flows across it, through a fine valley, to the south eastern angle, passing the town of Brecon. A little to the east of the town of Brecon is a considerable lake, well stored with fish, out of which a rivulet runs to the Wye. The Brecon Canal unites with the Monmouth Canal eight miles and a half from Newport, and one mile from Pontypool; it crosses the river Avon, is carried through a tunnel 220 yards in length, passes the town of Abergavenny towards the river Uske, and proceeds parallel with that river to Brecon, being 33 miles in length, with 68 feet rise to Brecon. From the fall of this canal from Brecon to the Bristol Channel, it appears, that Brecon is 411 feet 8 inches above the level of the sea.

ricul-e.

The agriculture of this county is superior to that of most of the other counties of Wales, and appears to have begun to improve about the middle of the last century, as the Breconshire Agricultural Society was instituted in 1775, being one of the first associations of the kind in the Island. The mode of culture on the good soils is conducted in the best manner; but where the land is naturally poor, the tillage is very bad. In the Vale of Uske, the Norfolk rotation is followed with skill and success; and tolerably abundant crops of barley, clover, wheat, and turnips are obtained. The Highland farmers, in general, are too poor to attempt any material improvements. In the vales the farms seldom exceed 150 or 200 acres; the rents are high; in the neighbourhood of Glazbury and Hay, nearly 40s. the cyfair, which is about one-third less than the statute acre; the poorest grounds do not let for more than four or five shillings the cyfair.

Brecon-shire.

The principal exports of the county are wool, butter, and cheese; of the former, a considerable quantity is spun and knit into stockings in the hundred of Biulth, and in different parts of the Highlands; the stockings are bought by hosiers, and carried to the English market. Some sheep, a few horned cattle, and a considerable number of swine, are frequently driven to Worcester, London, Bristol, &c. The cattle and horses are small, but the former have been much improved by intermixing the Glamorganshire and Herefordshire breeds; and the latter by the introduction of the Suffolk Punch sort. A considerable number of otters frequent the rivers, the furs of which form another branch of the exports of this county.

Manufactures.

The principal manufactures are flannel, linsey-woolsey, and other coarse cloths. These manufactures are not so flourishing as they were formerly; as, from the latter end of the sixteenth, to the beginning of the eighteenth century, considerable fortunes were acquired in Brecon and its vicinity, by the manufacture of woollen cloths. At present, the workmen confine themselves, almost entirely, to weaving what is spun by private families, into what is called *hannergive*, raw cloth. Latterly, several forges and iron founderies have been established near the borders of Glamorganshire, which abound with coal and iron-ore; and these have succeeded extremely well. The profits of the mines for the year ending 5th April 1813, according to the returns under the Property Act, were L. 2254, and of iron works L. 1006.

Poor-rates.

The poor and other parochial rates of this county, in the year ending Easter 1803, amounted to the sum of L. 12,200, 7s. 8¼d. In the year ending the 25th of March 1815, there was paid in parochial rates the sum of L. 20,307, 3s. 10d.

Population.

In the year 1801, the population amounted to 31,633 inhabitants; of whom 14,346 were employed in agriculture, and 4204 in various trades and manufactures.

In 1811 there were

Inhabited houses - - -	7555
Families inhabiting them -	7919

BREWING.

Brewing.

As this important art has been, in a great measure, overlooked in the *Encyclopædia Britannica*, and as nothing like a satisfactory account of it is to be found in any book on the subject, which we have seen, we consider it necessary for us to lay down the principles on which it depends, somewhat in detail. We shall, therefore, divide this article into five chapters. In the first, we shall take as short a view as possible of the History of the art; in the second, we shall give an account of the different kinds of Grain employed in Brewing; in the third, we shall treat of the process of Malting; in the fourth of Brewing; and in the fifth, we shall give an account of the nature and properties of the different kinds of ale and beer manufactured by the brewer. The *Explanation of the Plates* will contain a description of the vessels used in a London porter brewery.

CHAP. I.

HISTORY OF BREWING.

No notice is taken of beer or ale in the books of Moses, from which it is probable that they were unknown till after the death of this legislator. All the ancient Greek writers agree in assigning the honour of the discovery of beer to the Egyptians, whose country, being annually inundated by the Nile, was not adapted for the cultivation of vines. Herodotus, who wrote about 450 years before the commencement of the Christian era, informs us, that the Egyptians made their wine from barley, because they had no vines. *'Οινῳ δ' εκ κριθεων πεποιημενῳ διαχρεονται ὀυ γαρ σφι ἐισι ἐν τῃ χωρῃ ἀμπελοι·* *Herodoti*, Lib. ii. c. 78. Pliny says that this liquid in Ægypt was called *zythum* (*Plinii Hist. Nat.* Lib. xxii. c. 25). The same name was given to it by the inhabitants of Galatia, who, according to Diodorus Siculus, were unable to cultivate grapes on account of the coldness of their climate. Beer was distinguished among the Greeks by a variety of names. It was called *ὀινον κριθινον* (barley wine) from its vinous properties, and from the material employed in its formation. In Sophocles, and probably in other Greek writers, it is distinguished by the name of *βρυτον*. Dioscorides describes two kinds of beer, to one of which he gives the name of *ζυθον* and to the other *κουρμι*; but he gives us no description of either sufficient to enable us to distinguish them from each other. (*Dioscorides*, Lib. ii. c. 79 and 80.) Both, he informs us, were made from barley, and similar liquids were manufactured in Spain and Britain from wheat.

From Tacitus we learn, that, in his time, beer was the common drink of the Germans; and from his imperfect description of the process which they followed, it is not unlikely, or rather there can be no doubt, that they were acquainted with the method of converting barley into malt. "Potui humor ex hordeo aut frumento in quandam similitudinem vini corruptus." (*De Moribus German*, c. 23.) Pliny gives us some details respecting beer, though they are by no means satisfactory. He distinguishes it by the name of *cerevisia* or *cervisia*, the appellation by which it is always known in modern Latin books.

This liquid does not appear to have come into general use in Greece or Italy; but in Germany and Britain, and some other countries, it appears to have been the common drink of the inhabitants, at least as early as the time of Tacitus, and probably long before. It has continued in these countries ever since, and great quantities of beer are still manufactured in Germany, the Low Countries, and in Britain.

The first treatise published on the subject, as far as we know, was by Basil Valentine. This treatise, according to Boerhaave (for we ourselves have never had an opportunity of seeing it), is both accurate and elegant. In the year 1585, Thaddæus Hagecius ab Hayck, a Bohemian writer, published a treatise entitled *De Cervisia ejusque conficiendi ratione, natura, viribus et facultatibus*. This little treatise, consisting only of 50 pages, is written with great simplicity and perspicuity, and gives as accurate a description of the whole process of brewing as any treatise on the subject which we have seen. In the early part of the eighteenth century, Mr Combrune, who, we believe, was a practical London brewer, published a book entitled *The Theory and Practice of Brewing*. This book has gone through many editions, and we believe is still reckoned the standard book on the subject. But the attempts made in it to give a rational theory of brewing are far from satisfactory. Nor can any stress be laid upon the experiments which it contains on the colour of malt, according to the temperature at which it is dried. The fact is, that malt may be rendered brown, or even black, by exposure to a very low heat; while it may be exposed to a very considerable temperature without losing its colour. The writer of this article has seen malt exposed on the kiln to a heat of 175° without losing its colour, or without losing the power of vegetating when put into the ground; and he has reason to believe that these properties would have remained unaltered had the temperature been raised still higher. It is not the degree of heat applied, but the rapidity with which it is raised, that darkens the colour of malt. If the heat, at first, does not exceed 100°, and if after the malt is dried as much as it can be at that temperature, the heat be raised to 120°, kept sometime at that temperature, and then raised gradually higher,—if we continue to proceed in this manner, the temperature of the kiln may be elevated at least to 175° without in the least discolouring the malt.

In the year 1784, Mr Richardson of Hull published his *Theoretic Hints on Brewing Malt Liquors*, and his *Statical Estimates of the Materials of Brewing, showing the Use of the Saccharometer*. These

books are reprehensible, on account of the air of mystery thrown about the subject, and the avowal of the author, that he conceals certain parts of the processes. If a brewer conceives he knows more of his art than his neighbours, and chooses to keep his knowledge to himself, there is nothing to be said; but if he publish a book upon the subject, and yet persists in his concealment, he deserves no quarter. His book, in such a case, can be looked upon in no other light than a quack bill to advertise the goodness of his wares. Mr Richardson, however, deserves considerable praise for the *saccharometer*, which he appears to have been the first to bring under the notice of the brewer. This instrument is of material service, by making brewers acquainted with the strength of their worts, and consequently with the proportion of soluble matter which is furnished by the materials that they employ. Mr Richardson's *saccharometer*, indeed, was not accurate, because it was founded on a wrong principle. The method which he took was to determine the weight of a barrel of pure water. The liquid being then converted into wort, a barrel of it was weighed again, and the increase of weight was considered as the matter which the water held in solution. Mr Richardson did not seem to be aware that, when water dissolves the sweet portion of malt, its bulk is altered. Therefore, the specific gravity of it does not indicate the quantity of solid matter which it holds in solution. A set of experiments made on purpose, by dissolving determinate weights of the solid extract of malt, in given quantities of water, is necessary to determine the point. The same objection applies to the *saccharometer* of Dring and Fage, and to various others in common use. That of Dicas is nearly correct, having been constructed upon proper principles. But perhaps the best is one constructed about twelve years ago by Dr Thomson, and used by the Excise officers in Scotland. It indicates the specific gravity of the wort; from which, by means of a sliding rule which accompanies the instrument, the weight of saccharine matter contained in it is at once determined.

One of the latest books on the subject which we have seen is entitled *Practical Treatise on Brewing and Distilling*. This book was published in 4to, in the year 1805. The author, whose name is Shannon, appears to have some practical knowledge of brewing; but he must have been quite illiterate, as he was totally unable to write either grammar or common sense. The book is a tissue of absurdities from beginning to end; and the impracticability of his proposed improvements is surpassed only by the absurdity of his theory, which consists of scraps and sentences, taken out of chemical books, and tacked together, so as to have no meaning whatever.

CHAP. II.

OF THE KIND OF GRAIN USED BY BREWERS.

Every kind of grain, with perhaps hardly an exception, may be employed for the purposes of the brewer. In America, it is not uncommon to make beer with the seeds of Indian corn or Zea mais. In order to convert it into malt, it is found necessary to bury it for some time under the ground, and when germination has made sufficient progress, it is dug up and kiln-dried. (See *Philosophical Transactions*, XII. 1065.) Mr Mungo Park informs us, that, in Africa, the Negroes make beer from the seeds of the *Holcus spicatus*, and the process employed, as he describes it, seems to differ but little from the one followed in this country. (See Park's *Travels*, p. 63, 8vo edition.) Dioscorides assures us, that, in Spain and Britain, wheat was employed for the manufacture of beer. And the writer of this article has been informed by a gentleman in the service of the East India Company, that he has made beer from wheat at Madras. We have ourselves seen oats employed for the same purpose in Great Britain; and in Germany and the North of Europe, we believe that it is not uncommon to apply rye to the same purpose. But the material which answers this purpose best, and which is almost solely used for this purpose in Great Britain, and we believe in every part of Europe where beer is manufactured, is barley.

Species of Barley.

Barley is the seed of the *Hordeum vulgare*, a plant which has been cultivated from time immemorial, chiefly for the manufacture of beer. There are two species of *hordeum* under cultivation in Britain; 1. The *Hordeum vulgare*, or barley in which the seeds are disposed in two rows on the spike. This is the species usually cultivated in England and in the southern parts of Scotland. 2. The *Hordeum hexastichon*, called in the south of Scotland *bear*, and in Aberdeenshire *big*. In this species, the grains are disposed in two rows as in the other; but three seeds spring from the same point, so that the head of big appears to have the seeds disposed in six rows. Big is a much more hardy plant than barley, and ripens more rapidly. Hence it thrives better than barley in cold and high situations. On this account, it is sown in preference in the Highlands and northern parts of Scotland, where the climate is colder than more to the south. We have been assured, that there is a third species of *hordeum* cultivated in Scotland, in which the seeds in the spike are arranged in four rows. To this the term *bear* is exclusively confined by some. We have not ourselves had an opportunity of seeing this species, nor do we find it noticed by botanists. The trivial name *tetrastichon* might be applied to it.

The grains of barley are much larger than those of big, and the cuticle which covers them is thinner. Indeed, the thickness of the skin of barley itself varies according to the heat of the climate in which it is cultivated, being always the thinner the warmer the climate. Thus it will be found that the cuticle of Norfolk barley is thinner than that of Berwickshire or East Lothian barley. And if Norfolk barley be sown in Scotland for several successive years, its cuticle is found to become thicker.

Its Specific Gravity.

The specific gravity of barley is rather greater than that of big. The specific gravity of barley, tried in more than 100 different specimens, was found by us to vary from 1.333 to 1.250, and that of big from 1.265 to 1.227. The average weight of a Win-

Brewing. chester bushel of barley, was found to be 50.7 lbs. avoirdupois, and the average weight of a bushel of big 46.383 lbs. The heaviest barley tried, weighed 52.265 lbs. *per* bushel, and the heaviest big 48.586 lbs. This big grew in Perthshire, and the season was peculiarly favourable. It was not absolutely free from a mixture of barley, as was ascertained by sowing a quantity of it; but the proportion of barley was very small. The average weight of a grain of barley is 0.6688 grain, or very nearly two-thirds of a grain; the average weight of a grain of big is 0.5613 grain. The average length of a grain of barley, from many thousand measurements, is 0.345 inch, while that of a grain of big is 0.3245 inch. So that the average of both would give us very nearly the third of an inch, which it ought to do, according to the origin of our measures, as commonly stated. The average breadth of a grain of barley is 0.145 inch, while the average breadth of a grain of big is 0.136 inch. The average thickness of a grain of barley is 0.1125 inch, while the average thickness of a grain of big is 0.1055 inch. Thus we perceive that the grain of big is smaller than the grain of barley in all its dimensions.

Weight of the Husk. To determine the relative weight of the skins of barley and big, we made choice of three parcels of grain, all excellent in their kinds, namely, Norfolk barley, Haddington barley, and Lanark big. The weights of the whole grain, and of the cuticles of each of these, was as follows:

	Weight of a corn in grains.		Weight of cuticle in grains.
Norfolk barley,	0.6809	-	0.110 or $\frac{1}{6}$
Haddington barley,	0.7120	-	0.123 or $\frac{1}{6}$
Lanark big, -	0.5408	-	0.125 or $\frac{1}{4.3}$

From this we see, that there is little difference between the weight of the skin of Norfolk and Haddington barley, but a very considerable one between Haddington barley and Lanark big. Hence it would seem that this difference is not owing to the climate in which the barley vegetates, but rather to a difference in the nature of the two species.

Bulk. The bulks of these two species of grain to each other, is as follows:

Barley,	-	0.00217 cubic inch.
Big,	-	0.001777 cubic inch.

These quantities represent the average bulk of a corn of each kind. Thus it appears that a grain of barley is rather more than $\frac{1}{6}$th part larger than a grain of big.

Finally, from a comparison of many thousand corns of each species with each other, it appears that the inequality between the size of different grains of big, is greater than between different grains of barley. Indeed, if we examine an ear of big, when nearly ripe, we shall perceive that the corns towards the bottom of the ear are smaller than those towards the summit and about the middle of the ear. Several of these bottom grains are usually abortive, or consist only of skin, but this is not always the case. In an ear of barley, on the contrary, we shall find almost all the grains nearly of a size; though, in some cases, the grain constituting the upper termination of the spike is rather smaller than the rest.

These circumstances may strike the reader as too minute and trifling to be stated in such detail; but we shall find afterwards, that they will furnish us with an explanation of some anomalous circumstances that occur when these two species of *hordeum* are converted into malt. The value of barley (or its produce in alcohol) is rather improved, while big, on the contrary, is deteriorated by malting it, at least 20 *per cent.*

Constituents. The constituents of the kernel of barley and big, as far as we are able to ascertain at present, are the same. Barley has been subjected to an elaborate chemical analysis by Einhoff, who obtained from 3840 parts of barley-corns the following constituents:

Volatile matter,	-	430
Husk or cuticle,		720
Meal,	-	2690
		3840

From the same quantity of barley-meal, he obtained,

Volatile matter,	- - -	360
Albumen,	- - -	44
Saccharine matter,	- -	200
Mucilage,	- - -	176
Phosphate of lime with mucilage,	-	9
Gluten,	- - -	135
Husk, with some gluten and starch,	-	260
Starch, not quite free from gluten,		2580
Loss,	- - - -	76
		3840

The writer of this article has likewise extracted from barley, by means of alcohol, a small quantity of an oily matter, which has an asparagus green colour, and does not burn with the same readiness as an oil. It has very much the appearance of olive oil coagulated, but its consistence is less, and its colour is darker. It has little smell, and its taste resembles the flavour of spirits from raw grain. We have likewise found in big a quantity of nitrate of soda. Hence, it is likely, that this salt exists as a common constituent of barley. We obtained it by steeping big in water for two days, concentrating the liquid, and setting it aside in a dry place. Many rhomboidal crystals of nitrate of soda gradually make their appearance as the liquid evaporates.

We shall terminate this chapter by a TABLE, exhibiting the most remarkable properties of a considerable number of specimens of British barley and big, as determined by the writer of this article. The different specimens are distinguished by the name of the county in which they grew. By the *bushel* in the table is meant the Winchester bushel of 2150.42 cubic inches.

Brewing.

CHAP. III.

OF MALTING.

It is always customary to convert barley into malt before employing it in the manufacture of ale. Not that this conversion is absolutely necessary, but that it adds considerable facility to the different processes of the brewer. The writer of this article has several times tried the experiment of making ale from unmalted barley, and found it perfectly practicable. Several precautions, however, are necessary in order to succeed. The water let upon the ground barley in the mash-tun must be considerably below the boiling temperature. For barley meal is much more apt to *set* than malt, that is, to form a stiff paste, from which no wort will separate. The addition of a portion of the chaff of oats serves very much to prevent this *setting of the goods*, and facilitates considerably the separation of the wort. Care must likewise be taken to prevent the heat from escaping during the mashing, and the mashing must be continued longer than usual. For it is during the mashing that the starch of the barley is converted into a saccharine matter. This change seems to be owing merely to the chemical combination of a portion of water with the starch of the barley; just as happens when common starch is converted into sugar, by boiling it with very dilute sulphuric acid, or any other acid. This method of brewing from raw grain answers admirably for small beer. Some years ago it was practised to a considerable extent by several brewers of small beer in Edinburgh, and their beer was considered as greatly preferable to small beer brewed in the usual manner. The practice was stopped by a decision of the Court of Exchequer,—a decision, which, in our opinion, proceeded upon arbitrary grounds, and which was at all events detrimental to the public; for surely it is highly impolitic to prevent ameliorations in the manufactures, in order to guard against any deficiency in the produce of the taxes. A wise government would have permitted the improvement, and would have levied the malt-tax in a different manner. In our trials the raw barley did not answer so well for making strong ale as for small beer. The ale was perfectly transparent, and we kept it for several years without its running into acidity. But it had a peculiar flavour, by no means agreeable. Probably a little practice might have enabled us to get rid of this flavour, in which case, raw grain would answer, in every respect, as well for brewing as malt does.

A duty was first charged upon malt during the troubles of Charles I.'s reign. But it continued very moderate till the war with Bonaparte began in 1802. It was then raised to the following sums *per* bushel:

	L.	s.	d.		
English malt -	0	4	4	or	100
Malt of Scotch barley	0	3	$8\frac{1}{8}$	or	84.856
Malt of Scotch big	0	3	$0\frac{1}{2}$	or	69.472

But two shillings of this tax were to continue only till the end of the war, and for six months after its conclusion. In consequence of this very heavy tax, several regulations were imposed upon the maltster, with a view to facilitate the levying the duty, and to prevent him from defrauding the revenue. The most important of these are the two following: 1. The barley must remain in the cistern in which it is steeped with water for a period not less than 40 hours. When the malt is spread upon the floor, the maltster is not at liberty to sprinkle any water upon it, or to moisten the floor. We shall now describe the process of malting, as it is practised by the best informed malt-makers in Great Britain.

Malting consists of four processes, which follow each other in regular order; namely, *steeping*, *couching*, *flooring*, and *kiln-drying*.

Steeping.

1. The steep is a square cistern sunk at one end of the malt barn, lined with stone, and of a sufficient size to hold the whole barley that is to be malted at a time. The barley is put into this cistern, with the requisite quantity of pure water to cover it. It is laid as evenly as possible upon the floor of the cistern. Here it must remain at least 40 hours; but in Scotland, especially when the weather is cold, it is customary to allow it to remain much longer. We have seen barley steeped in Edinburgh for 112 hours by one maltster, and by another usually 98 or 92 hours. It is the common practice to introduce the water into the cistern before the barley, and it is usually once drawn off, and new water added during the steeping.

Three changes take place on the barley while in the steep. 1. It imbibes moisture, and increases in bulk. 2. Some carbonic acid gas is evolved, most of which remains dissolved in the steep-water. 3. A portion of the husk or skin of the barley is dissolved, in consequence of which the steep-water acquires a yellow colour, and contracts a peculiar smell, not unlike that of moist straw.

Moisture imbibed.

The quantity of moisture imbibed by the barley varies according to the goodness of the barley, and the length of time during which it is allowed to remain in the steep. But the general average may be stated at 0.47; or 100 lbs. of barley, steeped the usual time, weigh, when newly taken out of the steep and dried, 147 lbs. English barley acquires more weight than Scotch barley, while Scotch barley acquires greater weight than big. But big cannot bear to be steeped for so long a time as barley. The swell of the grain in the steep obviously depends upon the quantity of water absorbed; but it is not so great as that absorption, scarcely ever exceeding one-fifth of the original bulk of the barley, while the increase of weight amounts to nearly one-half of that of the original weight of the grain. The result of a good many trials by the writer of this article, gives the bulk of 100 measures of different kinds of barley, after steeping, as follows:

Increase of Bulk.

English barley -	124	measures
Scotch barley -	121.1	
Scotch big -	118.	

The greatest swell observed was from 100 to 183, which took place in barley from the County of Suf-

folk; the smallest was from 100 to 109, which took place in Perth big.

While the malt is in the steep cistern, it is repeatedly gauged by the Exciseman, and the duty on the malt is levied by what is called the best gauge, or that which gives the greatest bulk of grain. It is in his power likewise to determine the quantity of malt in the subsequent processes, and if any of them exceeds the best gauge in the cistern, to levy the duty by it. But these subsequent gauges are not susceptible of the same precision as the gauges in the cistern, when the grain is surrounded on all sides by perpendicular walls.

Carbonic acid evolved. That carbonic acid is evolved during the steeping of grain, is obvious from the most simple experiments. If the steep-water be mixed with lime-water, the whole becomes milky, and carbonate of lime is deposited. If the steep-water be agitated, it froths on the surface like ale. If it be heated, it gives out carbonic acid gas, which may be collected over mercury. But we never were able to observe bubbles of gas extricate themselves from the grain during the steep, except once or twice during warm weather, when the steep-water was allowed to remain rather too long without being changed. In these cases, something like a commencement of fermentation, or perhaps of putrefaction, appeared to take place. But, in general, there is reason to believe, that nearly all the carbonic acid evolved in the steep remains in solution in the water, or at least is extricated from the water in an imperceptible manner. From the observations of Saussure, it seems probable, that the formation of carbonic acid in the steep is owing to the oxygen gas held in solution by the steep-water.

Matter dissolved by the Steep-water. The steep-water gradually acquires a yellow colour, and the peculiar smell and taste of water in which straw has been steeped. At the same time, the barley becomes whiter; showing clearly that the water has absorbed a portion of colouring matter which existed in the husk or skin of the grain. The average quantity of matter dissolved by the water amounts to about $\frac{1}{70}$th of the weight of the barley. The steep-water becomes much deeper coloured when big is steeped in it than it does with barley; because big is darker coloured, and its husk is thicker, and contains more colouring matter. The matter of big taken up by the steep-water amounts to about $\frac{1}{40}$th of the weight of the whole grain. When this steep-water is evaporated, it leaves a matter of a yellow colour and disagreeable bitter taste, which deliquesces in a moist atmosphere. The only salt which it contains in any notable quantity is nitrate of soda.

Thus the only notable alterations which the kernel of barley undergoes in the steep are the absorption of water, and the resulting increase of bulk. The matter taken up by the water seems to proceed only from the skin, and the evolution of carbonic acid may, perhaps, be owing to some commencement of alteration which this dissolved matter experiences. It can scarcely be ascribed to any change going on within the kernel itself.

The Couch. 2. When the barley is judged by the maltster to have remained long enough in the steep, which is the case when its two ends can be easily squeezed together between the finger and the thumb, the water is let off, and the grain allowed to drain. It is then thrown out of the cistern upon the malt floor, where it is formed into as regular a rectangular heap as possible, which is called the *couch*. While in this position, it is gauged by the exciseman; and, if it measure more than it did in the steep, he is at liberty to charge the duty upon the quantity to which the grain now amounts. But, as the barley in the couch cannot be rendered perfectly regular, it requires a good deal of skill, and considerable attention, to gauge it with tolerable accuracy. On that account, the duty, we believe, is seldom levied from the couch gauge. The grain is allowed to remain in the couch without any alteration for about 26 hours.

Sweating. 3. If we plunge a thermometer into the grain, and observe it from time to time, we shall find that the barley continues for some hours without acquiring any perceptible increase of heat. During this period, the moisture on the surface of the corns gradually exhales or is absorbed, so that they do not perceptibly moisten the hand. But at last the thermometer begins to rise, and continues to do so gradually, till the temperature of the grain is about ten degrees higher than that of the surrounding atmosphere. This happens usually in about 96 hours after it has been thrown out of the steep. It now exhales an agreeable odour, which has some resemblance to that of apples. If we thrust our hand into the heap, we shall find it to feel warm, while, at the same time, it has become so moist as to wet the hand. The appearance of this moisture is called *sweating* by the maltsters, and it constitutes a remarkable period in the process of malting. We have reason to believe that a little alcohol is at this period exhaled by the grain.

Sprouting of the Roots. If we examine the grains in the inside of the heap at the time of sweating, we shall perceive the roots beginning to make their appearance at the bottom of each seed. At first they have the appearance of a white prominence, which soon divides itself into three rootlets. In big, the number of rootlets seldom exceed three; but in barley they frequently amount to five or six. These rootlets increase in length with great rapidity, unless their growth be checked by artificial means. And the principal art of the maltster is directed to keep them short till the grain is sufficiently malted. The writer of this article has seen them increase in length nearly to two inches in the course of a single night; and when he purposely favoured the growth, in order to ascertain the effect upon the malt, he has seen them get to the length of three inches or more. In such cases, the heat of the grain rose very rapidly, and on one occasion was little inferior to 80°. Indeed, it is probable that, if not checked, the temperature would rise sufficiently high to char the grain, if not to set it on fire.

The too great growth of the roots, and the too high elevation of temperature, is prevented by spreading the grain thinner upon the floor, and carefully turning it over several times a day. At first the depth is about 16 inches; but this depth is diminished a little at every turning, till at last it is re-

Brewing.

duced to three or four inches. The number of turnings is regulated by the temperature of the malt; but they are seldom fewer than two each day. In Scotland, the temperature of the grain is kept as nearly as possible at 55°; but in England we have generally found the temperature of the grain on the malt floor about 62°. It has been generally supposed that the Hertfordshire method of making malt is the best; but, after a very careful comparison of the two methods, we were unable to perceive any superiority whatever in the English mode.

Acrospire.

About a day after the sprouting of the roots, the rudiments of the future stem begins to make its appearance. This substance is called by the maltsters the *acrospire*. It rises from the same extremity of the seed with the root, and, advancing within the husk or skin, would at last (if the process were continued long enough) issue from the other extremity in the form of a green leaf; but the process of malting is stopped before the acrospire has made such progress.

While the grain is on the malt floor, it has been ascertained that it absorbs oxygen gas, and emits carbonic acid gas. But to what amount these absorptions and emissions take place, has not been ascertained. They are certainly small; for the average loss which the grain sustains when on the malt floor is only 3 *per cent.*, a considerable portion of which must be ascribed to roots broken off, and grains of barley bruised during the turning. As the acrospire shoots along the grain, the appearance of the kernel or mealy part of the corn undergoes a considerable change. The glutinous and mucilaginous matter in a great measure disappears, the colour becomes whiter, and the texture so loose, that it crumbles to powder between the fingers. The object of malting is to produce this change. When it is accomplished, which takes place when the acrospire has come nearly to the end of the seed, the process is stopped altogether.

At this period, it was formerly the custom in Scotland to pile up the whole grain into a pretty thick heap, and allow it to remain for some time. The consequence is, the evolution of a very considerable heat, while, at the same time, the malt becomes exceedingly sweet. But this plan is now laid aside, because it occasions a sensible diminution in the malt, without being of any essential service. For the very same change takes place afterwards, while the malt is in the mash-tun, without any loss whatever.

The time during which the grain continues on the malt floor varies according to circumstances. The higher the temperature at which the grain is kept, the more speedily is it converted into malt. In general, 14 days may be specified as the period which intervenes in England from throwing the barley out of the steep, till it is ready for the kiln; while in Scotland, it is seldom shorter than 18 days, and sometimes three weeks. This, no doubt, is an advantage in favour of English malting; as every thing which shortens the progress, without injuring the malt, must turn out to the advantage of the manufacturer.

4. The last part of the process is to dry the malt upon the kiln, which stops the germination, and enables the brewer to keep the malt for some time without injury. The kiln is a chamber, the floor of which usually consists of iron plates full of holes, and in the roof there is a vent to allow the escape of the heated air and vapour. Under this room is a space in which fire of charcoal or coak is lighted. The heated air which supplies this fire passes up through the holes in the iron plates, and makes its way through the malt, carrying off the moisture along with it. At first, the temperature of the malt is not higher than 90°; but it is elevated very slowly to 140°, or even higher. We believe, that in many cases, it rises at last almost as high as 212°, though we have never witnessed any such high temperature ourselves. But we have seen pale malt dried at a temperature of 175°, without any injury whatever. The great secret in drying malt properly, consists in keeping the heat very low at first, and only raising it very gradually, as the moisture is dissipated. For a high temperature, applied at first, would infallibly blacken, or even char the malt, and would certainly diminish considerably the quantity of soluble matter which it contains. We shall here insert the table drawn up by Mr Combrune, from his own experiments, of the colour of malt dried in different temperatures.

Brewing. Kiln-drying.

Heat.		
119°	-	White
124	-	Cream-colour
129	-	Light yellow
134	-	Amber-colour
138	-	High amber
143	-	Pale brown
148	-	Brown
152	-	High brown
157	-	Brown inclining to black
162	-	High brown speckled with black
167	-	Blackish brown with black specks
171	-	Colour of burnt coffee
176	-	Black

We have given this table, not on account of any information which it contains, but to put our readers on their guard against the false conclusions of this writer. We have taken malt dried at the temperature of 175°, put it into a garden pot filled with soil, and have seen it vegetate apparently as well as raw grain placed in the same situation. Now, this is only one degree lower than that in which Mr Combrune says malt is converted into charcoal, and it is four degrees higher than that in which his malt assumed the colour of burnt coffee. Certainly malt reduced to the colour of burnt coffee by heat, would be deprived of the power of vegetating. Mr Combrune's experiments were made by putting malt into an earthen pan, which he placed over a charcoal fire in a stove, while he kept stirring the malt the whole time of the experiment. The bulb of the thermometer was placed half-way between the upper surface of the malt and the bottom of the vessel. Now, the reader will perceive at once, that the earthen pan would be much hotter than that part of the malt where the thermometer was placed. By the constant stirring of the malt, the whole of

it was gradually exposed to the burning action of the surface of the pan. Had the experiment been made without stirring the malt at all, and had the thermometer been placed near the surface, in that case, the changes in the colour of the malt at the surface would have indicated the temperature to which it was exposed. But in the way that Mr Combrune conducted his experiments, the temperatures which he obtained were entirely fallacious. We have not the least doubt, that the temperature of the earthen pan, towards the end of his experiment, was above 400°.

Mr Combrune's law, however, that the heat of the water in mashing ought to be regulated by the colour of the malt; namely, that the paler the malt is, the lower ought the temperature of the mashing water to be, is founded on accurate observations. The fact is, that boiling water would answer better than any other for mashing, because it would dissolve most speedily the soluble part of the malt. The only reason for not using it is, that the tendency of the malt to *set* increases with the temperature of the water. Now, the higher the colour of the malt, the less is its tendency to set; of course, we may use water of a higher temperature to mash with it. For the same reason, when raw grain is used, the temperature of the mashing water must be still lower than when malt is employed; because raw grain has a very great tendency to *set*.

The old malt-kilns had a bottom of hair-cloth instead of the iron plates full of holes, which constitute a more recent improvement. We have seen the thermometer in such a kiln, when the bulb touched the hair-cloth, rise as high as 186°. In general, the temperature of the malt-kiln is very carelessly regulated. We have seen malt for the very same purpose dried at a temperature which never rose higher than 136°; while a portion of the very same malt, put into another kiln, was heated as high as 186°. But such a careless mode of drying malt is reprehensible, and must be more or less injurious to the brewer. In general, the more rapidly malt is dried the more does its bulk increase. This method, accordingly, is practised by those who malt for sale, as is the case with most of the English maltsters; because malt is always sold by measure, and not by weight. The brewers would find it more for their interest to buy malt by weight than by measure. In that case, the maltsters would dry their malt at as low a temperature as possible. But this would signify very little, or rather would be advantageous to the brewer; because dried malt soon recovers the moisture lost on the kiln when kept for some time in sacks. And, when malt is dried at a low temperature, we are sure that none of it is injured by the fire. It will, therefore, go farther in the production of beer. The time of kiln-drying varies considerably, according to the quantity of malt exposed to the action of the heat. But when that quantity is not too great, we may estimate the time of kiln-drying, in general, at two days. After the fire is withdrawn, the malt is allowed to remain on the kiln till it has become nearly cold.

By the kiln-drying, the roots of the barley, or, as the maltsters call them, the *comings*, are dried up and fall off. They are separated from the malt by passing it over the surface of a kind of wire-screen, which allows the *comings* to drop through, while the wires are too near each other to permit the grains of malt to pass.

Changes produced by Malting.

If 100 lbs. of barley malted in this manner, with all the requisite care, be weighed just after being kiln-dried and cleaned, they will be found, on an average, to weigh 80 lbs. But if the raw grain be kiln-dried at the same temperature as the malt, it will lose 12 *per cent.* of its weight. Hence 12 *per cent.* of the loss which barley sustains in malting, must be ascribed to moisture dissipated by the kiln-drying; so that the real loss of weight which barley sustains when malted, amounts to 8 *per cent.* This loss, from a great many trials made in the large way, with all the requisite care, we conceive may be accounted for in the following manner:

Carried off by the steep-water - -	1.5
Dissipated while on the floor - -	3.0
Roots separated by cleaning -	3.0
Waste - - - -	0.5
	8.0

These numbers were obtained from above thirty different maltings, conducted in four different malting-houses, with as much attention to every circumstance as was compatible with practical malting. The matter carried off by the steep-water, which amounts to about $\frac{1}{60}$th of the weight of the whole grain, we conceive to be dissolved from the skin or husks. It may, therefore, be left out of view. The waste is owing to grains of malt crushed by the workmen while turning the malt on the floor, and afterwards dissipated or destroyed during the subsequent processes. We were not able to collect these bruised grains and weigh them; the number therefore given for them in the preceding table is hypothetical; but from a great many circumstances, which it would be too tedious to adduce here, we believe that, in our trials, $\frac{1}{200}$th part of the whole very nearly represents the amount of the crushed grains. Thus the real loss of weight by malting (supposing nothing lost by steeping, and no grains crushed) is only 6 *per cent.* and of this loss 4 *per cent.* may be safely ascribed to the roots; so that not above 2 *per cent.* at most can be assigned to the carbon dissipated by the evolution of carbonic acid on the floor, and on the kiln. Indeed we have reason to conclude, from a good many trials, that the greatest part of this loss of 2 *per cent.* is sustained on the kiln. For, if malt dried carefully at a low temperature be afterwards kiln-dried, or exposed (as was our method) to the heat of a steam bath, it never afterwards recovers its former weight by exposure to the air. And every time this experiment is repeated, by artificially moistening and drying the same malt, a new loss of weight is sustained. The same observation was made by Saussure, who conceived that the loss was to be ascribed to the formation and dissipation of water in the barleycorn. But we have no proof that any such formation takes place. It is more probable that the loss is owing to the formation and escape of carbonic acid gas.

Brewing.

Big sustains a considerably greater loss of weight when malted than barley. The average loss of weight in our trials with barley was only 8 *per cent.*, while that of big was 15 *per cent.*, or nearly double. This we conceive is owing to the destruction of a much greater number of the corns during the process of malting big than barley. But, in all our experiments on big, that grain was manifestly oversteeped. To this, perhaps, a good deal of the difference may be ascribed. Our maltsters had not been in the habit of malting big, and therefore were not likely to do it so much justice as they did to the barley. Hence it would be improper to venture upon any general conclusions from the experiments which we made upon the malting of big.

The bulk of the malt is usually greater than that of the barley from which it was obtained. But this varies a good deal, according to the goodness of the grain, and the mode of drying the malt. In our trials, made all in the same way, 100 bushels of the different kinds of grain gave, on an average, the following results :—

English barley, - -	109
Scotch barley, - -	103
Scotch big, - -	100.6

The greatest quantity in bushels obtained from 100 bushels of English barley was $111\frac{1}{4}$, the least 106 bushels. The greatest quantity obtained from 100 bushels of Scotch barley was 109, and the least 98 bushels. The greatest quantity obtained from 100 bushels of big was 103 bushels, the least 97 bushels. Hence it appears that, on malting English barley, there is a profit of 9 *per cent.*, while big yields scarcely any thing more than its bulk before malting. The English maltster makes more bushels of malt than he pays duty for; but the maltster of big, on the contrary, obtains fewer.

Tables of Malting.

We shall subjoin here two Tables, which exhibit in one view the result of a considerable number of trials made by the author of this article, on malting different varieties of grain. The barley is distinguished by the name of the county where it grew. To understand the first table, the reader must know that Excisemen estimate the quantity of malt by subtracting one-fifth from the best or highest gauge in the steep or couch, and charge the duty accordingly.

Brewing. Nature of Process.

Thus it appears that the process of malting is nothing else than causing the barleycorns to germinate, and stopping that process before the green leaf makes its appearance. A quantity of roots are formed, which are afterwards rubbed off and separated, and the weight of which amounts to about 4 *per cent.* of the grain malted. The kernel of the grain undergoes a remarkable change by this process. It consists almost entirely of starch; but it was agglutinated in the grain, so as to make a solid and very firm mass; whereas, in the malt, it is quite loose and mealy. Hence it would appear that the glutinous and mucilaginous matter of the barleycorn is chiefly employed in forming the roots; and that this is the purpose for which it was laid up in the grain. How far the starch is altered does not appear. It is probable that it has undergone some change. Malt has a slightly sweet taste, much more agreeable than the taste of the raw grain, without any of that strong and cloying sweetness which distinguishes wort. But the most distinguishing character of the starch of malt is the ease with which it dissolves in hot water; though cold water does not act upon it sensibly. Whether this property be peculiar to the starch of barley or be induced by the malting, we cannot say. We conceive it probable that barley starch is more easily soluble in water than wheat starch, from the ease with which raw grain is constantly employed by distillers to form their worts. In its other chemical characters, the starch of barley malt agrees with that of wheat starch.

Soluble part of Malt.

We would err very much, however, were we to suppose that the whole kernel or starchy part of the malt is dissolved by the hot water used in brewing. At least one half of the malt still remains after the brewing is over, constituting the grains, which are known to constitute a most nourishing article of food for cattle, and therefore to contain much more than the husks or skin of the malt corn. One hundred lbs. of malt, from different kinds of grain, after being exhausted as much as usual of the soluble part of the kernel by hot water, were found to weigh as follows:—

English barley -	50.63 lbs.
Scotch barley - -	50.78
Scotch big -	52.69

100 lbs. of raw grain being converted into malt, and the soluble part of the malt extracted by hot water, the residue weighed:

English barley -	51.558 lbs.
Scotch barley - -	50.831
Scotch big -	53.500

In another set of experiments, 100 lbs. of malt left the following residues:

English barley -	54.9 lbs.
Scotch barley, - -	56.9
Scotch big, - -	56.6

100 lbs. of the raw grain being converted into malt, and the soluble part of the malt extracted by hot water, the residues weighed:

English barley -	54.8 lbs.
Scotch barley - -	56.9
Scotch big - -	56.6

Hence we see that, in all these cases, the bulk of the malt was very nearly the same as the previous bulk of the barley before it was malted.

In another set of experiments, 100 lbs. of malt left the following residues:

English barley -	54.0 lbs.
Scotch barley - -	56.1
Scotch big - -	56.6

100 lbs. of the raw grain being converted into malt, and the soluble part of the malt being extracted by hot water, the residues weighed:

English barley -	54.63 lbs.
Scotch barley - -	56.09
Scotch big -	56.59

Here also the bulk of the malt differed but little from that of the raw grain. The first of these sets of experiments was made with grain of the best quality, the second with grain of the middling quality, and the third with grain of the third quality.

It is probable that an additional portion of the kernel would be dissolved if the malt were ground finer than it is customary to do. The reason for grinding it only coarsely is to render it less apt to set. But this object might be accomplished equally well by bruising the malt between rollers, which would reduce the starchy part to powder, without destroying the husk. This method, indeed, is practised by many brewers, but it ought to be followed by all.

CHAP. IV.

OF BREWING.

Brewing consists of five successive processes, which are distinguished by the following names: 1. *Mashing*, 2. *Boiling*, 3. *Cooling*, 4. *Fermenting*, 5. *Cleansing*. We shall afterwards give a description and view of the utensils employed in a large London porter brewery, where they have been carried to the greatest perfection. But we conceive it better to give a description of the processes themselves, in the first place, without referring them to any specific form of vessels; observing only, that the size of all the utensils must be proportional to the quantity of beer which it is proposed to make at once.

Specific Gravity of Malt.

1. The specific gravity of malt varies a good deal, according to the way in which it is dried upon the kiln. But its mean specific gravity may be stated at 1.201. In general the specific gravity of big malt is rather inferior to that of malt from barley. Let us suppose, for the sake of stating the comparative quantities, that it is our object to employ in a

single brewing 50 bushels of malt. The first thing to be done is to grind the malt in a mill, and the best kind of mill for the purpose, is that in which the malt is made to pass between two iron rollers.

Mashing.

We must be provided with a copper boiler, capable of containing at least the 50 bushels of malt; or its solid contents must, at the smallest, amount to 382 ale gallons, which are rather more than 107,521 cubic inches or $62\frac{1}{5}$ cubic feet. This copper boiler must be placed over brick work upon a furnace, and there must be conveniences for filling it with water and for letting the water off, when sufficiently heated, into the mash-tun.

The mash-tun is a wooden vessel composed of staves properly fixed by means of iron hoops, and usually placed in the middle of the brew-house. It has a false bottom full of holes at some little height above the true bottom. Its capacity varies according to the extent of the brewery establishment. But a mash-tun, capable of mashing 50 bushels of malt, must be, at least, one-third larger than the bulk of the malt, or it must be capable at least of containing 75 bushels.

A quantity of water equal, at least, in bulk to that of the malt, is to be put into the boiler, and heated up to 190° or 180° according to the fancy of the brewer and the quality of the malt. But the best brewers, in general, employ the lowest temperature. This water is then to be let into the mash-tun, and the malt, previously ground, is to be let down into it immediately after. It is then mixed with the water and all the clots carefully broken, either by workmen, who use for the purpose very narrow wooden shovels, or, when the capacity of the mash-tun is very great, as in the London breweries, by a machine which is driven by a steam-engine. Great care must be taken to break all the clots, because the whole of the malt within them would otherwise escape the action of the water, and be lost to the brewer. When the water and malt are sufficiently mixed, the mash-tun is covered and left in this state about three hours. But the time varies according to circumstances.

Though the specific gravity of a malt corn be greater than that of water, yet if it be thrown into that liquid it always swims. The reason is, that between the skin and the kernel there is lodged a quantity of air, which it is not easy to drive away. Accordingly, brewers are in the habit of judging of the goodness of malt by throwing a certain quantity of it into water, and, reckoning the grains which fall to the bottom, these indicate the proportion of unmalted grain which the malt contains. Of course the more of them that exist in any given quantity of malt, the worse must the malt be considered. But though malt, when we consider only single corns, is about a sixth heavier than water, yet a bushel of malt does not weigh so much as one-third of a bushel of water. For, on one occasion, the hot-water in the mash-tun, before the addition of the malt, stood at the height of 22 inches. On adding the malt, it rose to the height of 29 inches. The bulk of the water was 51 bushels; that of the malt before grinding $47\frac{1}{2}$ bushels. We see from this, that the real space occupied in the mash-tun by the $47\frac{1}{2}$ bushels of malt, was only seven inches; while the 51 bushels of water occupied the space of 22 inches. Therefore about two-thirds of the bulk of the ungrounded malt consisted of interstices filled with air.

The temperature of the water is considerably lowered when it is mixed with the malt, but we have been unable to determine how much, from the impossibility of thrusting a thermometer down to the centre of the mash-tun, the only place that would give a correct result. But we may state a few out of the many observations which we have made on the subject: 51 bushels of water of the temperature 192° were mixed with $47\frac{1}{4}$ bushels of malt; after mixture, the temperature at the surface of the mash was 140°. Two hours and a half after, when the wort began to run off, its temperature was 156°, and at that time the surface of the mash was at the temperature of 136°. If we suppose in this case, that the whole mash lost four degrees as well as the surface, and take the mean between the bottom and top, we shall have the mean heat of the whole after the mashing, 150°. So that the water has lost 32° of heat, while the malt (its temperature before mixture was 48°) gained 102°.

The weight of the water, reckoning it at 51 bushels, was -	3965.25 lbs.
That of the malt was -	1788.80 lbs.

This would make the specific heat of the malt 0.69, which is probably considerably above the truth. For, according to the experiments of Dr Crawford, the specific heat of barley is only 0.421. So that our supposition, that the mean temperature after mashing was only 150°, is not quite accurate. Were we to suppose the specific heat of malt to be 0.42, which cannot be very far from the truth, in that case the mean temperature, after mashing, would be 169°, if the water was 192° and the malt 48°, and the weight of each as above stated.

In another experiment, in which 60 bushels of malt were mashed, the heat of the water was 180°, that of the malt 56°, the temperature, on adding the malt to the water and mixing it well, was at the surface 141°. Four hours after, when the wort began to be drawn off, its temperature was 150°, and that of the surface of the mixture of malt and water in the mash-tun, was 138°.

	lbs.
The bulk of water was $66\frac{1}{5}$ bushels, its weight - - -	5147
The weight of the malt was -	2283.6

Any person may easily, from these data, calculate what the heat of the mixture after mashing ought to be, supposing the specific heat of the malt to be 0.42. The common formula for the calculation, is $S = \frac{W \times w - m}{B \times m - b}$, in which S denotes the specific heat of the malt, W the weight of water used, w its temperature, B the weight of malt used, b its temperature, and m (which in the present case is the quantity sought) the temperature after mix-

Brewing. ture. We do not think it worth while to give any more examples of these changes of temperature, though we are in possession of abundance of them; because we do not conceive that they can lead to any useful results.

Wort. After the mash has continued for about three hours (or longer or shorter according to circumstances), a stop-cock, placed below the false bottom in the mash-tun, is opened, and the wort allowed to run out into a vessel prepared to receive it, and known by the name of *underback*. At the same time the cover is taken off the mash-tun, and quantities of water of the temperature of 180° are occasionally sprinkled over it from the boiler, which had been again filled with water to be heated, as soon as the water for mashing was drawn off. No specific directions can be given respecting the quantity of hot-water added in this manner by sprinkling, because that must depend upon the views of the brewer. If he wishes to have ale of very great strength, he will of course add less water; if the ale is to be weak he will add more. The best way is to determine the strength of the liquor as it flows into the underback by means of a saccharometer, or by taking its specific gravity. When the specific gravity (at 60°) sinks to 1.04 or 1.05, or when it contains only $36\frac{1}{2}$ or $46\frac{1}{2}$ lbs. *per* barrel of solid matter in solution, it would be useless or injurious to draw any more off for making strong ale. But an additional portion may still be drawn off and converted into small beer. We have seen the brewers in Edinburgh continue to draw off small beer from the mash-tun till the liquid indicated only $23\frac{1}{2}$ lbs. *per* barrel, or even till it indicated only $17\frac{1}{2}$ lbs. *per* barrel; that is, till its specific gravity at 60° was reduced to 1.027 or 1.020. Indeed the strength of small-beer is often much weaker than this, when it is obtained from malt without drawing off any strong ale wort; but when it is the residue of strong ale, it is necessary to make it stronger, otherwise its quality will be bad. About a dozen of years ago, it was customary with some of the small-beer brewers in Edinburgh, to make the small-beer of considerable strength; and after the Excisemen had determined its quantity, and the duty to be paid on it, they diluted it largely with water, just when they were sending it out of the house. This fraud was easily put in practice, because the small-beer is usually disposed of the moment it is mixed with the yeast, and before it has undergone any fermentation whatever. It ferments sufficiently in the small casks in which it is sent to the consumers. In Edinburgh it is customary to bottle this small-beer, which makes it clear and very brisk, and consequently very agreeable to the palate.

Neither can any general rule be laid down for the specific gravity or strength of the wort, when it begins to flow from the mash. It will obviously depend upon the goodness of the malt, and upon the quantity of mashing water employed, when compared with the quantity of malt. We have seen it begin to flow from the mash-tun of the specific gravity 1.084, 1.0805, 1.0815, 1.0835, 1.091, 1.094; or containing respectively $78\frac{1}{4}$, $74\frac{1}{2}$, $75\frac{1}{2}$, 78, 85, and $87\frac{3}{4}$ lbs. *per* barrel.

The wort, as it first flows from the mash-tun, is a transparent liquid of a fine amber colour, a peculiar smell, and a rich, luscious, sweet taste. If it is cloudy, as sometimes happens, it is a proof that the water used for mashing was of too high a temperature. We have seen the wort run cloudy from the mash-tun, when the temperature of the water had been as high as 200° or 191°, but never when it was no higher than 180°. This affords an additional reason with the brewers for keeping the temperature of the mashing-water low. But we have some doubts about the accuracy of the reason. For, when the wort is afterwards boiled, it always deposits a copious flocky sediment. The boiling would doubtless render even turbid wort transparent, and would not probably increase the sediment much. At the same time, it must be acknowledged, that some obscurity hangs upon this part of the process of brewing. For we have seen wort continue opaque during the whole process of boiling, cooling, and fermenting, and requiring ultimately to be clarified or *fined*, as the brewers termed it, by means of isinglass. The substance which rendered the ale in this case turbid, seemed to be a variety of starch, or some particular form of that substance; for it was completely precipitated by infusion of nutgalls, and the precipitate was redissolved by the application of a moderate heat.

The flowing of the wort from the mash-tun takes up six or eight hours. As it advances, the colour diminishes, the smell becomes less agreeable, and the taste less sweet. At last the colour becomes nearly opal, and the smell becomes sour, and somewhat similar to the odour given out by an infusion of meal and water left till it has become sour. Yet it produces no change on vegetable blue colours.

Constituents of Wort. If the wort which first comes over be evaporated to dryness, it leaves behind it a yellow-coloured residuum, which has a sweet taste, dissolves readily in water, absorbs water from the atmosphere, and becomes clammy, and similar in appearance to treacle. Its specific gravity is 1.552. This does not differ much from the specific gravity of common refined sugar, if we take a mean of the experiments of Fahrenheit and Hassenfratz. Fahrenheit found the specific gravity of sugar 1.6065, while Hassenfratz found it 1.4045, the mean of which is 1.5055. There can be no doubt that this residue contains a good deal of sugar, precisely the same in its properties with the sugar into which starch is converted by boiling it in a very dilute acid. But it is mixed likewise with a considerable portion of starch, which has become soluble in water, without being converted into sugar. For wort gives a copious precipitate with the infusion of nutgalls, and this precipitate is redissolved by a moderate increase of temperature, properties which characterize starch.

From the experiments of Saussure it would appear, that starch sugar is nothing else than a combination of starch and sugar. Hence it is probable, that, during the mashing, a combination takes place between the starch of the malt and the water, the result of which is the formation of starch sugar. This sugar agrees in its properties with the sugar of grapes. It crystallizes in needles grouped together

Brewing.

in the form of small sphericles like granulated honey. It does not go so far in sweetening as common sugar; and, like sugar of grapes, it ferments without the addition of yeast. We have attempted in vain to separate the saccharine part of the residue of wort from the starch. When alcohol is poured over it, no solution takes place, but such is the affinity of the residue of wort for water, that it deprives the alcohol of a portion of its water, just as carbonate of potash or muriate of lime does, and a very viscid liquid, consisting of the residue of malt dissolved in a very small quantity of water, is formed at the bottom of the vessel.

It is exceedingly difficult to evaporate wort, without partly decomposing the extractive residue. The best way is to put it upon a very flat dish, and to apply a heat not greater than 120°. We have charred it completely in a glass vessel, filled with alcohol, without applying heat sufficient to make the alcohol boil. Indeed, we never succeeded in obtaining the residue of wort, without its colour being a good deal darker than that of the wort from which it was obtained.

The wort which runs off last contains very little saccharine matter; but some starch and mucilaginous matter may still be detected in it. The flavour and beauty of the ale is increased, if we take only the wort that runs first off, and throw away the last drawn worts, or employ them only in the manufacture of small beer.

Boiling the Wort.

2. The next process in brewing is the *boiling* of the wort. The wort is pumped up from the *underback* into the copper boiler, where it is boiled for several hours, till it has acquired the degree of strength which is wanted by the brewer.

It may be proper to give some examples of quantities to enable the reader to form a better idea of the effect of the boiling.

From 60 bushels of malt there were obtained 23.465 barrels of wort, of the strength of 64.37 lbs. *per* barrel, or of the specific gravity 1.0683. It was boiled down to 19.736 barrels of the strength of 82.7 lbs. *per* barrel, or of the specific gravity 1.089.

From 60 bushels of big malt there were obtained 23.8193 barrels of the specific gravity 1.0648, or of 58.75 lbs. *per* barrel of saccharine matter. It was boiled down to 19.736 barrels of the specific gravity 1.078, or of $72\frac{1}{2}$ lbs. *per* barrel of saccharine matter.

From 72 bushels of malt 15.1388 barrels of the specific gravity 1.071, or of 60.6 lbs. *per* barrel, it was boiled down to $13\frac{1}{4}$ barrels of the specific gravity 1.1055, or of $98\frac{2}{3}$ lbs. *per* barrel of saccharine matter.

From 50 bushels of malt 13.444 barrels of wort were obtained of the specific gravity 1.068, or of 63.125 lbs. of saccharine matter *per* barrel. It was boiled down to 11.083 barrels of the specific gravity 1.1015, or of $94\frac{1}{2}$ lbs. *per* barrel.

Various contrivances have been fallen upon to economize the boiling process; but these will come under our consideration with more propriety when we give an account of the utensils in a London brewery.

The flocky precipitate which forms during the boiling of the wort, as far as we have been able to determine its properties, approaches nearly to the nature of gluten, or vegetable albumen; for these two substances differ very little from each other.

Hops.

While the wort is in the boiler, the requisite quantity of hops are added to flavour the ale, and render it capable of being kept for a considerable length of time without souring. Hops, as is well known, are the seed-pods of the *Humulus lupulus*, or *hop-plant*, which is cultivated in considerable quantities in the south of England, especially in Kent and Hampshire. The seed-pods of this creeping plant are collected when ripe, and dried upon a kiln. They are then packed up in bags, and sold to the brewers. Hops are well known to have a peculiar bitter taste, and a weak aromatic odour, and to possess sedative qualities to a considerable extent. A pillow, filled with hops, has often been found to induce sleep, when every thing else has failed. If they be digested for some days in alcohol, that liquid acquires a slight greenish colour, a peculiar taste, and an odour in which that of the hop can be distinctly perceived. If the alcohol, previously freed from the undissolved matter, be distilled in a retort, there remains behind a solid green-coloured oil. It is to this oil that hops owe their peculiar smell. Its taste is peculiar, sharp, and scarcely bitter, but putting one in mind of the peculiar flavour of good ale. This oil is the part of the hops which gives ale its distinguishing flavour. It is apt to be dissipated by long boiling. Hence, when hops are too long boiled in wort, the aromatic odour and peculiar flavour are nearly dissipated, and a bitter taste substituted in its place. It is the opinion of brewers, that the intoxicating qualities of ale are to be partly ascribed to the oil of the hop. Indeed, it has been pretty common to ascribe intoxicating qualities to bitter tasted substances in general. Thus, a woman of the name of Johnston, who kept a public house a little to the south side of the Meadows, near Edinburgh, about the beginning of the last century, was famous for brewing a pleasant and very intoxicating ale; and the last quality was universally ascribed to the broom tops, which she employed as a bitter instead of hops. This woman's name is remembered, because her ale and her house are celebrated in the poems of Allan Ramsay. But this opinion, though very general, does not appear to be founded upon any precise experiments or observations. We are not acquainted with any volatile oil which produces intoxication; though some of them, as oil of turpentine, act with great energy upon the stomach. No infusion of any bitter whatever, not even of hops, is known to produce intoxication; nor is any effect in the least similar to intoxication produced when considerable quantities (2 oz. for example, *per* day) of Peruvian bark are swallowed in substance.

Besides the volatile oil, hops contain likewise a quantity of bitter principle, which may be easily extracted from them by water. As far as we were able to determine the point, this bitter matter possesses the characters of the bitter principle in perfection. No reagent that we tried is capable of throwing it down except acetate of lead, a somewhat ambiguous precipitant, because it throws down the greater number of vegetable substances, and because

the lead in this salt is partially thrown down by carbonic acid, if it happens to be present in the solution. Nitrate of silver is likewise a precipitant, throwing down the bitter principle of hops in light yellow flocks. But this precipitant is also somewhat ambiguous, for the same reason that renders acetate of lead so. The bitter principle of hops is likewise very soluble, both in water and alcohol.

Hops communicate both their flavour and their bitter taste to wort. The quantity employed varies very much, according to the taste of the persons who are to drink the ale. The stronger the ale is, the greater the quantity of hops is which it can bear without injury. In general, English brewers employ a much greater quantity of hops than the Scotch brewers. To elucidate the subject, we shall give a few examples of the quantity of hops used in making Edinburgh ale; which is known to be mild, and, in general, is much relished by most of those who are in the habit of drinking ale.

Sixty bushels of malt yielded 11¾ barrels of strong ale wort (measured at the end of the boiling), and 40 lbs. of hops had been mixed with it in the boiler.

Forty-seven and a quarter bushels of malt furnished 10.83 barrels of wort, measured after being boiled and cooled, and 36 lbs. of hops had been mixed with it in the boiler.

Sixty bushels of malt furnished fifteen barrels of wort, measured after boiling and cooling, and 45 lbs. of hops had been mixed with it in the boiler.

Sixty bushels of malt, from big, furnished 14.7 barrels of wort, after being boiled and cooled. It was mixed with 40 lbs. of hops in the boiler.

In another brewing in which 72 bushels of malt, from big, furnished 10½ barrels of wort, 66 lbs. of hops had been added in the boiler.

In general, when the ale has considerable strength, the Edinburgh brewers are in the habit of adding one pound of hops for every bushel of malt employed. Sometimes, indeed, when they wish their ale to be very superior in flavour and quality, they employ a greater quantity of hops than even this. Thus, we have seen 100 lbs. of hops boiled in the strong ale wort extracted from 72 bushels of malt. When the ale is but weak, and consequently cheap, the usual allowance is one pound of hops to a bushel and a half of the malt.

Cooling the wort.

3. After the wort has been boiled down to the requisite strength, which, in Edinburgh, is commonly between the specific gravities 1.09 and 1.10, it is let out into the *coolers*. The coolers are floors of wood, surrounded with a wooden ledge, and water tight, placed in the most airy and exposed situation in the brewery. They are of such a size as to hold the whole of the wort at a depth not exceeding three or four inches; so that, in large breweries, they are of an enormous extent. The object is to cool down the wort, as rapidly as possible, to the temperature of the atmosphere; because, if it were allowed to remain long hot it would run the risk of becoming sour, which would spoil the whole process. A great deal of the superiority of some breweries over others, depends upon the construction of the coolers, or, rather, upon their being as well adapted as possible for reducing the temperature of the wort speedily to that of the atmosphere. A free current of air ought to pass over them, and great care should be taken to keep them perfectly clean.

The wort is either pumped out of the boiler into the coolers, or it is let into them by simply opening a stop-cock, according to the construction of the brewhouse. It soon spreads itself over all the surface of the coolers, and a very great evaporation is the consequence. This evaporation ought always to be taken into consideration by the brewer; because it both materially adds to the strength of the ale and diminishes its quantity. The amount of it depends upon the temperature of the air compared with that of the atmosphere, and upon the skill with which the coolers have been constructed. We shall give a few examples of the quantity of evaporation which took place during the cooling of worts, in coolers by no means remarkable for the goodness of their construction.

Temperature of the wort when let into the coolers.	Temperature of do. when cold.	Quantity of Wort when let into the Coolers in Ale Barrels.	Ditto when cooled.	Quantity evaporated in Ale Barrels.	Time of Cooling in hours.
160°	56°	16.1388	14.8611	1.2777	11½
176°	51	18.6666	17.2222	1.4444	11½
208°	50	11.5555	8.75	2.8055	9½
208°	52	16.6388	12.0832	4.5556	14
208°	50	14.0555	10.2222	3.8333	9
208°	53	14.7777	10.5	4.2777	16
210°	52	13.6944	9.1388	4.5556	8
208	51	13.3333	9.3055	4.0278	8
206	52	12.6388	8.2777	4.3611	6
200	52	14.0555	9.4444	4.6111	6½
200	54	13.6944	9.1388	4.5556	6
200	53	11.0833	8.5000	2.5833	7
204	56	14.0555	10.6111	3.4444	8
Mean		14.1067		3.5640	

In the first two examples in the above Table, the quantity of wort was estimated just when it was let down into the coolers; in all the others it was estimated in the boiler before it was pumped out. It appears from the preceding table, that rather more than one-fourth of the whole wort is dissipated by evaporation during the cooling. And, if we had excepted from the general consideration the two first examples, the proportion evaporated would have been still greater.

When the wort is let out of the boiler into the

Brewing.

cooler, the hops still remain, and, as they are soaked with wort, a considerable loss would be sustained if they were thrown away. Thus we found, in one instance, that 45 lbs. of hops retained half a barrel of wort after they were drained so completely that no more wort would drop out. In another case, 35 lbs. of hops, retained in the same way, 0.3666 of a barrel, which is rather more than one-third of a barrel. To recover this wort it is proper to subject the hops to pressure. We do not know whether this is attended to by the great brewers, though it probably is. By several of the Edinburgh brewers it is too much neglected.

In cold weather, where the brewery is small, and the apartment in which the fermenting vessels are placed, cold, it is proper not to reduce the temperature of the wort so low as that of the atmosphere. From want of attention to this circumstance, we have seen wort refuse to ferment for some time, and the brewer under the necessity of heating it artificially before fermentation could be brought on. In such cases, the wort is very apt to be lost altogether by contracting acidity. The temperature, in such cases, ought not to be reduced lower than 56°. But when the apartment in which fermentation is carried on is warm, 51° or 52° is a very good temperature. When the brewer is obliged to make ale in warm summer weather, it is material to reduce the temperature as low as possible. In such cases, great advantage would attend cooling the wort in coolers without any roof or covering whatever, but quite open to the sky; because, in clear nights, the wort might be cooled in this way, eight or ten degrees lower than the temperature of the atmosphere. The reason is obvious. It is owing to the rays of heat, which, in such a case, radiate from the wort, and are not returned again by the clear sky. Wort, being a good radiator of heat, would be particularly benefited by this method of cooling. We have no doubt that it might be put in practice with advantage in hot climates; and that, by means of it, good ale or porter might be manufactured in the East and West Indies. Such a manufacture, if successful, would be particularly relished in India, and would, we doubt not, prove a lucrative article of manufacture to an enterprising man.

As there is a duty levied on ale and beer according to their quantity, Excisemen are in the habit of gauging the wort while in the boiler and when on the coolers. Not that the duty is levied according to the quantities there found; but to serve as a check upon the more accurate guages taken in the fermenting tuns. For a certain allowance being made for evaporation, while the wort is in the cooler, which the excisemen, from long observation, are enabled to do with some accuracy, they have it in their power, from these checks, to determine whether any of the wort from the coolers has been secreted or carried off with a view to evade the excise laws.

Fermentation.

4. When the wort is sufficiently cooled down by exposure on the coolers, it is let down into the fermenting-tuns, or, as the brewers call them, the gyle-tuns, in order to be fermented; by which process, it is converted from the luscious sweet-tasted liquor called *wort*, to the brisk intoxicating liquor which constitutes *ale*. The gyle-tuns are cylindrical wooden vessels, varying in size, according to the extent of the brewery. In the London breweries, and in the distilleries, they are of prodigious size; but in private houses they often do not exceed the size of a wine hogshead, or even of a beer barrel. The fermentation is perhaps conducted with the greatest economy in large vessels; but good ale may be made in comparatively small quantities. How far this is the case with porter, it is more difficult to say. Good porter has scarcely ever been made, except by those who manufacture it upon a large scale.

The fermenting tuns are not to be filled by the wort; because a considerable increase in bulk takes place during the fermentation, in consequence of which the liquor would run over, unless allowance were made for it.

The fermentation of ale or beer is never carried to any great length. The object of the brewer is, to retain the flavour and good qualities of the ale or beer, not to develope the greatest quantity of spirits, which can hardly be done without allowing the wort to run into acidity. The violence of the fermentation depends upon the quantity of yeast added. Brewers, accordingly, mix yeast with their worts only in very sparing quantities; while the distiller adds it in great doses, and repeatedly.

Nature of Yeast.

Yeast is a frothy substance of a brownish-grey colour, and bitter taste, which is formed on the surface of ale or wine while fermenting. If it be put into sacks the moisture gradually drops out, and the yeast remains behind in a solid form. It has very much of the flavour and taste of cheese when in this state; but its colour is still darker. This dried yeast promotes or excites fermentation; but it does not answer quite so well as fresh yeast. At one period, some of the Scotch distillers employed considerable quantities of it; but all of them with whom we conversed on the subject, affirmed, that it was much less profitable than even the bad porter yeast which they were in the habit of bringing down from London. From the resemblance which dried yeast has to cheese, one would be disposed to infer that it is a species or variety of gluten. But if we attempt to induce fermentation in wort by adding the gluten of wheat, we will be unsuccessful.

When yeast is kept for some time in cylindrical glass vessels, a white substance, not unlike curd, separates and swims on the surface. If this substance be removed the yeast loses the property of exciting fermentation. This white substance possesses many of the properties of gluten, though it differs from it in others. Its colour is much whiter, it has not the same elasticity, and its particles do not adhere with the same force. In short, it agrees much more nearly, in its properties, with the curd of milk than with the gluten of wheat. We are disposed to consider this substance as the true fermenting principle in yeast; though we were never able to procure a sufficient quantity of it to put its fermenting powers to the test of experiment. We have sometimes seen a similar substance separate in the fermenting tuns in distilleries, when the fermentation was nearly at an end; or, rather, when such a quantity

of spirit had been generated as put an end to the fermenting process altogether. But we could never learn that the distillers had formed any opinion respecting this curdy substance. It did not interfere with the success of their operations, and, on that account, they bestowed little attention to it. We attempted, once or twice, to collect such a quantity of it as might enable us to try its powers as a ferment, but we did not succeed.

The only chemist who has attempted to subject yeast to a chemical analysis is Westrumb. But, though this philosopher was distinguished for his accuracy, the task was too difficult for the resources of the science of the time (1796) when he published his *Experiments*. From 15360 parts of fresh beer yeast he obtained the following substances:

Potash	13
Carbonic acid	15
Acetic acid	10
Malic acid	45
Lime	69
Alcohol	240
Extractive	120
Mucilage	240
Saccharine matter	315
Gluten	480
Water	13595
	15142
Loss	218
Total	15360

As yeast may be reduced to a dried state without depriving it of the power of acting as a ferment, it is clear that the carbonic acid, acetic acid, alcohol, and water are not essential to it. We cannot suppose that either potash, lime, or malic acid, is essential. The saccharine matter, we know, is capable of fermenting of itself; but if it were the essential ingredient, it would be quite unnecessary to add yeast to wort at all, as we know that the wort contains abundance of saccharine matter in solution. We know likewise, from experiment, that neither extractive, mucilage nor gluten possesses the property of exciting fermentation. Thus none of the substances found by Westrumb in yeast, can be considered as the true fermenting principle. Dobereiner found that, when yeast is steeped in alcohol, it loses the property of acting as a ferment. This may be owing to the alcohol dissolving and carrying off the true fermenting principle. But we are rather disposed to ascribe it to the presence of a portion of alcohol in the yeast. We know that a certain portion of alcohol destroys fermentation. Thus we have found by a great many trials, conducted on rather a large scale, that the stronger a wort is made, the greater is the quantity of unaltered saccharine matter which remains in it after the fermentation has been carried to the greatest possible length. Hence the present mode of levying the duties on spirits upon the wash is not only very injurious to the goodness of the spirits manufactured; but is attended with a positive and very heavy loss to the community. Distillers' wash may be fermented a second time, and would in this way yield a considerable additional quantity of spirits. We have frequently seen it made into good small-beer. The proper mode of levying the duty would be on the quantity of saccharine matter in the wash. This might easily be determined by a good *saccharometer*. A certain part of the duty might likewise be levied upon the spirits produced. This would act as a sort of check upon the first estimate, and would considerably diminish the risk of fraud. Indeed, the mode of determining the duty by the quantity of saccharine matter, would not be more liable to evasion than the present mode. It could be evaded in no other way than by concealing a portion of the wash, which would be equally efficacious according to the present mode.

We conceive, therefore, that when yeast is mixed with alcohol, it may retain so much of that liquor as to prevent it from acting as a ferment. When we attempt to wash away the alcohol, we may destroy the yeast by washing away that portion of it which really acts as a ferment, which is probably small in quantity.

It seems to us not unlikely, that the portion of yeast which really acts as a ferment, is a quantity of saccharine matter which it contains, that has begun to undergo the decomposition produced by fermentation, but has not yet completed the change. For nothing more seems to be necessary than to begin the fermentative process in wort; the process then goes on of itself. It would be curious to know whether a high temperature (96° or 100°) might be substituted in distilleries for the great quantities of yeast at present employed. We believe that the reason why such great quantities of yeast are necessary in distilleries, is the very great strength of the wash employed; as they are obliged by law to produce a quantity of proof spirits amounting nearly to $\frac{1}{5}$th of the whole bulk of the wash. Nothing can be more preposterous than such a method, nor more contrary to the real interest of the community, which obviously must be to produce the greatest quantity of good spirits from a given quantity of grain.

The quantity of yeast mixed with the wort in the fermenting tuns by brewers, is very small, amounting, at an average, to a gallon of yeast for every three barrels of wort. The following table will give the reader an idea of the quantities of yeast really mixed by the Edinburgh brewers with their strong ale worts in different brewings. It is obvious, however, that the quantity of yeast must be regulated in some measure by its goodness.

Brewing.

Quantity of wort in barrels.	Specific gravity.	lbs. *per* barrel of saccharine matter.	Quantity of yeast added in gallons.
10.611	1.106	99	3.5
10.83	1.104	$97\frac{1}{4}$	4
14.944	1.096	$89\frac{1}{2}$	2.5
14.8055	1.093	$86\frac{3}{4}$	3.75
14.6388	1.093	$86\frac{3}{4}$	2.83
14.722	1.082	$76\frac{1}{2}$	2.83
10.201	1.091	$86\frac{1}{4}$	1
9.75	1.091	$86\frac{1}{4}$	1
11.478	1.098	$91\frac{1}{2}$	1
9.25	1.096	89.67	1

The four last brewings, in which the quantity of yeast added was smaller than in the six first, took place during the month of May, when the heat is apt to make the fermentation run to excess. The variation in the quantity, so conspicuous in the first six brewings, is partly to be ascribed to differences in the goodness of the yeast; but chiefly to the carelessness and want of method which distinguished the brewer in question beyond any one we ever met. But we have taken his quantities, to show that differences in the quantity of yeast are not material; for all the preceding brewings, except the first, furnished very good ale. The wort in the first brewing had been cooled too much; the consequence was, that it fermented very badly, and finally ran into acidity.

Soon after the yeast has been mixed with the wort, an intestine motion begins to appear in the liquid; air bubbles separate from it, and a froth collects slowly upon the surface. This froth is of a yellowish grey colour. At first it has the appearance of cream; but, in a few days, it collects in considerable quantities, especially if the weather be warm. At the same time, the temperature of the wort increases, and a very considerable quantity of carbonic acid gas is given out by it. The increase of temperature which takes place during the fermenting of ale may be stated, at an average, to amount to 12° or 15°. Sometimes it amounts to 20°, and sometimes does not exceed 5°. But, in such cases, there is generally some fault in the skill of the brewer. But the following Table, exhibiting the highest temperatures of different ales during their fermentation, will satisfy the reader of these changes of temperature better than any general explanation:

Quantity of Wort fermented in two Tuns. In Barrels.	Date at which it was let into the fermenting Tuns.	Temperature at that time.	Temperature when at the highest Point of Fermentation.	Date at which this Temperature took place.	Strength of Wort when let into fermenting Tuns, in lbs *per* Barrel.	Quantity of Yeast added in Gallons.
10.83	March 10.	50°	63°	March 17.	88.75	4
14.944 in 1 tun.	March 17.	55	61	March 21.	85.62	$2\frac{1}{2}$
14.8055	March 24.	46	68	April 2.	78.125	$3\frac{3}{4}$
14.6388 in 1 tun.	March 29.	57	70	April 2.	80.625	2.83
14.722	March 31.	56	71	April 3.	73.75	2.83
17.43 in 1 tun.	April 4.	51	64	April 10.	65.00	2.83
8.72 in 1 tun.	April 6.	50	65	April 13.	93.75	$3\frac{1}{2}$

We shall now give some examples of the change of temperature by fermentation, when the brewings were conducted in summer, and of course assisted by the heat of the weather.

Quantity of Wort fermented in Barrels.	Date of letting it into the fermenting Tun.	Temperature at that time.	Temperature when at highest.	Date of ditto.	Strength of Wort in lbs. *per* Barrel.	Yeast used in Gallons.
9.75	May 24.	51°	71°	May 30.	95.93	1
11.4782	May 28.	49	72	June 2.	91.56	1
9.25	May 31.	46	67	June 6.	89.37	1
10.2777	June 4.	46	$67\frac{1}{2}$	June 13.	105.82	1
10.5	June 7.	44	71	June 15.	102.187	1
10.2222	June 11.	55	82	June 15.	110.0	1
10.694	June 18.	53	80	June 24.	96.4	1
13.5	June 21.	53	$67\frac{1}{2}$	June 25.	61.25	1

We shall likewise give the result of two brewings, with raw grain, made also during summer.

Quantity of Wort Fermented in Barrels.	Date of letting do. into the Fermenting Tun.	Temperature at that time.	Temperature when at highest.	Date of ditto.	Strength of Wort in lbs. *per* Barrel.	Yeast used in Gallons.
10.5555	June 26	48°	62°	July 1.	56.25	1
14.3055	July 6.	58	68°	July 8.	72.5	$1\frac{1}{4}$

We see, from the preceding tables, that the length of time which elapses before the fermentation reaches its acme (supposing this to be measured by the temperature) varies very considerably. The shortest interval in the table is three days, and the longest nine days; the average of the whole is very nearly six days, which is exactly the mean between the longest and the shortest times. If the reader will glance his eye over the tables, he will perceive that, in general, the higher the temperature of the wort is when let down into the fermenting tuns, the more rapidly does the fermentation come on. As the worts were cooled by exposure to the greatest cold of the night, and as the coolers were screened from the effects of the radiation of heat, the temperatures given in the third column of the preceding tables may be considered as measuring very nearly the greatest degree of cold which took place in Edinburgh at the dates contained in the second column. Hence it follows, as might have been expected, that the warmer the weather, the more rapid is the fermentation. Hence the advantage of letting down the worts rather warm in cold weather, and cooling them down as much as possible in warm weather. For this purpose, we cannot too much recommend coolers which can occasionally be uncovered altogether, and exposed to the unclouded sky. A roof, perhaps, might be contrived, composed of very light materials, which might be easily slid off, or which might turn upon a pivot. For a roof would be occasionally necessary to screen the worts from rain. In warm weather, brewing should be confined to clear and unclouded days, when the cooling process could be carried farthest of all. We have little doubt that wort might easily be cooled down to the freezing point, if requisite, in our warmest summer weather.

Little can be said about the length of time during which the fermentation of ale lasts; because it varies very much according to the heat of the weather, and the degree to which the wort has been cooled down. The following Table will give some idea of the length of time which elapsed during the fermentations contained in the preceding tables:

FIRST TABLE.

1st - -	8 Days.

Theory of Fermentation.

The theory of fermentation has occupied the attention of chemists ever since the manufacture of ale began to be attended to by men of science; but it is only of late that much light has been thrown upon the subject. Lavoisier was the first person who attempted to give any thing like a theory of this intricate process. He attempted to determine the composition of common sugar, a substance which may be fermented just as well as the soluble part of malt, and which yields similar products. He endeavoured, likewise, to determine the constituents of alcohol, the substance formed by fermentation. With these data, and with a knowledge of the composition of water and carbonic acid, he formed a plausible theory, which was valuable as a first approximation, though there can be little doubt that it was erroneous in every particular. Since that time, several experiments on the subject have been made by Thenard. Guy-Lussac and Thenard, and Berzelius, have determined the constituents of sugar with much care; and Theodore de Saussure has made very elaborate, and, we believe accurate, experiments on the composition of alcohol. These facts will enable us to form a conception of what takes place during fermentation. We shall first state the general theory, as resulting from experiments on common sugar, and then give some experiments, which we ourselves have made on the saccharine matter of malt.

If a weak solution of sugar in water be kept in a warm place, it will ferment of itself, and be converted into a spiritous liquor. This we have tried more than once, and always successfully, provided the weather was warm. A solution of sugar of grapes in water ferments still more speedily. This is said, likewise, to be the case with sugar of starch; and, of course, with the saccharine matter of malt. In our general view of fermentation, then, we may leave out of view the small quantity of yeast; because it is not absolutely necessary, but seems merely to render the effect more rapid, and consequently prevent the change of the liquid into acidity, which almost always takes place when the fermentation is slow.

When the fermentation is complete, the sugar disappears altogether, and two new substances are found in its place. These are, carbonic acid and alcohol. All that happens, then, is the resolution of sugar into the two new substances, carbonic acid and alcohol. It is requisite to know how much of each of these substances is formed from a given weight of sugar.

According to Lavoisier's experiments, 100 parts of sugar yielded, when fermented,

Alcohol, -	57.70
Carbonic acid,	35.34

He does not give us the specific gravity of his alcohol, but it could scarcely be less than 0.825; for when his experiments were made, alcohol of greater

Brewing.

strength was scarcely known. Now, such alcohol contains at least 11 *per cent.* of water; for that quantity has been actually extracted from it. From Saussure's experiments, it is probable that the real quantity of water contained in alcohol of the specific gravity 0.825, is 18.387 *per cent.* or almost a fifth. On this supposition sugar, according to Lavoisier's experiments, yields

Alcohol,	-	47.1
Carbonic acid,		35.34
		82.44

or *per cent.*

Alcohol,	-	57.1
Carbonic acid,		42.9
		100.0

Thenard mixed 60 parts of yeast with 300 of sugar, and fermented the mixture at the temperature of 59°. He informs us, that, in four or five days, all the saccharine matter had disappeared. The quantity of carbonic acid evolved amounted by weight to 94.6 parts. It was perfectly pure, being completely absorbed by water. The fermented liquid being distilled, yielded 171.5 parts of alcohol, of the specific gravity 0.822. When the residue of the distillation was evaporated, 12 parts of a nauseous acid substance remained, and 40 parts of the yeast still continued unaltered in appearance, though Thenard assures us that it had lost the whole of its azote. Thus the products of the fermentations were

Alcohol of 0.822,	-	171.5
Carbonic acid,	- -	94.6
Nauseous residue,	-	12.0
Residual yeast,	- -	40.0
		318.1
Loss,	-	41.9
Total,	-	360.0

But as the nauseous residue and residual yeast, nearly make up the quantity of yeast employed, let us consider only the products of decomposed sugar, supposing the loss to be proportionally divided between the carbonic acid and alcohol. Now, alcohol of the specific gravity 0.822, contains one-tenth of its weight of water, which can be separated from it; and if we suppose, with Saussure, that absolute alcohol contains 8.3 *per cent.* of water, then the products of sugar decomposed by fermentation, according to Saussure's experiments, are as follows:

Alcohol,	-	47.70
Carbonic acid,		35.34
		83.04

or, in 100 parts,

Alcohol,	-	57.44
Carbonic acid,		42.56
		100.00

This result approaches so nearly that of Lavoisier, that there is reason to suspect that the coincidence is more than accidental.

According to the experiments of Thenard and Guy-Lussac, sugar is composed of

Carbon,	- - -	42.47
Oxygen and hydrogen in the same proportion as in water,	- -	57.53
		100.00

According to one analysis of Berzelius, it is composed of

Hydrogen,	-	6.802
Carbon,	-	44.115
Oxygen,	-	49.083
		100.000

and according to another, of

Hydrogen,	-	6.891
Carbon,	-	42.704
Oxygen,	-	50.405
		100.000

Alcohol, according to the analysis of Saussure, is composed of

Hydrogen,	-	13.70 or 3 atoms.
Carbon,	- -	51.98 or 2
Oxygen,	-	34.32 or 1
		100.00

And carbonic acid is composed of

Carbon,	-	27.3 or 1 atom.
Oxygen,	-	72.7 or 2

Hence it is obvious that sugar can be resolved into alcohol and carbonic acid only, on the supposition that it contains 3 atoms of oxygen,
3 atoms of carbon,
3 atoms of hydrogen,

proportions which do not accord with any of the analyses stated above. Supposing its composition to be so, the weight of each of the constituents *per cent.* is as follows:

Hydrogen,	-	6.66
Carbon,	-	40.03
Oxygen,	-	53.31
		100.00

On this supposition, an integrant particle of sugar contains nine atoms, namely, three of oxygen, three of carbon, and three of hydrogen; which are capable of arranging themselves differently, so as to form an integrant particle of alcohol (containing six atoms), and an integrant particle of carbonic acid (containing three atoms).

An integrant particle of sugar is composed

Brewing.

	Oxygen. 3 *Atoms.*	Carbon. 3 *Atoms.*	Hydrogen. 3 *Atoms.*
A particle of alcohol of	1	2	3
A particle of carbonic acid of	2	1	0
	3	3	3

The weight of a particle of alcohol, -	2.877
The weight of a particle of carbonic acid,	2.751

According to these numbers, 100 parts of sugar ought by fermentation to be decomposed into

Alcohol, -	50.76
Carbonic acid,	49.24
	100.00

or it ought to form very nearly equal weights of each of these constituents.

This explanation of fermentation, though in some points hypothetical, must be admitted to approach pretty near the experiments made upon the subject. These experiments are attended with so much difficulty, that rigid accuracy cannot be expected. In all likelihood, we can never arrive at the truth by any other method than that which we have followed upon this occasion. Nor will this method be any longer doubtful, as soon as it is ascertained with precision, that sugar can be resolved into alcohol and carbonic acid, and as soon as we know the proportions of the two substances evolved. We conceive that both Lavoisier and Thenard have stated the quantity of carbonic acid too low, from not being aware that the whole of the sugar is never decomposed by fermentation. This we conclude from some experiments of our own, made on a large scale, of which we shall now proceed to give an account.

Nine different brewings of pure malt were made. The worts were weak, and they were fermented as strongly as possible by means of large quantities of yeast, added at intervals, as is practised by the distillers. The following table exhibits the specific gravity of these worts before and after the fermentation was over:

Specific gravity of the wort.	Specific gravity of ditto after fermentation.
1.040	1.0014
1.056	1.0016
1.050	1.000
1.0492	1.0012
1.0465	1.0045
1.045	1.0047
1.0465	1.0007
1.051	1.0007
1.0524	1.0004

From this table we see, that only one of the worts was reduced by fermentation so low as the specific gravity of pure water. As a good deal of alcohol was evolved in each by the fermentation, it is obvious that they must have all contained a certain portion of saccharine matter undecomposed, notwithstanding the violence of the fermentation, which elevated the temperature of the worts more than 50 degrees. On evaporating a portion of the worts of each of these brewings, we obtained a quantity of undecomposed saccharine matter, which amounted, at an average, to one-fifth of the quantity originally present. At first they contained, at an average, 45 lbs. *per* barrel of saccharine matter. The *spent wash*, after distillation, contained still 9 lbs. *per* barrel. This liquor was capable of being fermented a second time, and yielding more spirits.

Now, as these worts were very weak, and as they were fermented in very advantageous circumstances, and in much greater quantities than either Lavoiser or Thenard could have employed in their experiments, we do not conceive that more than four-fifths of the sugar which they employed in their experiments could have been decomposed. Now, if to the carbonic acid actually developed in their trials we add a fifth part, the number will approach very nearly to the one which we have deduced from the supposition that sugar is decomposed by fermentation into an integrant particle of alcohol, and an integrant particle of carbonic acid.

On comparing the quantity of alcohol of 0.825 obtained in our experiments from the quantity of saccharine matter actually decomposed by fermentation, the result was, that 100 parts of saccharine matter yielded almost exactly 50 parts of such alcohol. This would amount to about 40.9 parts of real alcohol. There could be no doubt that a portion of the alcohol was lost during the distillation, which was conducted in the rapid way followed some years ago by the distillers in Scotland. If we suppose one fifth lost, which is probably not much beyond the truth, the real produce of alcohol from the saccharine matter of malt would be almost exactly one half of its weight, which it ought to be, according to the preceding supposition, that it is decomposed into alcohol and carbonic acid.

When the fermentation is languid, it is customary to beat in the yeast which has collected on the top; that is to say, the whole is stirred till the wort and yeast are thoroughly mixed.

Cleansing.

5. The last step of the process of brewing is called *cleansing*. When the violence of the fermentation is over, the head of yeast, which covers the top of the fermenting tun, diminishes in height by the gradual escape of the carbonic acid gas, which heaved it into bubbles. If the wort were allowed to remain in the gyle-tun after this has happened, the yeast would again mix with it; and the consequence would be, a disagreeable bitter taste, known among brewers by the name of *yeast bitter*. The fermentation would likewise continue, though in a languid manner, and the ale would soon run into acidity. These accidents are prevented by drawing off the ale into small casks. This is called *cleansing*. The casks are filled quite full, and left with their bungs open. The drawing off of the ale from the gyle-tun lowers its temperature, and, of course, checks the fermentation. On this account, the cleansing is sometimes practised in summer, when the elevation of temperature in the wort is at its height.

We have repeatedly observed a curious circum-

Brewing.

stance, during the cleansing, not very easily accounted for. If you take the temperature of the ale at the upper surface of the gyle-tun, and then observe the temperature of the ale when it flows from the stop-cock at the bottom of the tun, we shall generally find it one or two degrees hotter in this latter place than at the former. We ought naturally to expect the highest temperature at the top of the gyle-tun.

The ale still continues to ferment after it is put into the small casks; but, as these casks are always kept full, the yeast, as it comes to the surface, flows out at the bung, and thus separates altogether from the beer. It is this separation that has induced brewers to distinguish it by the name of *cleansing*. In these casks, then, the yeast divides itself into two portions. The greatest part rises up with the carbonic acid evolved, and flows out at the bung-hole; while another portion subsides to the bottom, and constitutes what is called the dregs of the beer. It is essential to the cleansing, that the casks should be always full; otherwise the yeast will not run off, and the beer will not become transparent. This object is accomplished in small breweries by a man constantly going round, and filling up the casks as they *work down*. But in the London breweries there is an ingenious mechanical contrivance, which answers the purpose perfectly.

When the fermentation has subsided, the beer will in general be found transparent. It is bunged up in the casks, and preserved for sale; or in London, where the quantity is too great for this, the beer is removed into large stone vats, capable of holding several thousand barrels, from which it is gradually distributed to the consumers.

In London, where the beer is usually sent to the public-houses as soon as the fermentation is over, and before it has had time to become fine, it is usual to send along with it a quantity of *finings*, as it is called; that is, a solution of isinglass in weak sour beer, made from a fourth mash of the same malt. The publican puts a certain quantity of this into every cask. It forms a kind of web at the surface of the liquid; and, gradually sinking to the bottom, carries with it all the flocculent matter, and leaves the beer transparent.

Tables of Brewing.

We shall terminate this chapter with a Table, exhibiting the results obtained by brewing with malt made from a considerable number of different varieties of barley and big.

CHAP. V.

Of Ale and Beer.

fference tween eer and e.

The English word *ale* is obviously the same with the Swedish word *öl*, which is applied to the same kind of fermented liquor; while the word *beer* is synonymous with the German word *bier*. These two words in Great Britain are applied to two liquors obtained by fermentation from the malt of barley; but they differ from each other in several particulars. Ale is light-coloured, brisk, and sweetish, or, at least, free from bitter; while beer is dark-coloured, bitter, and much less brisk. What is called *porter* in England, is a species of beer, and the term porter at present signifies what was formerly called *strong beer*. The original difference between these two liquids was owing to the malt from which they were prepared. Ale malt was dried at a very low heat, and consequently was of a pale colour; while beer or porter malt was dried at a higher temperature, and had, of consequence, acquired a brown colour. This incipient charring had developed a peculiar and agreeable bitter taste, which was communicated to the beer, along with the dark colour. This bitter taste rendered beer more agreeable to the palate, and less injurious to the constitution than ale. It was consequently manufactured in greater quantities, and soon became the common drink of the lower ranks in England. When malt became high priced in consequence of the heavy taxes laid upon it, and the great increase in the price of barley which took place during the war of the French Revolution, the brewers found out, that a greater quantity of wort of a given strength could be prepared from pale malt than from brown malt. The consequence was, that pale malt was substituted for brown malt in the brewing of porter and beer. We do not mean that the whole malt employed was pale; but a considerable proportion of it. The wort, of course, was much paler than before, and it wanted that agreeable bitter flavour which characterized porter, and made it so much relished by most palates. The porter brewers endeavoured to remedy these defects by several artificial additions. They prepared an artificial colouring matter, by heating a solution of coarse sugar in an iron boiler till it became black, and was reduced to the consistency of treacle. The smoke issuing from it was then set on fire, and the whole was allowed to burn for about ten minutes, when the flame was extinguished by putting a lid on the vessel. This substance was mixed with a certain quantity of water, before it was cold. The porter is coloured by adding about two pounds of this colouring matter for every barrel of wort while in the gyle-tun. Some brewers make their colouring matter with infusion of malt instead of sugar; and, in 1809, M. de Roche took out a patent for preparing the colouring matter from the husks of malt, by burning them like coffee, and then infusing them in water. We believe that all these colouring matters are of the same nature. Of course, the brewer ought to employ that one of them which is cheapest.

rter.

To supply the place of the agreeable bitter which was communicated to porter by the use of brown malt, various substitutes were tried. Quassia, cocculus indicus, and, we believe, even opium were employed in succession; but none of them were found to answer the purpose sufficiently. Whether the use of these substances be still persevered in, we do not know, but we rather believe that they are not, at least by the London porter-brewers.

It was this change in the use of the malt, which occasioned the great falling off in the London porter, which has been so much complained of, and ascribed to so many causes. We do not believe that the schemes of Mr Jackson, of notorious memory, though they enriched himself, produced the injurious effects upon the London breweries that have been ascribed to them. This man, whose character was notorious, kept an apothecary's shop on Tower Hill, and, speculating on the means of amassing a speedy fortune, he hit upon the idea of brewing beer from various drugs instead of malt and hops. But instead of commencing practical brewer himself, he struck out the more profitable trade of teaching his process to the London brewers. Mrs Piozzi informs us, that, even from one great brewer, he contrived to realize an ample fortune. His methods must have been practised upon a considerable scale for some time; but we have no doubt that they have been all abandoned long ago. It was the French war, and the enormous tax upon malt, that was the real cause of the deterioration of the quality of London porter. Nor will it ever recover its former good qualities, till the tax on malt is re-

Brewing.

duced to its former rate; or, unless the price of porter be greatly enhanced, which is not likely to happen. We have sometimes thought, that, if quassia were reduced to powder, and burnt like coffee, it might probably be employed, with great advantage, both as a colouring matter of porter, and as likely to furnish the agreeable bitter, at present considered as peculiar to brown malt.

The quantity of malt employed annually in Great Britain in brewing ale and beer, may be easily deduced from the annual statements of the amount of the malt tax, printed by order of the House of Commons.

Malt employed annually in Great Britain.

In the year 1813, the gross produce of the malt tax for England, was L. 4,188,450, 6s. 9d. Now, as this duty is levied at the rate of four shillings and fourpence *per* bushel, it follows, that the quantity of malt made in England, and charged with duty, amounted to 2,416,384.81 quarters. If we admit, that the quantity of malt actually made, exceeds, by 5 *per cent.* what is charged with duty, in that case, the whole malt actually made in England during the year 1813, was 2,537,204 quarters.

In Scotland the actual receipts during the year 1813, were L. 134,106, 12s. 0¾d. This, at the rate of three shillings and eightpence and half a farthing *per* bushel, which is the rate of the duty for Scotland, makes the amount of the quarters of malt made in that kingdom during the year 1813, to be 91,436.32. We cannot here make the allowance of 5 *per cent.* for the increase of bulk from malting; because we do not know what portion of this malt was made from English and what from Scotch barley. But as the duty in the Highlands of Scotland is lower than in the Lowlands, and, as it cannot be doubted, that a very considerable proportion of the barley malted in Scotland is the growth of England, perhaps we shall not err very far if we reckon the whole of the malt actually made in Scotland in 1813, at 100,000 quarters, which is only one twenty-sixth part of the whole malt made in Great Britain. Hence it follows, that four times as much beer is consumed in England as in Scotland, in proportion to the population of the two countries. This is a prodigious advantage in favour of Scotland; for there cannot be a doubt, that beer is inferior in salubrity to plain water as a beverage, and that, if the money spent by the common people in England on beer, were employed to buy food, they would be much more healthy, stout, and happy than they are at present.

In the year 1814, the gross receipts of the malt tax in England amounted to L. 4,772,332, 5s. 5½d. This, at the rate of four shillings and fourpence *per* bushel, indicates 2,753,268.6 quarters of malt; and, making an allowance of 5 *per cent.*, it follows, that the whole malt made in England in 1814, amounted to 2,890,932 quarters.

In Scotland, during the same year, the gross receipts on the malt duty amounted to L. 125,787, 7s. 10¼d., which, at the rate of three shillings and eightpence one-eighth *per* bushel, indicates 85,521.18 quarters of malt. We may increase this on account of the increase of malt not reckoned in the tax, and on account of the tax in the Highlands being lower than in the Lowlands, to 90,000 quarters of malt, which is a tenth less than the quantity malted in 1813, while, in England, the quantity malted had increased considerably. Thus, it appears, that the whole quantity of malt made in Great Britain during the year 1814, was 2,980,932 quarters.

Malt made in 1813, in quarters,	2,637,204
Ditto in 1814, - -	2,980,932
Mean, - -	2,809,068

But this consumption of barley, enormous as it is, by no means gives us the whole of that grain consumed annually in Great Britain in the manufacture of spiritous liquors. For the distillers employ at least two-thirds of the barley which they use in the state of raw grain. Now, this quantity does not pay any malt tax, and, of course, is not included in the preceding estimate. It might be possible to form an idea of this quantity from the duty levied upon spirits; but such an inquiry would be foreign to the subject of this article.

But perhaps the following Table, exhibiting the quantity of porter brewed by the thirteen principal houses in London, during each of the last nine years, will give the reader a more accurate conception of the extent to which this trade is carried in this country.*

* There are many other porter-brewers in London besides those whose names are contained in this Table. The following were the seven next in order to those given in the Table for 1812, with the quantity of porter manufactured by each:

Martineau and Co. - -	24,143 barrels.	Tickels - - -	18,071 barrels.
Hodgson - - -	24,143	Dickinson - - -	16,292
Pryors - - -	20,210	Green and Co. - -	14,090
Starkey - -	18,136		

If we were to give an opinion respecting the different modes followed in the different houses, we would place Martineau at the head of the trade in point of accuracy and skill.

The following Table exhibits the quantity of strong ale brewed by the seven principal houses in London, in the year ending the 5th of July 1815:

Stretton and Co. -	27,094 barrels.	Hale and Co. - -	10,134 barrels.
Wyatt - - - -	22,146	Ball and Co. - -	7,985
Charrington and Co. -	20,444	Thorpe and Co. -	5,433
Goding and Co. -	14,491

To form a proper estimate of the quantity of porter contained in this Table, it is necessary to know that the London barrel contains 36 gallons.

The usual limits of the wort of strong ale in this country, may be stated at from 60 to 120 pounds *per* barrel, or from the specific gravity 1.064 to 1.11275 at the temperature of 60°. The highest priced ales are not always the strongest; as the price depends in a great measure on the reputation of the brewer. The fermentation of ale is not carried far; the consequence is, that a considerable portion of the saccharine matter still remains in the liquid, apparently unaltered. By means of the infusion of nut-galls, too, traces of starch may be still detected in strong ale even after it has been kept for some time in bottles. The annexed Table exhibits the original strength of the wort before the fermentation began, and likewise the diminution of specific gravity produced by the fermentation, or the *attenuation*, as this diminution is termed by brewers and distillers.

As a certain quantity of alcohol is evolved in the ale by the fermentation, it is obvious that the last column is not quite accurate. The real quantity of saccharine matter in each of these also must be greater than what is indicated in that column, because the effect of the saccharine matter, in increasing the specific gravity of the ale, is counteracted by the alcohol, which tends to diminish that specific gravity. By casting the eye over the preceding Table, it will be seen that the attenuation does not follow the ratio of the strength. It was greatest of all in the third, and least in the first brewing. These brewings being the same with those given in the fourth chapter, in order to illustrate the quantity of yeast used in fermenting, the reader, by comparing the two Tables together, will be able to form some

Original specific gravity of the Wort.	lbs. *per* barrel of saccharine matter in it.	Specific gravity of the Ale.	lbs. *per* barrel of saccharine matter in it.	Attenuation or proportion of saccharine matter decomposed.

* During the last four years in the table, we have substituted Cox and Campbell.
† During the last four years, we have substituted Hollingsworth and Company.

Brewing.

conclusions respecting the effect of different quantities of yeast, and different temperatures upon the attenuation of strong ale.

Strength of Porter.

Porter is much weaker than strong ale. The average specific gravity of porter-wort, according to Shannon (as deduced from his strength by the *saccharometer*), is 1.0645, which indicates 60 pounds *per* barrel of saccharine extract. Hence the reason why it is so much less glutinous and adhesive than strong ale. The fermentation which porter undergoes is, we believe, much less than that of ale. But we have no very accurate information on the subject. According to the experiments of Mr Brande, brown stout, which is the strongest porter made in London, contains 6.8 *per cent.* by measure, of alcohol of the specific gravity 0.825. If he had given us the specific gravity of this porter before distillation, it would have enabled us to determine in some measure the error in the attenuation, as indicated by the *saccharometer*.

The porter-brewers in London use three kinds of malt; namely, pale malt, amber malt, and brown malt. These three are mashed separately, and the worts from each are afterwards mixed together in the same fermenting vessel. In some breweries, as in that of Barclay and Perkins in the Borough, there are three separate mash-tuns. In other breweries, the custom is to mash one kind of malt the first day, another kind the second day, and a third kind the third day. The first day's wort is put into the fermenting vessel, and mixed with yeast; and the other two worts are added to it successively as they are formed. Hence it is very difficult to determine with accuracy the strength of the worts in the London breweries. It could only be done by knowing the quantity of wort from each malt, and its specific gravity when let into the fermenting vessel. We have had an opportunity of determining the strength of the porter wort in all the principal breweries in London. The average specific gravity of brown-stout wort is 1.0624. The wort of the best common porter is of the specific gravity 1.0535; that of the worts or weakest is as low as 1.0374. The average specific gravity deduced from 20 brewings was 1.0500. Such wort contains about 46.4 lbs. *per* barrel of saccharine matter. Judging from the taste of some of the worts, quassia seems to be employed in considerable quantity by some of the brewers, and much more sparingly, if at all, by others. The fermentation of porter is carried on with considerable rapidity, so that it is over in two or three days. The specific gravity of the porter is usually brought down to 1.013 or 1.017. The specific gravity of the best brown-stout, after standing some months in the bottle, is 1.0106. The proportion of pale and brown malt used in the different houses varies. One of the best brewers in London uses nearly 2 parts pale malt to 1 part brown. (J.)

EXPLANATION OF THE PLATES.

Figs. 1. and 2., Plate XL., explain the arrangement of the Utensils and Machinery in a Porter-Brewery on the largest scale; in which, however, it must be observed, that the elevation fig. 1. is, in a great degree, imaginary, as to the plane upon which it is taken; but the different vessels are arranged so as to explain their uses most readily, and, at the same time, to preserve, as nearly as possible, the relative positions which are usually assigned to each, in works of this nature.

The malt for the service of the brewery is stored in vast granaries or malt-lofts, usually situated in the upper part of the buildings. Of these, we have only been able to represent one at A, fig. 1.; the others, which are supposed to be on each side of it, cannot be seen in this view. Immediately beneath the granary A, is the mill, in the upper floor of which are two pair of rollers, for bruising or crushing the grains of the malt. (An enlarged representation of the rollers is given at figs. 3. and 4.) In the floor beneath the rollers are the mill-stones *bb*, where the malt is sometimes ground, instead of the simple bruising which it receives by passing between the rollers.

The malt, when prepared, is conveyed by a trough into a chest *d*, from which it can be elevated by the action of a spiral screw *e* (see also figs. 5. and 6.), into the large chest or binn B, for ground malt, situated immediately over the mashing-tun D. The malt is reserved in the binn till wanted; and it is then let down into the mashing-tun, where the extract is obtained by hot water supplied from the copper G.

The water, for the service of the brewery, is obtained from the well E, by a lifting pump worked by the steam-engine, and the forcing-pipe *f* of this pump, conveys the water up to the large reservoir or water-back F, placed at the top of the engine-house; from this cistern iron pipes are laid to the copper G, and also every part of the establishment where cold water can be wanted for cleaning and washing the vessels. The copper G can be filled with cold water by only turning a cock; and the water, when boiled therein, is conveyed by the pipe *g*, into the mashing-tun D; it is introduced beneath a false bottom, upon which the malt lies, and rising up through the holes in the false bottom, it extracts the saccharine matter from the malt; a greater or less time being allowed for the infusion, according to circumstances. The instant the water is drawn off from the copper, fresh water must be let into it, in order to be boiled ready for the second mashing; because the copper must not be left empty for a moment, otherwise the intense heat of the fire would melt the bottom. For the convenience of thus letting down, at once, as much liquor as will fill the bottom of the copper, a pan or second boiler is placed over the top of the copper, as seen in fig. 3. Plate XLI., and the steam rising from the copper, communicates a considerable degree of heat to the contents of the

4

pan, without any expence of fuel. This will be more minutely explained hereafter.

During the process of mashing, the malt is agitated in the mash-tun to expose every part to the action of the water. This is done by a machine contained within the mash-tun, and put in motion by the horizontal shaft H, leading from the mill. The mashing-machine is shown in fig. 1. Plate XLI. When the mashing is finished, the wort, or extract, is drained down from the malt, into a vessel I, of similar dimensions to the mash-tun, and situated immediately beneath, from which it is called the under-back. Here the wort does not remain longer than is necessary to drain off the whole of it from the tun above. It is then pumped up by the three-barrelled pump *k*, into the pan at the top of the copper, by a pipe which cannot be seen in the Plate.

The wort remains in the copper pan until the water, for the succeeding mashes, is discharged from the copper. But this waiting is no loss of time, because the heat of the copper and the steam arising from it, makes the wort, which had become cooler, ready for boiling. The instant the copper is empty, the wort is let down from the pan into the copper, and the second wort is pumped up from the under-back into the copper pan. The proper proportion of hops is thrown into the copper through the near hole, and then the door is shut down, and screwed fast, to keep in the steam, and cause it to rise up through pipes into the pan; and by bubbling up, through the wort in the pan, it communicates so much heat, that it is soon ready for boiling in its turn; for it is to be observed, that the different worts follow each other, through all the different vessels, with the greatest regularity, so that there is no loss of time, but every part of the apparatus is constantly employed. When the boiling of the wort has continued a sufficient time to coagulate the grosser part of the extract and to evaporate part of the water, the contents of the copper are run off through a large cock into the jack-back K; which is a vessel of sufficient dimensions to contain it, and provided with a bottom of cast-iron plates, perforated with small holes, through which the wort drains and leaves the hops. The hot wort is drawn off from the jack-back through the pipe *h*, by the three-barrelled pump, which throws it up to the coolers L; this pump being made with different pipes and cocks of communication, to serve all the purposes of the brewery except that of raising the cold water from the well. The coolers L, are very shallow vessels, built over one another in several stages; and that part of the building in which they are contained, is built with open lattice-work on all sides, to admit the free current of air. When the wort is sufficiently cooled to be put to the first fermentation, it is conducted in pipes, from all the different coolers, to the large fermenting vessel or gyle-tun M, which, with another similar vessel behind it, is of sufficient capacity to contain all the beer of one day's brewings.

When the first fermentation is concluded, the beer is drawn off from the great fermenting vessels M, into the small fermenting casks, or cleansing vessels N, of which there are a great number in the brewery. They are placed four together, and to each four a common spout is provided to carry off the yeast and conduct it into the troughs *u*, placed beneath. In these cleansing vessels the beer remains till the fermentation is completed, and it is then put into the store-vats, which are casks or tuns of an immense size, where it is kept till wanted, and is then drawn off into barrels and sent away from the brewery. The store-vats are not represented in the Plate, but are of a conical figure and of different dimensions, from fifteen to forty feet diameter, and usually twenty feet in depth. The steam-engine which puts all the machinery in motion is explained by the figure. On the axis of the large fly-wheel, is a bevelled cog-wheel, which turns another similar wheel upon the end of an horizontal shaft, which extends from the engine-house to the great horse-wheel, which it turns by means of a cog-wheel. The horse-wheel puts in motion all the pinions for the mill-stones *bb*, and also the horizontal axis which works the three-barrelled pump *k*. The rollers *aa* are turned by a bevelled wheel upon the upper end of the axis of the horse-wheel, which is continued for that purpose; and the horizontal shaft H, for the mashing-engine, is driven by a pair of bevelled wheels. There is likewise a sack-tackle, which is not represented. It is a machine for drawing up the sacks of malt from the court-yard to the highest part of the building, whence the sacks are wheeled on a truck to the malt-loft A, and the contents of the sacks are thrown in.

The horse-wheel is intended to put in horses occasionally, if the steam-engine should fail; but these engines are now brought to such perfection that it is very seldom any accidents occur with them.

Fig. 2. Plate XL. is a representation of the fermenting-house at the brewery of Messrs. Whitbread and Co. Chiswell Street, London, which is by far the most complete in its arrangement of any work of the kind, and was erected after the plan of Mr Richardson, who conducts the brewing at those works. The whole of fig. 2. is to be considered as devoted to the same object as the large vessel M, and the casks N, fig. 1. In fig. 2. *r* is the pipe which leads from the different coolers to convey the wort to the great fermenting vessels or squares M, of which there are two, one behind the other; *ff* represents a part of the great pipe which conveys all the water from the well E, fig. 1. up to the water cistern F. This pipe is conducted purposely up the wall of the fermenting-house, fig. 2., and has a cock in it, near *r*, to stop the passage. Just beneath this passage a branch-pipe *p*, proceeds and enters a large pipe *xx*, which has the former pipe *r*, withinside of it. From the end of the pipe *x*, nearest to the squares M, another branch *nn* proceeds, and returns to the original pipe *f*, with a cock to regulate it. The object of this arrangement is to make all, or any part of, the cold water flow through the pipe *xx*, so as to surround the wort-pipe *r*, which is only made of thin copper, and lower the temperature of the wort passing through the pipe *r*, until, by the thermometer, it is found to have the exact temperature which is desirable, before it is put to ferment in the great square M. By means of the cocks at *n* and *p*, the quantity of cold water,

which shall pass in contact with the surface of the pipe *r*, can be regulated at pleasure, so as to have a command of the heat of the wort when it enters into the square.

When the first fermentation in the squares M is finished, the beer is drawn off from them by pipes marked *v*, and conducted by its branches *w* to the different rows of fermenting tuns marked NN, which fill all the building. Between every two rows are placed large troughs, to contain the yeast which they throw off. The Plate shows that the small tuns are all placed on a lower level than the bottom of the great vessels M, so that the beer will flow into them, and, by standing in them all, will fill them to the same level. When they are filled, the communication-cock is shut; but, as the working off of the yeast diminishes the quantity of beer in each vessel, it is necessary to fill them up again. For this purpose, the two large vats OO are filled from the great vessels M, before any beer is drawn off into the small casks N, and this quantity of beer is reserved at the higher level for filling up. The two vessels OO are, in reality, placed between the two squares M, but we have been obliged to place them so that they can be seen. Near each filling-up tun *o* is a cistern *t*, with a pipe of communication from the tun O, and this pipe is closed by a float-valve. The small cisterns *t* have always a communication with the pipes, which lead to the small fermenting vessels N; and therefore the surface of the beer in all the tuns and in the cisterns will always be at the same level; and as this level subsides by the working off of the yeast from the tuns, the float sinks, and opens the valve, so as to admit a sufficiency of beer from the filling up tuns *o*, to restore the surfaces of the beer in all the tuns, and also in the cistern *t* to the original level. In order to carry off the yeast which is produced by the fermentation of the beer in the tuns OO, an iron dish or vessel is made to float upon the surface of the beer which they contain; and from the centre of this dish a pipe *o* descends, and passes through the bottom of the tun, being filled through a collar of leather, so as to be tight, at the same time that it is at liberty to slide down as the surface of the beer descends in the tun. The yeast flows over the edge of this dish, and is conveyed down the pipe to a trough beneath.

Beneath the fermenting house are large arched vaults P, built of stone, and lined with stucco. Into these the beer is let down when sufficiently fermented, and is kept till wanted. These vaults are used at Mr Whitbread's brewery instead of the great store vats of which we have before spoken, and are in some respects preferable, because they preserve a great equality of temperature, being beneath the surface of the earth.

Figs. 3. and 4. Plate XL. represent the malt-rollers, or machine for bruising the grains of malt. A is the hopper, into which the malt is let down from the malt-loft above; and from this the malt is let out gradually through a sluice or sliding-shuttle *a*, and falls between the rollers BD. These rollers are made of iron, truly cylindrical, and their pivots are received in pieces of brass let into iron frames, which are bolted down to the wooden frame of the machine. A screw, E, is lapped through the end of each of these iron frames; and by these screws the brasses can be forced forwards, and the rollers made to work closer to each other, so as to bruise the malt in a greater degree. G is the shaft by which one of the rollers is turned; and the other receives its motion by means of a pair of equal cog-wheels H, which are fixed upon the ends of the pivots, at the opposite ends of each of the rollers: *d* is a small lever, which bears upon the teeth of one of these cog-wheels, and is thereby lifted up every time a cog passes. This lever is fixed on the extremity of an axis, which passes across the wood frame; and in the middle of it has a lever *c*, fig. 3. bearing up a trough *b*, which hangs under the opening of the hopper A. By this means the trough *b* is constantly jogged, and shakes down the malt regularly from the hopper A, and lets it fall between the rollers: *e* is a scraper of iron plate, which is always made to bear against the surface of the roller by a weight, to remove the grains which adhere to the roller.

Fig. 5. is the screw by which the ground or bruised malt is raised up, or conveyed from one part of the brewery to another. K is an inclined bar or trough, in the centre of which the axis of the screw H is placed, and the spiral iron plate or worm, which is fixed projecting from the axis, and which forms the screw, is made very nearly to fill the lower part of the inside of the box. By this means, when the screw is turned round by the wheels FF, or by any other means, it raises up the malt from the box *d*, and delivers it at the spout G.

The screw is equally applicable for conveying the malt horizontally in the trough *k* as inclined; and similar machines are employed in various parts of breweries for conveying the malt wherever the situation of the works require.

Fig. 1. Plate XLI. is the mashing-machine. WW is the tun, made of wood staves, hooped together. In the centre of it rises a perpendicular shaft NN, which is turned slowly round by means of the bevelled wheels KI at the top. RR are two arms projecting from the axis, and supporting the short vertical axis S at the extremities, so that, when the central axis is turned round, it will carry the axle S round the tun in a circle. The axis S is furnished with a number of arms T, which are shown in fig. 2, and have blades placed obliquely to the plane of their motion. When the axis is turned round, these arms agitate the malt in the tun, and give it a constant tendency to rise upwards from the bottom.

The motion of the axis S is produced by a wheel Q on the upper end of it, which is turned by a wheel P, fastened on the lower end of the tube O, which turns freely round upon the central axis N. On the upper end of the same tube O is a bevelled wheel M, receiving motion from a wheel L, which is fixed upon the end of the horizontal axis F, which gives motion to the whole machine. This same axis has a pinion G upon it, which gives motion to the wheel H, fixed upon the end of an horizontal axle, which, at the opposite end, has a bevelled pinion I, working the wheel K, before mentioned. By this means the rotation of the central axis N will be very slow, compared with the motion of the axis S; for the latter

will make 17 or 18 revolutions on its own axis in the same space of time that it will be carried once round the tun by the motion of the axis N. At the beginning of the operation of mashing, the machine is made to move with a slow motion; but, after having wetted all the malt by one revolution, it is made to revolve quicker. For this purpose the ascending shaft A, which gives motion to the machine, has two bevelled wheels BC fixed upon a tube X, which is fitted upon the shaft. These wheels actuate the wheels D and E upon the end of the horizontal shaft F; but the distance between the two wheels B and C is such, that they cannot be engaged both at once with the wheels D and E; but the tube X, to which they are fixed, is capable of sliding up and down on the axis A sufficiently to bring either wheel B or C into action with its corresponding wheel E or D upon the horizontal shaft; and as the diameters of BE and CD are of very different proportions, the velocity of the motion of the machine can be varied at pleasure, by using one or other: *b* and *c* are two levers, which are forked at the ends, and embrace collars at the ends of the tube X; and the levers being united by a rod, the handle *b* gives the means of moving the tube X and its wheels BC up or down, to obtain the action of the different wheels.

Figs. 3. and 4. represent a large close copper. AA is the copper, and B the pan placed over it. The copper has a large tube E rising up from the dome of it, to convey the steam; and from the top of this, four inclined pipes R descend, the ends being immersed beneath the surface of the water or wort contained in the pan. By this means the steam which rises from the copper issues from the ends of the pipes R, and rises in bubbles through the liquor in the pan, so as to heat it. In the centre of the copper is a perpendicular spindle *a*, which, at the lower end, has arms *dd* fixed projecting from it, and is turned round by a cog-wheel *b* at the upper end. From the arms *dd*, chains are hung in loops, which drag round upon the bottom of the copper, when the axis is turned; and this motion stirs up the hops, to keep them from burning to the bottom: *fg* is a chain and roller to draw up the spindle *a*, when the rowser is not wanted; and *ee* are iron braces proceeding from the outside of the copper, to retain the axis *a* firmly in the centre of the copper. D is the waste-pipe for carrying off the steam into the chimney, when it is not required to heat the liquor in the pan. The copper represented in the drawing is made in the same manner as usual; but the fire is applied beneath it in a manner very different from the common brewing-coppers. The method was devised with a view to the burning or consuming the smoke; and was employed in the brewery of Messrs Meux and Company, London, about the year 1803.

The fire-place is divided into two by a wall extended beneath the bottom of the boiler, as shown by Z in the plan, fig. 4. where the dotted circle A represents the bottom of the copper, and the circle X its largest part. The section in fig. 3. shows only one of these fire-places, of which C is the fire-grate; the raw coal is not thrown in through the fire door in the manner of common furnaces, but is put into a narrow inclined box of cast-iron *h*, built in the brick-work, and shaped like a hopper; the coals contained in this hopper fill it up, and stop the entrance of the air so as to answer the purpose of a door; and the coals at the lowest part or mouth of the hopper, are brought into a state of ignition before they are forced forwards into the furnace, which is done by introducing a rake or poker at *i*, just beneath the lower end of the hopper *h*, and forcing the coals forwards upon the grate bars C. Immediately over the hopper *h*, a narrow passage is left to admit a stream of fresh air along the top of the hopper to pass over the surface of the fuel, which is burning at the lower end of the hopper *h*. By this means the smoke rising from that portion of fuel, is carried forwards over the burning coals upon the grate C, and is thereby consumed. Beyond the grate bars *c*, a breast wall S is erected, to direct the flame upwards, against the bottom of the boiler A, and thence descending under the bottom, the flame is received into the flues, which make each a half turn round the lower part of the copper, as shown in the plan at *t t*, and then enter the chimney or perpendicular flue W at the same point; the entrance being regulated by a damper to make the draught more or less intense. There is also a sliding door or damper E, which closes up the lower part of the chimney, and by means of these two dampers the fire under the copper can be regulated to the greatest precision; for by opening the damper F it admits the cold air to enter immediately into the chimney, W, and thus take off the rapidity of the draught; and, at the same time, by closing the dampers from the flues into the chimney, the intensity of the draught through the fire is checked, which is very necessary to be done when the contents of the copper are drawn off. Immediately over the fire-grate *c*, an arch of fire-bricks or stone, *s*, is placed beneath the bottom of the copper, to defend it from the intense heat. The chimney is supported on iron columns RR. Behind the fire-grate *c*, is a cavity, *r*, for the reception of the masses of scoriæ which are always formed in so large a fire. They are pushed back off the grate into this receptacle with an iron hook, as fast as they accumulate. The bottom of this receptacle is formed of sliding iron doors, which can be opened by drawing them out, and in this way the clinkers are discharged; or the whole of the fire may be driven back off the grate into this cavity, and will then fall through into the ash-pit and be removed from the copper, which is very necessary to be done when the copper is to be cooled, so that men may descend into it to clean out the sediment which is left after boiling the wort. For a more particular description of this method of setting boilers, see *Philosophical Magazine*, Vol. XVII.

Fig. 6. represents one of the sluice-cocks which are used to make the communications of the pipes with the pumps or other parts of the brewery. BB represents the pipe in which the cock is placed. The two parts of this pipe are screwed to the sides of a box CC, in which a slider A rises and falls, and intercepts at pleasure the passage of the pipe. The slider is moved by the rod *a*, which passes through a stuffing-box in the top, the box which

contains the slider, and has the rack b fastened to it. The rack is moved by a pinion fixed upon the axis of a handle e, and the rack and pinion is contained in a frame d, which is supported by two pillars. The frame contains a small roller behind the rack, which bears it up towards the pinion, and keeps its teeth up to the teeth of the pinion. The slider A is made to fit accurately against the internal surface of the box C, and it is made to bear against this surface by the pressure of a spring, so as to make a perfectly close fitting.

Fig. 5. is a small cock to be placed in the side of the great store-vats, for the purpose of drawing off a small quantity of beer, to taste and try its quality. A is a part of the stave or thickness of the great store-vat; into this the tube B of the cock is fitted, and is held tight in its place by a nut $a\,d$ screwed on withinside. At the other end of the tube B, a plug c is fitted, by grinding it into a cone, and it is kept in by a screw. This plug has a hole up the centre of it, and from this a hole proceeds sideways and corresponds with a hole made through the side of the tube when the cock is open; but when the plug c is turned round, the hole will not coincide, and then the cock will be shut. D is the handle or key of the cock, by which its plug is turned to open or shut it; this handle is put up the bore of the tube (the cover E being first unscrewed and removed), and the end of it is adapted to fit the end of the plug of the cock. The handle has a tube or passage bored up it to convey the beer away from the cock when it is opened, and from this the passage f, through the handle, leads to draw the beer into a glass or tumbler. The hole in the side of the plug is so arranged, that when the handle is turned into a perpendicular direction with the passage f downwards, the cock will be open. The intention of this contrivance is, that there shall be no considerable projection beyond the surface of the tun; because it sometimes happens that a great hoop of the tun breaks, and falling down, its great weight would strike out any cock which had a projection; and if this happened in the night much beer might be lost before it was discovered. The cock above described being almost wholly withinside, and having scarcely any projection beyond the outside surface of the tun, is secure from this accident.

Fig. 7. is a small contrivance of a vent peg, to be screwed into the head of a common cask when the beer is to be drawn off from it, and it is necessary to admit some air to allow the beer to flow. AA represents a portion of the head of the cask into which the tube B is screwed. The top of this tube is surrounded by a small cup, from which project the two small handles CC, by which the peg is turned round to screw it into the cask. The cup round the upper part of the tube is filled with water, and into this a small cup D is inverted; in consequence, the air can gain admission into the cask when the pressure within is so far diminished that the air will bubble up through the water, and enter beneath the small cup D. (R.)

BRICK, a kind of artificial stone made of baked clay.

History. 1. The art of making bricks is so simple that it must have been practised in the earliest ages of the world; probably before mankind had discovered the method of fashioning stones to suit the purposes of building. The Book of Genesis informs us, that burnt-bricks were employed in the construction of Babel. Now, as this structure appears to have been raised about 400 years after the period of the flood, we may say, without much exaggeration, that the method of making bricks existed from the very origin of society. Bricks seem to have been in common use in Egypt while the Israelites were in subjection to that nation; for the task assigned them was the making of brick; and we are informed in Exodus, that the Israelites built two Egyptian cities. No particulars are given in scripture of the method of making bricks; but as straw was one of the ingredients, and as it very seldom rains in Egypt, it is probable that their bricks were not burnt, but merely baked by the heat of the sun. The same mode of making bricks seems still to be practised in the East. For the ruins of the tower near Bagdad, which some have considered as the Tower of Babel, others as the Tower in Babylon described by Herodotus (lib. i. c. 181.), is formed of unburnt-bricks. We have seen specimens from that place; they are large, but thin, and have a brown colour. It is not at all likely that structures of unburnt-brick should be able to resist the weather since the time of Nebuchadnezzar; it is much more probable that the tower in question was raised by the Arabs in comparatively modern times.

The art of brick-making was carried to considerable perfection by the Greeks. Pliny informs us, that they made use of bricks of three different sizes, distinguished by the following names; *didoron*, or six inches long; *tetradoron*, or twelve inches long; and *pentadoron*, or fifteen inches long (lib. xxxv. c. 14). That the Romans excelled in the art of making bricks we have the amplest evidence, since brick structures raised at Rome 1700 years ago, Trajan's pillar for example, still remain as entire as when first built. Brick-making has been carried to great perfection by the Dutch, who have long been in the habit of forming their floors, and even of paving their streets, in some cases, with bricks. And it is remarkable how long their bricks will continue uninjured in such situations. Though brick-making has been long carried on in England, and especially in the neighbourhood of London, upon a very great scale, and though the process upon the whole is conducted in this country with very considerable skill, yet it must be acknowledged, that English bricks are by no means so durable as Dutch bricks. We are disposed to ascribe this inferiority not so much to the nature of the materials employed in the manu-

facture of English bricks, as to the mode most frequently employed in London in building houses. Few of the London houses, comparatively speaking, are freeholds. Most of them are built upon ground let for a lease of a certain number of years, which seldom exceeds 99 years. After the expiration of this period, the house becomes the property of the landlord who let the ground. Thus it becomes the interest of the builder to construct the house so, that it shall last only as long as the lease. Hence the goodness of the bricks becomes only a secondary object. Their cheapness is the principal point. The object, therefore, of the brickmakers is not to furnish durable bricks, but to make them at as cheap a rate as possible. Accordingly, the saving of manual labour, and of fuel, have been carried by the makers of London bricks to very great lengths. We cannot but consider this mode of proceeding as very objectionable, and as entailing a much heavier expence upon London than would have been incurred had twice the original price been laid out upon the bricks when they were first used, and had the houses been constructed to last a thousand instead of a hundred years. No doubt, certain advantages attend these ephemeral structures. The inhabitants are enabled, once every century, to suit their houses to the prevailing taste of the day. Thus, there are no antiquated houses in London. But as the increase of the price of all the materials of building has more than kept pace with the increase of the wealth of individuals, it is to be questioned whether the houses are always improved when they are pulled down and rebuilt.

Nature and kinds of clay.

2. The best material for making brick is what in the English language is called *loam*, a term usually applied to a natural mixture of sand and clay. Such a mixture may be converted into brick without any addition whatever. Marl likewise answers the purpose of common bricks very well,—indeed better than most other mixtures. Marl is a natural mixture of limestone and clay in variable proportions. Now, the more lime it contains, the better does it answer for a manure; and the less lime it contains, the more suitable it is to the brickmaker.

It would be in vain to attempt a particular detail of the constituents of clays, because they vary too much from each other to admit of any correct generalization. We believe, however, that clays very frequently consist of decomposed felspar, in which case we may conceive them as composed of about three parts of silica in the state of a very fine powder, and one part of alumina. This is the case with porcelain clay. Indeed, the porcelain clay of Cornwall appears incontrovertibly to be nothing else than decayed felspar, or perhaps felspar which never had assumed any other form than that of clay. The rock from which it is taken is an agglutinated mixture of quartz and this clay. The quartz is separated by washing. Such a rock might probably be converted into most beautiful brick, merely by cutting it out in the proper shape, and subjecting it to the requisite heat; or rather by kneading the whole into a paste with the requisite quantity of water, moulding it into bricks, and drying and burning them.

Potter's clay is a compound of

Silica	43.5
Alumina	33.2
Lime	3.5
Oxide of iron	1.0
Water	18.0
	99.2
Loss	8
Total	100.0

When the clay proceeds from the decomposition of hornblende, as is likewise often the case, it contains about $3\frac{1}{2}$ parts of silica, 1 of alumina, 1 of lime, and about $1\frac{1}{2}$ of oxide of iron. Sometimes the grains of sand which exist in clay consist of fragments of felspar. In such cases the clay may be fused by heat.

No mixture of alumina and silica, in any proportions whatever, can be fused by the strongest heat which can be raised in our furnaces. Hence such mixtures are best adapted for making fire-bricks, crucibles, and glasshouse pots. Stourbridge clay is such a mixture, blackened by coaly matter. It answers these purposes better than any other clay in England. Neither can a mixture of lime and alumina be fused, in whatever proportions the ingredients be mixed. But a mixture of silica, lime, and alumina, is very fusible, and the fusion is most readily effected when we employ two parts of silica to one of lime. The presence of oxide of iron also renders clay fusible, but not unless its proportion be much greater than ever is likely to occur in any clay used for the manufacture of bricks.

For making common bricks, the most durable mixture ought to be common clay and limestone or chalk. Perhaps the best proportions would be three parts of clay, and one part of limestone or chalk in powder. When such a mixture is exposed to heat, it would experience an incipient fusion, and would thereby be rendered much harder and denser than common bricks. The consequence would be, that it would imbibe much less water, and would therefore be much less liable to crack and fall to pieces in winter than common bricks. For when water has insinuated itself into the pores of a common brick, and is converted into ice, it undergoes an expansion which dislocates the parts of the brick, and reduces it to fragments. This is often conspicuously the case with tyles, which, from their exposed situation, are more liable to be soaked with water than common bricks. Hence also covering the surface of the brick with a coating of paint has a great tendency to preserve them from cracking and breaking. This practice is frequently followed in England.

It would be foreign to the object of this article to enter into any long details respecting the chemical investigations, and the opinions entertained at different periods respecting the nature of clay. At first, it was supposed to be a peculiar species of earth, but Hellot demonstrated that it consisted at least of two constituents; for sulphuric acid had the property of destroying its plastic nature, and of rendering it scarcely more adhesive than sand. The

Brick.

portion that remained behind did not effervesce with acids. It was not, therefore, of a calcareous nature. Mr Pott went a step farther; he showed in the continuation of his *Lithogeognosia* that sulphuric acid formed, with the portion of clay which it dissolved, a salt possessing the properties of alum. In the year 1769, Baumé published his *Dissertation on Clays*, which he had drawn up in consequence of a premium offered by the Academy of Sciences at Bourdeaux, for the best solution of the following question: What are the principles and constituents of clay, and the natural changes which it experiences, and what are the methods of rendering it fertile? The Academy did not consider Baumé's solutions as satisfactory. He published his Memoir, in consequence, as a kind of defiance. He had been employed along with Macquer in making numerous experiments on clay, with a view to the improvement of the porcelain manufacture in France. Guided by these experiments, he drew as a conclusion that clay is a mixture of two different substances; 1. Silica in a state of purity; 2. Silica combined with an underdose of sulphuric acid. It was the second of these constituents that gave to clay its fatty and plastic nature. Margraaf had long before (in 1756) demonstrated that the ingredient of clay which Baumé took for a salt, and which he affirmed was soluble in water, was a peculiar species of earth, different from every other, which constitutes the basis of alum, which dissolves in sulphuric acid, but which does not form alum unless a portion of potash be added to the solution. Thus, by the labours of Hellot, Pott, Baumé, and Margraaf, the nature of clay was completely developed. It was ascertained to be a mixture of alumina and silica, in variable proportions. It was shown, also, that it sometimes contained sulphuric acid, and not unfrequently potash. Hence the reason why, in some cases, it could be converted into alum by digestion in sulphuric acid, without the necessity of adding any potash to the solution. Modern chemists have added considerably to these facts. They have shown that chalk, felspar, mica, hornblende, oxide of iron, coal, bitumen, &c. are not unfrequently mixed with it; and that these additions alter its qualities considerably, and render it fit or unfit for the different purposes to which clay is usually applied.

Preparation of the Clay, and Formation of the Brick.

3. Clay intended to be made into bricks ought to be dug out of the earth, and exposed to the air and weather for a considerable time before it is employed. The longer this exposure is continued, so much the better will it be fitted for making bricks. This exposure answers a variety of purposes. If the stones, by the decomposition of which the clay has been formed, are not entirely decomposed, this exposure serves to complete the process, by promoting the disentegrating action of the air and rain. The exposure serves, likewise, to pulverize the clay, which is essential to the making of good bricks. We have little doubt that the same amelioration in the clay would be produced by simply drying it in the open air, and then grinding it to powder in a mill. By such a process, the quality of the bricks would be prodigiously improved. Nor do we conceive that such an addition would greatly enhance the expences of the brickmaker, at least in those districts where the mill could be driven by water.

When the clay has been reduced to powder, the next step is to make it into a stiff paste with water. Too much water should not be employed, because it is injurious to the strength of the bricks; and the utmost care should be taken to mix the whole of the clay as equally as possible with the water. If some parts of the paste be moister than others, it will occasion an inequality in the texture of the bricks formed of it, will render them apt to crack, and will greatly injure both their strength and their beauty. Hence the great importance of working the clay for a considerable length of time before moulding it into bricks. It is in this part of the process that we believe British brickmakers in general are most defective. As far as we have had an opportunity of witnessing the process of kneading the clay, as conducted either in the neighbourhood of London or Edinburgh, we have always found a great sparing of labour. Hence we believe the reason why so many of the English bricks appear full of cracks, even when sold to the builder. Such bricks ought never to be purchased, as it is perfectly obvious that they cannot make a durable building.

The kneading of the clay is performed, in some places, by men's feet; in others, by the feet of horses, and in others by machinery. The last method is undoubtedly the best; and we conceive likewise that it might be made the cheapest. It would be easy to devise machinery for kneading the clay, upon principles similar to those employed in mashing by the London porter brewers. And, if such a machine were driven by water, we conceive that it would not be nearly so expensive as either men or horses.

When the clay is sufficiently kneaded, it is moulded into the form of a brick, by being put into a very simple wooden mould; and the upper part of the brick is made smooth and even by cutting off the superfluous part with a wooden knife. The process is very simple, and is conducted by the workmen with great rapidity. A good brickmaker will mould about 5000 bricks in a day. He disengages the bricks from the mould by a gentle stroke on the back of the mould; and the wet bricks are at first arranged in rows upon long boards. When sufficiently dry to be handled, they are turned, and at last piled up in loose walls, which are thatched with straw to keep off the rain. In this position they are allowed to remain till they have become as dry as they can become in the open air.

In many cases, the clay used for brick-making is destitute of the requisite quantity of sand. If such clay were made into bricks, it would shrink so much in the burning, that the bricks would lose their shape, and would probably crack in every direction. To prevent this, it is necessary to add a certain quantity of sand. This sand should not be very fine. It answers best when the particles are of such a size as to be readily distinguished by the naked eye. Even when as large as coriander seeds, it has been found to answer better than very fine sand. The brickmakers in the neighbourhood of London bring their sand from the bottom of the

Brick.

Thames near Woolwich, where it is raised by boats employed for that purpose, and brought up the river for the use of the brickmakers.

Burning of Bricks.

4. No general directions can be given respecting the quantity of sand to be mixed with the clay, because that depends upon the nature of the clay, and upon the uses for which the bricks are intended. The more sand is added, the more accurately do the bricks retain their shape, and the less apt are they to crack during the burning; but, at the same time, their strength is diminished. Chemical lutes are often composed of four parts of sand and one part of clay. Such mixtures do not contract much in burning, and, therefore, are not apt to crack and drop off, which is the reason why chemists employ them. But they have not the adhesiveness of brick after being burnt, and would not, therefore, answer the purposes of the brickmaker. In stone-ware, the mixture consists of about four parts of clay and one of fine sand. It burns to a hard, cohesive substance, capable of striking fire with steel. Such a proportion then, in many cases, would answer the purposes of the brickmaker.

The London brickmakers make another addition to the clay, which, we believe, is peculiar to them. They add to every three parts of the clay about one part of the ashes from the fire-places of the city of London. These ashes contain some earthy matter; but they consist, in a great measure, of small coal unburnt, and little altered, which has fallen through the interstices of the grate. The consequence is, that such a mixture, when sufficiently heated, takes fire and burns of itself, though very slowly; so that the London bricks are burnt, in a great measure, by means of the fuel mixed with the clay of which they are composed.

It is essential to dry the bricks thoroughly, in the open air, before burning them. For when heat is applied to wet clay, the water which it contains being prevented from escaping by the adhesiveness of the mixture, is converted into steam, and cracks and breaks the mass of clay to pieces. Indeed, after the bricks are rendered as dry as they can become in the open air, they ought to be exposed, at first, to a gentle heat, which ought to be raised to redness, very slowly, and in proportion as the moisture of the brick is dissipated. Water adheres with such obstinacy to clay, that it is never all driven off by the heat at which bricks are burnt. But the portion which remains is so intimately combined with the clay, as to constitute one solid mass, which has no great tendency to absorb an additional quantity of water.

Bricks are most commonly burnt in a kiln. This is a very simple structure, usually about 13 feet long, 10½ wide, and 12 feet high. The walls are one foot two inches thick, and incline a little to each other as they ascend. The bricks are placed on flat arches, having holes left in them like lattice-work. After the bricks are arranged on the kiln, to the number of about 20,000, they are covered with old bricks or tiles. Some brush-wood is then kindled in the kiln, and a moderate fire kept up till the bricks are rendered as dry as possible. The time required for this is two or three days, and the bricks are known to be dry when the smoke (which is at first black) becomes transparent. The mouth of the kiln is then filled up with pieces of brick and clay, leaving only room to introduce a faggot at a time. This structure at the mouth of the kiln is called a *shinlog*. The kiln is then supplied with faggots of furze, heath, fern, or whatever vegetable substance can be procured at the cheapest rate, till the arches look white, and the fire appears at the top. The fire is then diminished, and at length allowed to go out, and the kiln is permitted to cool. This burning process usually lasts about forty-eight hours.

Brick.

The method of burning bricks in the neighbourhood of London, is very different from this. We do not know whether it be practised any where else. It obviously originated from the difficulty of procuring a sufficient quantity of vegetable matter to burn the enormous number of bricks consumed every year in London. If we consider the immense extension of houses which has taken place in London within the last thirty years,—if we consider that this vast city, containing above 1,000,000 of inhabitants, is almost renewed once every century, we may be able to form some notion of the prodigious quantity of bricks which it must consume. In the country round London there is a particular kind of clay, well known by the name of London Clay. This clay is almost everywhere covered with a bed of gravel, which varies in thickness according to the elevation of the surface. Hence the whole of the country round London is fit for making bricks. Nothing more is necessary than to dig through the surface of gravel, and get to the clay.

We have already mentioned, that about a fourth part of the London bricks consists of small coal kneaded up along with the clay. When the bricks are sufficiently dry, they are piled up on each other in parallelopipedons to the intended height. Between each two rows of brick there is strewed a quantity of cinders, amounting to about three inches in thickness. At the distance of about nine feet from each other, perpendicular spaces are left, about a brick wide, which serve the purpose of flues. These are made by arching the bricks over so as to leave a space between each about a brick in width. Over the whole is strewed a pretty thick covering of cinders. The flues are filled likewise with cinders, or, if they cannot be had, with coal. The fire-place is usually at the west end, and is generally three feet high. The fire, when once kindled in the fire-place, propagates itself very slowly through the whole *clamp*, as bricks piled in this manner are called. So very slow is the progress, that bricks in the neighbourhood of London take about three months in the burning. The heat is very intense, and, as the fuel is mixed up with the clay itself, every part of the brick is sure to be sufficiently burnt.

We conceive that the mixture of about one-fourth of chalk with the clay of which the London bricks are made, would greatly improve their quality. The consequence would be an incipient fusion, which would render their surface much more compact and solid. The only difficulty would be to proportion the quantity of chalk so as to prevent complete fu-

Brick.

sion, which would run the bricks into each other, and destroy them entirely. Bricks made of materials which have undergone complete fusion, would be greatly superior to common bricks. They would perfectly resist the action of the weather, and would, therefore, last much longer than common bricks. In Sweden it is customary at some of the iron founderies, to cast the scoriæ into bricks, which they employ in constructing their furnaces. Such furnaces the writer of this article has seen; and he was assured by the gentleman who had the charge of the works, that they answered fully better than common bricks. It would be easy to make any quantity of such bricks in some of the large iron founderies of Great Britain. We are persuaded that such bricks might be brought into use for a variety of purposes with great advantage, and might even constitute a lucrative article of manufacture. Bricks made from the scoriæ of iron and copper founderies, would vie in beauty with marble and porphyry, and would possess a smoothness of surface and a lustre to which few marbles could reach.

Few parts of Great Britain are so well adapted for the making of bricks, according to the London plan, as the neighbourhood of Newcastle upon Tyne. There the enormous heaps of small coal, which are of no use whatever, would furnish abundance of fuel, at a much cheaper rate, than even the London ashes; while the magnesian limestone that occurs in such plenty in the neighbourhood of Sunderland, would enable the brickmaker to give the clay the requisite degree of fusibility.

As bricks form an article of taxation, and furnish a considerable revenue to Government, their size has been regulated by act of Parliament. They must not be less than $8\frac{1}{2}$ inches long, $2\frac{1}{2}$ thick, and 4 inches wide. But for various purposes, they are made of very different and very considerable sizes.

Fire-Bricks.

Fire-bricks are made in the same way as common bricks. But the materials are different. The best clay for their composition is Stourbridge clay; and, instead of sand, it is usual to mix the clay with a quantity of old fire-bricks, or crucibles, or glass pots, reduced previously to powder. This mixture answers the same purposes as sand, while it does not communicate the tendency to fusion, when it comes in contact with various fluxes, that is communicated by siliceous sand.

Swimming Bricks.

There is a kind of bricks mentioned by Pliny, as used by the ancients, which were so light as to swim in water. "Pitanæ in Asia, et in ulterioris Hispaniæ civitatibus Maxilua et Calento, fiunt Lateres, qui ciccati non merguntur in aqua." (*Plinii Natur. Histor.* lib. xxxv. c. 14.) Pliny does not mention the part of the world in which the earth employed in the manufactures of these bricks was found; though in all probability, it could not be far from the cities where the bricks are said by Pliny to have been made. He says that the material employed was a kind of pumice stone. But it was quite unknown to the moderns, till, in the year 1791, Fabbroni found a substance at Castel del Piano, not far from Santa Fiora, situated between Tuscany and the Papal dominions, which formed bricks capable of swimming in water. This is a white earthy matter, which constitutes a bed in that place, and was known in Italy by the name of *Latte di Luna*. In more recent mineralogical books, it is distinguished by the name of *farina fossilis (bergmehl)*. Hauy considers it as a variety of talc, and Brochant, as a variety of meerschaum. According to the analysis of Fabbroni, this substance is composed of

Silica	55
Magnesia	15
Alumina	12
Lime	3
Iron	1
Water	14
	100

But it has been recently analyzed by Klaproth, who found its constituents,

Silica	79
Alumina	5
Oxide of iron	3
Water	12
Loss	1
	100

We see from this analysis, that this mineral is neither a variety of talc nor of meerschaum. One would be disposed to consider it as a hydrate of silica. For both the alumina and oxide of iron are present in so small proportions, that we can scarcely consider them as in chemical combination.

Considering the composition of this earth, it is rather singular that it is capable of being agglutinated by a red heat. We rather suspect that the bricks of Fabbroni, which swim in water, have but very little strength. This, if it be the case, must greatly circumscribe their utility.

The colour of the London bricks is not red, as is the case with common bricks and tyles; but a light brownish yellow. This colour is more pleasing to the eye than common brick red, and on that account the London bricks are preferred for building houses. The brickmakers assign a curious enough reason for this colour. According to them, their bricks are kept as much as possible from the contact of air during their burning. The consequence of this is, that the iron contained in them is not oxidized to so great a degree as in common bricks. But this mode of reasoning is far from exact. If air were excluded entirely, the bricks would not be burnt at all, because the fire would be extinguished. But if enough of air be admitted to burn the coal mixed with the clay (which must be the case), that air must also act upon the iron, and reduce it to the state of peroxide. Indeed, there can be no doubt, that the iron in the London yellow bricks, is in the state of peroxide, as well as in the red bricks; for the peroxide of iron gives various colours to bodies, according to circumstances. We find bodies tinged with it, red, yellow,

and brown, according to the substances with which the oxide is combined. We ascribe the yellow colour of the London bricks to the ashes of the coals, which, by uniting with the peroxides of iron, form a kind of yellow ochre. (J.)

BRIDGE.

The mathematical theory of the structure of bridges has been a favourite subject with mechanical philosophers; it gives scope to some of the most refined and elegant applications of science to practical utility; and at the same time that its progressive improvement exhibits an example of the very slow steps by which speculation has sometimes followed execution, it enables us to look forwards with perfect confidence to that more desirable state of human knowledge, in which the calculations of the mathematician are authorised to direct the operations of the artificer with security, instead of watching with servility the progress of his labours.

Of the origin of the art of building bridges a sketch has been given in the body of the *Encyclopædia;* the subject has been rediscussed within the last twenty years by some of the most learned antiquaries, and of the most elegant scholars of the age; but additions still more important have been made to the scientific and practical principles on which that art depends; and the principal information, that is demanded on the present occasion, will be comprehended under the two heads of physico-mathematical principles, subservient to the theory of this department of architecture, and a historical account of the works either actually executed or projected, which appear to be the most deserving of notice. The first head will contain three sections, relating respectively (1) to the resistance of the materials employed, (2) to the equilibrium of arches, and (3) to the effects of friction; the second will comprehend (4) some details of earlier history and literature, (5) an account of the discussions which have taken place respecting the improvement of the port of London, and (6) a description of some of the most remarkable bridges which have been erected in modern times.

Section I.—*Of the Resistance of Materials.*

The nature of the forces on which the utility of the substances employed in architecture and carpentry depends, has been pretty fully investigated in the article Strength of the *Encyclopædia;* and the theory has been carried somewhat further, in the investigations of a late writer concerning Cohesion and Passive Strength of materials. Much, however, still remains to be done; and we shall find many cases, in which the principles of these calculations admit of a more immediate and accurate application to practice than has hitherto been supposed. It will first be necessary to advert to the foundation of the theory in its simplest form, as depending on the attractive and repulsive powers, which balance each other, in all natural substances remaining in a permanent state of cohesion, whether as liquids, or as more or less perfect solids.

A. *In all homogeneous solid bodies, the resistances to extension and compression must be initially equal, and proportional to the change of dimensions.*

The equilibrium of the particles of any body remaining at rest, depends on the equality of opposite forces, varying according to certain laws; and that these laws are continued without any abrupt change, when any minute alteration takes place in the distance, is demonstrated by their continuing little altered by any variation of dimensions, in consequence of an increase or diminution of temperature, and might indeed be at once inferred as highly probable, from the general principle of continuity observed in the laws of nature. We may, therefore, always assume a change of dimensions so small, that, as in all other differential calculations, the elements of the curves, of which the ordinates express the forces, as functions of, or as depending on, the distances as abscisses, may be considered as not sensibly differing from right lines, crossing each other, if the curves be drawn on the same side of the absciss, in a point corresponding to the point of rest, or to the distance affording an equilibrium; so that the elementary finite differences of the respective pairs of ordinates, which must form, with the portions of the two curves, rectilinear triangles, always similar to each other, will always vary as the lengths of the elements of the curves, or as the elements of the absciss, beginning at the point of rest; and it is obvious that these differences will represent the actual magnitude of the resistances exhibited by the substance to extension or compression. (Plate XLII. fig. 1.)

It was on the same principle that Bernoulli long ago observed, that the minute oscillations of any system of bodies, whatever the laws of the forces governing them might be, must ultimately be isochronous, notwithstanding any imaginable variation of their comparative extent, the forces tending to bring them back to the quiescent position being always proportional to the displacements; and so far as the doctrine has been investigated by experiments, its general truth has been amply confirmed; the slight deviations from the exact proportion, which have been discovered in some substances, being far too unimportant to constitute an exception, and merely tending to show that these substances cannot have been perfectly homogeneous, in the sense here attributed to the word. When the compression or extension is considerable, there may indeed be a sensible deviation, especially in fibrous or stratified substances; but this irregularity by no means affects the admissibility of any of the conclusions which will be derived from this proposition.

B. *The strength of a block or beam must be reduced to one half, before its cohesive and repulsive forces can both be called into action.*

We must suppose the transverse sections of the

Bridge.

body to remain plane and perpendicular to the axis, whatever the point may be to which the force is applied, a supposition which will be correctly true, if the pressure be made by the intervention of a firm plate attached to each end, and which is perfectly admissible in every other case. Now, if the terminal plates remain parallel, it is obvious that the compression or extension must be uniformly distributed throughout the substance, which must happen when the original force is applied in the middle of the block; the centre of pressure or resistance, collected by the plate, acting like a lever, being then coincident with the axis. But when the plates are inclined, the resistance depending on the compression or extension will be various in different parts, and will always be proportional to the distance from the neutral point, where the compression ends and the extension begins, if the depth of the substance is sufficient to extend to this point; consequently the forces may always be represented, like the pressure of a fluid, at different depths, by the ordinates of a triangle; and their result may be considered as concentrated in the centre of gravity of the triangle, or of such of its portions as are contained within the depth of the substance; and when both extension and compression are concerned, the smaller force may be considered as a negative pressure, to be subtracted from the greater, as is usual when any other compound forces are supposed to act on a lever of any kind. Now, when the neutral point is situated in one of the surfaces of the block, the sum of all the forces is represented by the area of the triangle, as it is by that of the parallelogram when the plates remain parallel, and these areas being in either case equivalent to the same external force, it is obvious that the perpendicular of the triangle must be equal to twice the height of the parallelogram, indicating that the compression or extension of the surface in the one case is twice as great as the equable compression or extension in the other; and since there is always a certain degree of compression or extension which must be precisely sufficient to crush or tear that part of the substance which is immediately exposed to it, and since the whole substance must in general give way when any of its parts fail, it follows that the strength is only half as great in the former case as in the latter. And the centre of gravity of every triangle being at the distance of one-third of its height from the base, the external force must be applied, in order to produce such a compression or extension, at the distance of one sixth of the depth from the axis; and when its distance is greater than this, both the repulsive and cohesive forces of the substance must be called into action, and the strength must be still further impaired. (Plate XLII. fig. 2.)

C. *The compression or extension of the axis of a block or beam is always proportional to the force, reduced to the direction of the axis, at whatever distance it may be applied.*

We may suppose one of the inflexible plates, attached to the extremities of the block, to be continued to the given distance, and to act as a lever held in equilibrium by three forces, that is, by the cohesive and repulsive resistances of the block, and the external force; and it is obvious that, as in all other levers, the external force will always be equal to the difference of the other two forces depending on the compression and extension, or to the mean compression or extension of the whole, which must also be the immediate compression or extension of the middle, since the figure representing the forces is rectilinear. And the effect will be the same, whatever may be the intermediate substances by which the force is impressed on the block, whether continued in a straight line or otherwise. When the force is oblique, the portion perpendicular to the axis will be resisted by the lateral adhesion of the different strata of the block, the compression or extension being only determined by the portion parallel to the axis; and when it is transverse, the length of the axis will remain unaltered. But the line of direction of the original force must always be continued till it meets the transverse section at any point of the length, in order to determine the nature of the strain at that point.

D. *The distance of the neutral point from the axis of a block or beam is to the depth, as the depth to twelve times the distance of the force, measured in the transverse section.*

Calling the depth a, and the distance of the neutral point from the axis z, the resistances may be expressed by the squares of $\frac{1}{2}a+z$ and $\frac{1}{2}a-z$, which are the sides of the similar triangles denoting the compression and extension (Prop. B.); consequently, the difference of these squares, $2az$, will represent the external force (Prop. C.). But the distance of the centres of gravity of the two triangles must always be $\frac{2}{3}a$; and, by the property of the lever, making the centre of action of the greater resistance the fulcrum, as the external force is to the smaller resistance, so is this distance to the distance of the force from the centre of action of the greater resistance; or $2az : (\frac{1}{2}a+z)^2 = \frac{2}{3}a : \left(\frac{aa}{12z} - \frac{a}{3} + \frac{z}{3}\right)$; and adding to this the distance of the centre of action from the axis, which must be $\frac{1}{2}a - \frac{1}{3}(\frac{1}{2}a+z) = \frac{1}{3}a - \frac{1}{3}z$, we have $\frac{aa}{12z}$ for the distance of the force from the axis; whence, calling this distance y, $z = \frac{aa}{12y}$.

E. *The power of a given force to crush a block is increased, by its removal from the axis, supposing its direction unaltered, in the same proportion as the depth of the block is increased by the addition of six times the distance of the point of application of the force, measured in the transverse section.*

Since the compression or extension of the axis is invariable, whatever the distance of the force may be, that of the nearest surface must be as much greater, by the properties of similar triangles, as the half depth, increased by the distance of the neutral

point, is greater than that distance itself, that is, in the ratio of $a + 6y$ to a, since z is to a as a to $12y$; (Prop. D.) and to $\frac{1}{2}a$ as a to $6y$: and the strength is reduced in the same proportion, as the partial compression or extension, by the operation of a given force, is increased. (Plate XLII. fig. 3.)

F. *The curvature of the neutral line of a beam at any point, produced by a given force, is proportional to the distance of the line of direction of the force from the given point of the axis, whatever that direction may be.*

Since the distance z of the neutral point from the axis is inversely as y, the distance of the force, and the radius of curvature, or the distance of the intersection of the planes of the terminal plates from the neutral point, must be to the distance z as the whole length of the axis is to the alteration of that length produced by the compression or extension, it follows that the radius of curvature must be inversely as the distance y, and inversely also as the compression, and the curvature itself must be conjointly as the force and as the distance of its application. If the direction of the force be changed, and the perpendicular falling from the given point of the axis on the line of the force be now called y, the distance of the force from the axis measured in the transverse section will be increased by the obliquity exactly in the same ratio as its efficacy is diminished, and the curvature of the neutral line will remain unaltered; although the place of that line will be a little varied, until at last it coincides with the axis, when the force becomes completely transverse: and the radius of curvature of the axis will always be to that of the neutral line as the acquired to the original length of the axis. (Plate XLII. fig. 4.)

G. *The radius of curvature of the neutral line is to the distance of the neutral point as the original length of the axis to the alteration of that length; or as a certain given quantity to the external force: and this quantity has been termed the Modulus of elasticity.*

Or $r : z = M : f$, and $r = \frac{Mz}{f} = \frac{Maa}{12fy}$, as is obvious from the preceding demonstration; y being the distance of the line of the force from the given point, whatever its direction may be.

H. *The flexibility, referred to the direction of the force, is expressed by unity, increased by twelve times the square of the distance, divided by that of the depth.*

Making the alteration of the axis unity, the corresponding change at the distance y will be to 1 as $z + y$ to z, or as $1 + \frac{y}{z}$ to 1, and will consequently be equal to $1 + \frac{12yy}{aa}$ (Prop. D.)

When the direction of the force becomes oblique, the actual compression of the axis is diminished, but its effect referred to that direction remains unaltered.

I. *The total compression of a narrow block, pressed in the direction of one of its diagonals, is twice as great as if the same force were applied in the direction of the axis.*

This proposition affords a simple illustration of the application of the preceding one. Calling the length of any portion of the axis x, beginning from the middle, and neglecting the obliquity, the distance of the force may be called $y = nx$, and the compression in the line of the force being everywhere as $1 + \frac{12yy}{aa}$, its fluxion will be $\mathrm{d}x + \mathrm{d}x\,\frac{12nnxx}{aa}$, and the fluent $x + \frac{4n^2x^3}{aa}$, which, when $y = \frac{1}{2}a$, becomes $x + x$, which is twice as great as if y were always $= 0$. But if the breadth of the block were considerable, so that it approached to a cube, the compression would vary according to a different law, each section parallel to the diagonal affording an equal resistance, and the exact solution of the problem would require an infinite series for expressing the value of $\int n^{\frac{1}{x}}\mathrm{d}x$.

K. *If a solid bar have its axis curved a little into a circular form, and an external force be then applied in the direction of the chord, while the extremities retain their angular position, the greatest compression or extension of the substance will ultimately be to the mean compression or extension which takes place in the direction of the chord, as $1 + \frac{4h}{a}$ to $1 + \frac{16hh}{15aa}$; a being the depth of the bar, and h the actual versed sine, or the height of the arch.*

We must here separate the actions of the forces retaining the ends of the bar into two parts, the one simply urging the bar in the direction of the chord, and the other, which is of a more complicated nature, keeping the angular direction unaltered; and we must first calculate the variation of the angular situation of the ends, in consequence of the bending of the bar by the first portion, and then the strain required to obviate that change, by means of a force acting in the direction of the middle of the bar, while the ends are supposed to be fixed. If each half of the bar were rectilinear, these two strains would obviously be equal, and would neutralise each other in the middle of the halves, which might be considered as the meeting of the ends of two shorter pieces, acting transversely or obliquely on each other, without any strain; the curvature produced by the whole strain being elsewhere as the distance from the line joining these points. But, since the bar is supposed to be curved, it becomes necessary to determine the place of these neutral points, by calculating the change of its angular position throughout its extent.

Considering, first, the middle of the bar as fixed, and calling the angular extent of the variable arc x, beginning from the middle, and the radius r, the ordinate y, or the distance of the arc from the chord, will be $r\varsigma x - b$, b being the cosine of the whole arc; and the fluxion of the change of the angular situation, being as the strain and the fluxion of the arc conjointly, will be expressed by $pr\varsigma x\mathrm{d}x - pb\mathrm{d}x$, of

which the fluent is $pr\int x - pbx$. In the second place, the curvature derived from the force acting between the two halves, when the ends are considered as fixed points, will be as $r - r\varsigma x$, and the fluent of the change of angular situation may be called $qrx - qr\int x$; and at the end, when x becomes equal to c, the whole extent of the arc, these two deviations must destroy each other, since the positions of the middle and of the ends remain unaltered; consequently $pr\int c - pbc = qrc - qr\int c$, whence $\frac{p}{q} = \frac{rc - r\int c}{r\int c - bc}$, and the exact proportion of p to q may be found, by means of a table of sines. But when the arc is small, $\int c$ being equal to $c - \frac{1}{6}c^3 + \frac{1}{120}c^5 \ldots$, $rc - r\int c$ is $\frac{1}{6}rc^3$, and $r\int c - bc = (r-b)\,c - \frac{1}{6}rc^3$; now $r-b$, the versed sine of the arc, becomes ultimately $\frac{1}{2}rc^2$, and $(r-b)\,c = \frac{1}{2}rc^3$; therefore $p : q = \frac{1}{6} : \frac{1}{3} = \frac{1}{2} : 1$; that is, the strain at the middle, expressed by p, must be half as great as the strain at the ends, expressed by q: consequently, when the force is considered as single, the distance of the line of its direction from the summit must ultimately be one-third of the versed sine or height.

Now if we call any portion of the chord x, we have for the corresponding value of y, the distance from the line of direction of this force, $\sqrt{(r^2 - x^2)} - d$, and for the fluxion of the compression or extension in the direction of the chord, $\mathrm{d}x\left(1 + \frac{12\,yy}{aa}\right)$, which will be true for both portions of the bar, whether y be positive or negative; but $y^2 = r^2 - x^2 + d^2 - 2d\sqrt{(r^2 - x^2)}$, and the fluent becomes $x + \frac{12}{aa}\left(r^2x - \frac{1}{2}x^3 + d^2x - 2d\,[r^2 \text{ ARC SINE } \frac{x}{r} - x\sqrt{(r^2-x^2)}]\right)$. When the arc is small, calling the whole versed sine h, we have $y = \frac{1}{2}h - \frac{xx}{2r}$, and $y^2 = \frac{1}{9}h^2 - \frac{hx^2}{3r} + \frac{x^4}{4r^2}$, and the fluent is $x + \frac{12}{aa}\left(\frac{1}{9}h^2x - \frac{hx^3}{9r} + \frac{x^5}{20\,r^2}\right)$, but when x becomes equal to the semichord c, h being $\frac{cc}{2r}$, the expression becomes $c + \frac{12}{aa}\left(\frac{c^5}{36r^2} - \frac{c^5}{18r^2} + \frac{c^5}{20r^2}\right) = c + \frac{4\,c^5}{15\,a^2r^2} = c + \frac{16\,h^2c}{15\,a^2}$, which shows the compression or extension in the line of the chord, while c expresses that which the bar would have undergone if it had been straight, and the force had been immediately applied to the axis; the actual change being greater in the proportion of $1 + \frac{16\,hh}{15\,aa}$ to 1.

The greatest strain will obviously be at the ends, where the distance from the line of direction of the force is the greatest, the compression or extension of the surface being here to that of the axis, as $a + 6y$ to a (Prop. E.) or as $1 + \frac{4h}{a}$ to 1; consequently the compression or extension in the line of the chord is to the greatest actual change of the substance as $1 + \frac{16\,hh}{15\,aa}$ to $1 + \frac{4h}{a}$.

Thus if the depth a were 10 feet, and the height or versed sine $h = 20$, the radius being very large, the whole compression of the chord would be to the whole compression of a similar substance, placed in the direction of the chord, as 5.267 to 1; and the compression at the surface of the ends would be to the compression of the axis there as 9 to 1; and disregarding the insensible obliquity, this compression may be considered as equal throughout the bar; so that the compression at the ends will be to the compression of the chord as 9 to 5.267, or as 17 to 10.

Supposing, for example, such a bar of iron to undergo a change of temperature of 32° of Fahrenheit, which would naturally cause it to expand or contract about $\frac{1}{3000}$ in all its dimensions; then the length of the chord, being limited by the abutments, must now be supposed to be altered $\frac{1}{3000}$ by an external force; and, at the extremities of the abutments, the compression and extension of the metal will amount to about $\frac{1}{3000}$; a change which is equivalent to the pressure of a column of the metal about 3300 feet in height, since M, the height of the modulus of elasticity, is found, for iron and steel, to be about 10,000,000 feet; and such would be the addition to the pressure at one extremity of the abutment, and its diminution at the other, amounting to about five tons for every square inch of the section, which would certainly require some particular precaution, to prevent the destruction of the stones forming the abutment by a force so much greater than they are capable of withstanding without assistance. Should such a case indeed actually occur, it is probable that the extremities would give way a little, and that the principal pressure would necessarily be supported nearer the middle, so that there would be a waste of materials in a situation where they could co-operate but imperfectly in resisting the thrust; an inconvenience which would not occur if the bar were made wider and less deep, especially towards the abutments.

SECTION II.—*Of the Equilibrium of Arches.*

We may now proceed to inquire into the mode of determining the situation and properties of the curve of equilibrium, which represents, for every part of a

system of bodies supporting each other, the general direction of their mutual pressure; remembering always that this curve is as much an imaginary line, as the centre of gravity is an imaginary point, the forces being no more actually collected into such a line than the whole weight or inertia of a body is collected in its centre of gravity. Indeed, the situation of the curve is even less definite than that of the centre of gravity, since in many cases it may differ a little according to the nature of the co-operation of the forces which it is supposed to represent. In reality, every gravitating atom entering the structure must be supported by some forces continued in some line, whether regular or irregular, to the fixed points or abutments, and every resisting atom partakes, in a mathematical sense, either positively or negatively, in transmitting a lateral pressure where it is required for supporting any part of the weight: and when we attempt to represent the result of all these collateral pressures by a simple curve, its situation is liable to a slight variation, according to the direction in which we suppose the co-operating forces to be collected. If, for instance, we wished to determine the stability of a joint, formed in a given direction, it would be necessary to consider the magnitude of the forces acting throughout the extent of the joint in a direction perpendicular to its plane, and to collect them into a single result, and it is obvious that the forces, represented by the various elementary curves, may vary very sensibly in their proportion, when we consider their joint operation on a vertical or on an oblique plane; although if the depth of the substance be inconsiderable, this difference will be wholly imperceptible, and in practice it may generally be neglected without inconvenience; calculating the curve upon the supposition of a series of joints in a vertical direction. If, however, we wish to be very minutely accurate, we must attend to the actual direction of the joints in the determination of the curve, and must consider, in the case of a bridge, the whole weight of the structure terminated by a given arch stone, with the materials which it supports, as determining the direction of the curve of equilibrium where it meets the given joint, instead of the weight of the materials terminated by a vertical plane passing through the point of the curve in question, which may sometimes be very sensibly less; this consideration being as necessary for determining the circumstances under which the joints will open, as for the more imaginary possibility of the arch stones sliding upwards or downwards. But we may commonly make a sufficiently accurate compensation for this difference, by supposing the specific gravity of the materials producing the pressure, and the curvature of the line which terminates them, to be a little increased, while the absciss remains equal to that of the curve of equilibrium intersecting the joints.

L. *If two equal parallelepipeds be supported each at one end, and lean against each other at the other, so as to remain horizontal, the curve of equilibrium, representing the general effect of the pressure transmitted through them, will be of a parabolic form.*

The pressure of the blocks, where they meet, will obviously be horizontal, but at the other ends it will be oblique, being the result of this horizontal pressure and of the whole weight of each block. And if we imagine the blocks to be divided into any number of parts, by sections parallel to the ends, which is the only way in which we can easily obtain a regular result, it is evident that the force exerted at any of these sections, by the external portions, must be sufficient to support the lateral thrust and the weight of the internal portions; and its inclination must be such that the horizontal base of the triangle of forces must be to the vertical perpendicular as the lateral thrust to the weight of the internal portion; or, in other words, the lateral thrust remaining constant, the weight supported will be as the tangent of the inclination. But calling the horizontal absciss x, and the vertical ordinate y, the tangent of the inclination will be $\frac{\mathrm{d}y}{\mathrm{d}x}$; which, in the case of a parallelepiped, must be proportional to the distance x from the contiguous ends; and $x=\frac{m\mathrm{d}y}{\mathrm{d}x}$; consequently $x\mathrm{d}x=m\mathrm{d}y$, and $\frac{1}{2}x^2=my$, which is the equation of a parabola. It is usual in such cases to consider the thrusts as rectilinear throughout, and as meeting in the vertical line passing through the centre of gravity of each block; but this mode of representation is evidently only a convenient compendium.

If the blocks were united together in the middle, so as to form a single bar or lever, the forces would be somewhat differently arranged; the upper half of the bar would contain a series of elementary arches, abutting on a series of similar elementary chains in the lower half, so as to take off all lateral thrust from the supports at the ends.

With respect to the transverse strains of levers in general, it may be observed, that the most convenient way of representing them is to consider the axis of the lever as composed of a series of elementary bars, bisected, and crossed at right angles, by as many others extending across the lever, or rather as far as two-thirds of the half depth on each side, where the centre of resistance is situated. The transverse force must then be transmitted unaltered throughout the whole system, acting in contrary directions at the opposite ends of each of the elementary bars constituting the axis; and it must be held in equilibrium, with respect to each of the centres, considered as a fulcrum, by the general result of all the corpuscular forces acting on the longer cross arms; that is, by the difference of the compression or extension on the different sides of the arms. This difference must therefore be constant; and in all such cases the strain or curvature must increase uniformly, and its fluxion must be constant; but if the transverse force be variable, as when the lever supports its own weight, or any further external pressure, the fluxion of the curvature must be proportional to it. Now the transverse force, thus estimated, being the sum of the weights or other forces acting on either side of the given point, the additional weight at the point will be represented by the fluxion of the weight, or by the second fluxion of the strain or curvature, which is ultimately as the

fourth fluxion of the ordinate. Also, the fluxion of the strain being as the whole weight on each side, it follows that when the strain is a maximum, and its fluxion vanishes, the whole weight, or the sum of the positive and negative forces on either side, must also vanish; as Mr Dupin has lately demonstrated in a different manner.

M. *In every structure supported by abutments, the tangent of the inclination of the curve of equilibrium to the horizon is proportional to the weight of the parts interposed between the given point and the middle of the structure.*

The truth of this proposition depends on the equality of the horizontal thrust throughout the structure, from which it may be immediately inferred, as in the last proposition. The materials employed for making bridges are not uncommonly such, as to create a certain degree of lateral pressure on the outside of the arch; but as there must be a similar and equal pressure in a contrary direction against the abutment, its effects will be comprehended in the determination of the point at which the curve springs from the abutment, as well as in the direction of the curve itself; so that the circumstance does not afford any exception to the general truth of the law. It is, however, seldom necessary to include the operation of such materials in our calculations, since their lateral pressure has little or no effect at the upper part of the arch, which has the greatest influence on the direction of the curve; and it is also desirable to avoid the unnecessary employment of these soft materials, because they tend to increase the horizontal thrust, and to raise it to a greater height above the foundation of the abutment.

We have therefore generally $\int w \mathrm{d}x = mt = m\frac{\mathrm{d}y}{\mathrm{d}x}$, w being the height of uniform matter, pressing on the arch at the horizontal distance x from the vertex, t the tangent of the inclination of the curve of equilibrium, y its vertical ordinate, and m a quantity proportional to the lateral pressure, or horizontal thrust.

N. *The radius of curvature of the curve of equilibrium is inversely as the load on each part, and directly as the cube of the secant of the angle inclination to the horizon.*

The general expression for the radius of curvature is $r = \frac{(\mathrm{d}z)^3}{\mathrm{d}x\mathrm{dd}y}$; and here, since $m\mathrm{d}y = \mathrm{d}x\int w\mathrm{d}x$, $\mathrm{d}x$ being constant, $m\mathrm{d}^2y = w\,(\mathrm{d}x)^2$; but $\mathrm{d}z$ being $= \mathrm{d}x\surd(1+t^2)$, $\frac{(\mathrm{d}z)^2}{\mathrm{dd}y} = \frac{m}{w}(1+t^2)$, and $r = \frac{m}{w}(1+t^2)^{\frac{3}{2}}$; and m being constant, r is inversely as the load w, and directly as the cube of the secant $\surd(1+t^2)$. The same result may also be obtained from a geometrical consideration of the magnitude of the versed sine of the elementary arc, and the effect of the obliquity of the pressure; the one varying as the square of the secant, the other as the secant simply.

O. *Consequently, if the curve be circular, the load must be everywhere as the cube of the secant.*

P. *If the curve of equilibrium be parabolic, the load must be uniform throughout the span.*

(Prop. L.) The uniformity of the load implies that the superior and inferior terminations of the arch, commonly called the extrados and intrados, should be parallel: but it is not necessary that either of them should be parabolic, unless we wish to keep the curve exactly in the middle of the whole structure. When the height of the load is very great in proportion to that of the arch, the curve must always be nearly parabolic, because the form of the extrados has but little comparative effect on the load at each point.

A parabola will therefore express the general form of the curve of equilibrium in the flat bands of brick or stone, commonly placed over windows and doors, which, notwithstanding their external form, may very properly be denominated flat arches. But if we consider the direction of the joints as perpendicular to the curve, it may easily be shown, from the properties of the wedge, that they must tend to a common axis, in order that the thrust may be equal throughout; and the curve must be perpendicular to them, and consequently circular; but the difference from the parabola will be wholly inconsiderable.

Q. *For a horizontal extrados, and an intrados terminated by the curve itself, which, however, is a supposition merely theoretical, the equation of the curve is* $x = \surd m\text{HL}\frac{y+\surd(yy-aa)}{a}$.

Since in this case $w = y$ (Prop. M.) we have $\int y\mathrm{d}x = m\frac{\mathrm{d}y}{\mathrm{d}x}$; and $m\mathrm{d}^2y = y\;(\mathrm{d}x)^2$; whence, multiplying both sides by $\mathrm{d}y$, we have $m\mathrm{d}y\mathrm{d}^2y = y\mathrm{d}y(\mathrm{d}x)^2$; and, taking the fluent, $\frac{1}{2}m\,(\mathrm{d}y)^2 = \frac{1}{2}y^2\,(\mathrm{d}x)^2$, and $mt^2 = y^2$, which must be corrected by making $y = a$ when t vanishes, so that we shall have $mt^2 = y^2 - a^2$, and $y = \surd(a^2+mt^2)$. But since $\frac{\mathrm{d}y}{\mathrm{d}x} = t = \surd\left(\frac{yy-aa}{m}\right)$, $\mathrm{d}x = \mathrm{d}y\surd\frac{m}{(yy-aa)}$, and $x = \surd\, m\text{HL}\left(y + \surd\,[y^2-a^2]\right) - \surd\, m\text{HL}a$; whence all the points of the curve may be determined by means of a table of logarithms. But such a calculation is by no means so immediately applicable to practice, as has generally been supposed; for the curve of equilibrium will always be so distant from the intrados at the abutments, as to derange the whole distribution of the forces concerned.

R. *For an arch of equable absolute thickness throughout its length, the equation is* $z = \surd(y^2 - m^2)$ *and* $x = m\text{HL}\frac{y+\surd(yy-mm)}{m}$.

The weight of any portion of the half arch being represented by its length z, we have $z = m\frac{\mathrm{d}y}{\mathrm{d}x}$; but $\mathrm{d}z = \mathrm{d}y\surd\left(1+\left(\frac{\mathrm{d}x}{\mathrm{d}y}\right)^2\right) = \mathrm{d}y\surd\left(1+\frac{mm}{zz}\right)$,

and $dy = \frac{dz}{\sqrt{\left(1+\frac{mm}{zz}\right)}} = \frac{zdz}{\sqrt{(zz+mm)}}$, of which the fluent is $\sqrt{(z^2+m^2)}$, requiring no further correction than to suppose y initially equal to m; and we have $z = \sqrt{(y^2-m^2)}$. Again, since $dz = dx\sqrt{\left(1+\frac{zz}{mm}\right)}$ we find in the same manner $dx = \frac{mdz}{\sqrt{(mm+zz)}}$, and $x = m\text{HL}\left(z+\sqrt{[mm+zz]}\right) - m\text{HL}m = m\text{HL}\frac{z+y}{m}$. This curve will, therefore, in some cases, be identical with that of the preceding proposition. It is commonly called the catenaria, since it represents the form in which a perfectly flexible chain of equable thickness will hang by its gravity.

S. *If the load on each point of an arch be expressed by the equation $w = a + bx^2$, the equation for the curve of equilibrium will be $my = \frac{1}{2}ax^2 + \frac{1}{12}bx^4$.*

Since the whole load $\int wdx$ is here $ax + \frac{1}{3}bx^3$, we have $m\frac{dy}{dx} = ax + \frac{1}{3}bx^3$, (Prop. M.) and $my = \frac{1}{2}ax^2 + \frac{1}{12}bx^4$.

This expression will, in general, be found sufficiently accurate for calculating the form of the curve of equilibrium in practical cases; and it may easily be made to comprehend the increase of the load from the obliquity of the arch-stones. The ordinate y, at the abutment, being given, the value of m may be deduced from it: and since at the vertex my is simply $\frac{1}{2}ax^2$, the radius of curvature r will here be $\frac{xx}{2y} = \frac{m}{a}$.

T. *If we divide the span of an arch into four equal parts, and add to the weight of one of the middle parts one-sixth of its difference from the weight of one of the extreme parts, we shall have a reduced weight, which will be to the lateral thrust as the height of the arch to half the span, without sensible error.*

The weight of the half arch being expressed by $ax + \frac{1}{3}bx^3$ when x is equal to the whole span, if we substitute x for $\frac{1}{2}x$, it will become $\frac{1}{2}ax + \frac{1}{24}bx^3$, for one of the middle parts, leaving $\frac{1}{2}ax + \frac{7}{24}bx^3$, for the extreme part, which gives $\frac{6}{24}bx^3$ for the difference of the parts, and $\frac{1}{6}$ of this, added to the former quantity makes it $\frac{1}{2}ax + \frac{1}{12}bx^3$: but since $my = \frac{1}{2}ax^2 + \frac{1}{12}bx^4$, dividing by mx, we have $\frac{y}{x} = \frac{\frac{1}{2}ax + \frac{1}{12}bx^3}{m}$.

It is also obvious, that if we subtract, instead of adding, one-sixth of the difference, we have $\frac{1}{2}ax$; and dividing by $\frac{1}{2}x$, we obtain a, and thence $r = \frac{m}{a}$, m being previously found by the proposition.

U. *When the load is terminated by a circular or elliptical arc, $w = a + nb - n\sqrt{(b^2-x^2)}$, and $my = \frac{1}{2}(a+nb)x^2 - \frac{1}{2}nb^2x \text{ ARC SINE } \frac{x}{b} - \frac{1}{2}nb^2\sqrt{(b^2-x^2)} + \frac{1}{6}n(b^2-x^2)^{\frac{3}{2}} + \frac{1}{3}nb^3$.*

The whole load $\int wdx$ is here $ax + nbx - \frac{1}{2}nb^2 \text{ ARC SINE } \frac{x}{b} - \frac{1}{2}nx\sqrt{(b^2-x^2)}$; and hence $my = \frac{1}{2}ax^2 + \frac{1}{2}nbx^2 - \frac{1}{2}nb^2x \text{ ARC SINE } \frac{x}{b} + \frac{1}{2}nb^3 - \frac{1}{2}nb^2\sqrt{(b^2-x^2)} + \frac{1}{6}n(b^2-x^2)^{\frac{3}{2}} - \frac{1}{6}nb^3$ (Prop. M.) And the radius of curvature at the vertex will again be $\frac{m}{a}$. When the curve is circular, the axes of the ellipsis being equal, $n = 1$.

If the extrados and intrados are concentric, the calculation requires us to take the difference between the results determining the weight for each curve: but it will commonly be equally accurate in such a case, to consider the depth of the load as uniform, at least when the joints are in the direction of the radii.

X. *The abutment must be higher without than within, by a distance, which is to its breadth, as the horizontal distance of the centre of gravity of the half arch from the middle of the abutment is to the height of the middle of the key-stone above the same point.*

This proposition follows immediately from the proportion of the horizontal thrust to the weight, determined by the property of the lever; the one acting at the distance of the height of the arch from the fulcrum, and the other at the distance of the centre of gravity from the abutment, so as to balance each other; and the oblique direction of the face of the abutment being perpendicular to the thrust compounded of these two forces. The same rule also serves for determining the proper position of the abutment of a beam or rafter of any kind, in order that it may stand securely, without the assistance of friction. But for a bridge, if we calculate the situation of the curve of equilibrium, we obtain the direction of the thrust at its extremity more conveniently, without immediately determining the place of the centre of gravity.

Y. *In order that an arch may stand without friction or cohesion, a curve of equilibrium, perpendicular to all the surfaces of the joints, must be capable of being drawn within the substance of the blocks.*

If the pressure on each joint be not exactly perpendicular to the surfaces, it cannot be resisted with-

out friction, and the parts must slide on each other: this, however, is an event that can never be likely to occur in practice. But if the curve, representing the general pressure on any joint, be directed to a point in its plane beyond the limits of the substance, the joint will open at its remoter end, unless it be secured by the cohesion of the cements, and the structure will either wholly fall, or continue to stand in a new form. (Plate XLII. fig. 5.)

From this condition, together with the determination of the direction of the joints already mentioned (Prop. P.), we may easily find the best arrangement of the joints in a flat arch; the object, in such cases, being to diminish the lateral thrust as much as possible, it is obvious that the common centre of the joints must be brought as near to the arch as is compatible with the condition of the circle remaining within its limits; and it may even happen that the superincumbent materials would prevent the opening of the joints even if the centre were still nearer than this: but if, on the other hand, the arch depended only on its own resistance, and the materials were in any danger of being crushed, it would be necessary to keep the circle at some little distance from its surfaces, even at the expence of somewhat increasing the lateral pressure.

When the curve of equilibrium touches the intrados of an arch of any kind, the compression at the surface must be at least four times as great as if it remained in the middle of the arch-stones (Prop. E.), and still greater than this if the cohesion of the cements is called into action. In this estimate we suppose the transverse sections of the blocks inflexible, so as to cooperate throughout the depth in resisting the pressure on any point; but in reality this cooperation will be confined within much narrower limits, and the diminution of strength will probably be considerably greater than is here supposed, whenever the curve approaches to the intrados of the arch.

The passage of the curve of equilibrium through the middle of each block is all that is necessary to insure the stability of a bridge of moderate dimensions and of sound materials. Its strength is by no means increased, like that of a frame of carpentry, or of a beam resisting a transverse force, by an increase of its depth in preference to any other of its dimensions: a greater depth does, indeed, give it a power of effectually resisting a greater force of external pressure derived from the presence of any occasional load on any part of the structure; but the magnitude of such a load is seldom very considerable, in proportion to the weight of the bridge.

It is of some importance, in these investigations, to endeavour to trace the successive steps by which the fabric of a bridge may commonly be expected to fail. Supposing the materials to be too soft, or the abutments insecure, or any part of the work to be defective, and to afford too little resistance, the length of the curve of the arch being diminished, or its chord extended, it will become flatter, and, consequently, sink; the alteration being by far the greatest, if other things are equal, where the depth is the least, that is, near the crown or key-stone; so that if the curvature was, at first, nearly equal throughout, the crown will sink so much as to cause a rapid increase of curvature on each side in its immediate neighbourhood, which will bring the intrados up to the curve of equilibrium, or even above it, the form of this curve being little altered by the change of that of the arch. The middle remains firm, because the pressure is pretty equally divided throughout the blocks, but the parts newly bent give way to the unequal force, and chip a little at their internal surface; but being reduced in their dimensions by the pressure, they suffer the middle to descend still lower, and are, consequently, carried down with it, so as to be relieved from the inequality of pressure depending on their curvature, and to transfer the effect to the parts immediately beyond them, till these in their turn crumble, and by degrees the whole structure falls. (Plate XLII. fig. 6.)

This explanation will enable us to understand some observations and experiments which the late Professor Robison has related as somewhat paradoxical. He says, that an arch built "of an exceedingly soft and friable stone," the arch-stones being also too short, began to show signs of weakness by the stones chipping about ten feet from the middle, and that it afterwards split at the middle, and fifteen or sixteen feet on each side of it, and also at the abutments. And in some experiments on models of arches in chalk, he found, that "the arch always broke at some place considerably beyond another point, where the first chipping had been observed;" a circumstance which he has not succeeded in sufficiently explaining.

Section III.—*Of the Effect of Friction.*

The friction or adhesion of the substances, employed in Architecture, is of the most material consequence, for insuring the stability of the works constructed with them; and it is right that we should know the extent of its operation; it is not, however, often practically necessary to calculate its exact magnitude, because it would seldom be prudent to rely materially on it, the accidental circumstances of agitation or moisture tending very much to diminish its effect. Nor is the cohesion of the cements employed of much further consequence than as enabling them to form a firm connexion, by means of which the blocks may rest more completely on each other than they could do without it; for we must always remember, that we must lose at least half of the strength, before the cohesion of the solid blocks themselves, in the direction of the arch, can be called into action, and at least three fourths before the joints will have any tendency to open throughout their extent.

Z. *The joints of an arch, composed of materials subject to friction, may be situated in any direction lying within the limits of the angle of repose, on either side of the perpendicular to the curve of equilibrium; the angle of repose being equal to the inclination to the horizon at which the materials begin to slide on each other; and the direct friction being to the pressure as the tangent of this angle is to the radius.*

It is obvious, that any other force, as well as that

of gravity, will be resisted by the friction or adhesion of the surfaces when its direction is within the limits of the angle at which the substances begin to slide; and it may be inferred from the experiments of Mr Coulomb and Professor Vince, that this angle is constant, whatever the magnitude of the force may be, since the friction is very nearly proportional to the mutual pressure of the substances. The tendency of a body to descend along any plane being as much less than its weight as the height of the plane is less than its length, and the pressure on the plane being as much less than the weight as the length is greater than the horizontal extent, it follows, that, when the weight begins to overcome the friction, the friction must be to the pressure as the height of the plane to its horizontal extent, or as the tangent of the inclination to the radius.

This property of the angle of repose affords a very easy method of ascertaining, by a simple experiment, the friction of the materials employed: taking, for example, a common brick, and placing it, with the shorter side of its end downwards, on another which is gradually raised, we shall find that it will fall over without beginning to slide; and when this happens, the height must be half of the horizontal extent, a brick being twice as long as it is broad: in this case, therefore, the friction must be at least half of the pressure, and the angle of repose at least 30°; and an equilateral wedge of brick could not be forced up by any steady pressure of bricks acting against its sides, in a direction parallel to its base. But the effects of agitation would make such a wedge totally insecure in any practical case; and the determination only serves to assure us, that a very considerable latitude may be allowed to the joints of our materials, when there is any reason for deviating from the proper direction, provided that we be assured of a steady pressure; and much more in brick or stone than in wood, and more in wood than in iron, unless the joints of the iron be secured by some cohesive connexion. It may also be inferred from these considerations, that the direction of the joints can never determine the direction of the curve of equilibrium crossing them, since the friction will always enable them to transmit the thrust in a direction varying very considerably from the perpendicular; although, with respect to any particular joint, of which we wish to ascertain the stability independent of the friction, it would be desirable to collect the result of the elements, of which that curve is the representative, with a proper regard to its direction.

Section IV.—*Earlier Historical Details.*

The original invention of arches, and the date of their general adoption in architecture, have been discussed with great animation by the late Mr King, Mr. Dutens, and several other learned antiquaries. Mr King insisted that the use of the arch was not more ancient than the Christian era, and considered its introduction as one of the most remarkable events accompanying that memorable period. Mr Dutens appealed to the structure of the cloacæ, built by the Tarquins, and to the authority of Seneca, who observes, that the arch was generally considered as the invention of Democritus, a Philosopher who lived some centuries before Christ, but that, in his opinion, the simplicity of the principle could not have escaped the rudest architect; and, that long before Democritus, there must have been both bridges and doors, in both of which structures the arch was commonly employed. There do indeed appear to be solitary instances of arches more ancient than the epoch assigned by Mr King to their invention. We find arches concealed in the walls of some of the oldest temples extant at Athens; the cloacæ are said to be arched, not at the opening into the Tiber only, but to a greater distance within it than is likely to have been rebuilt at a later period for ornament; and the fragments of a bridge, still remaining at Rome, bear an inscription which refers its erection to the latter years of the Commonwealth. But it seems highly probable, that almost all the covered ways, constructed in the earlier times of Greece and Rome, were either formed by lintels, like doorways, or by stones overhanging each other, in horizontal strata, and leaving a triangular aperture, or by both these arrangements combined, as is exemplified in the entrance to the treasury of Atreus at Mycenæ, where the lintel has a triangular aperture over it, by which it is relieved from the pressure of the wall above; and this instance serves to show how different the distribution of the pressure on any part of a structure may be, from the simple proportions of the height of the materials above it. Some other old buildings, which have been supposed to be arched, have been found, on further examination, rather to resemble domes, which may be built without centres, and may be left open at the summit, the horizontal curvature producing a transverse pressure, which supports the structure without an ordinary key-stone. And this has been suspected to be the form of the roofs and ceilings of ancient Babylon, where Strabo tells us that the buildings were arched over or "camerated," for the purpose of saving timber: and the bridge of Babylon, which must have been of considerable antiquity, is expressly said, by Herodotus, to have consisted of piers of stone, with a road formed of beams of wood only. It may however be rejoined, that though a dome is not simply an arch, yet it exceeds it in contrivance and mechanical complication; it generally exerts a thrust, and requires either an abutment, or a circular tie; and it is scarcely possible that the inventor of a dome should not have been previously acquainted with the construction of a common arch. Besides the term CAMARA, the Greeks had also PSALIS, APSIS, and THOLUS; the last was particularly appropriate to circular domes; but the variety of appellations seems to prove that the thing must have been perfectly familiar; and the term PSALIS is supposed to have been applied from the appearance of the wedged arch-stones, viewed in their elevation, which could not have been observable in a dome of any kind.

From these outlines of the origin of the art of building bridges, we may pass on rapidly to the latest improvements which have been made, in Great Britain, and on the Continent, in the practice of this department of architecture. A very ample detail of

the most important operations, that are generally required to be performed in it, may be found in the numerous Reports of the ingenious Mr Smeaton, published since his death by the Society of Civil Engineers in London. They contain a body of information comprehending almost every case that can occur to a workman, in the execution of such structures; and even where they have to record an accidental failure, the instruction they afford is not less valuable than where the success has been more complete.

Respecting the general arrangement of a bridge, and the number of arches to be employed, in the case of a wide river, Mr Smeaton has expressed his approbation of a few wide and flat arches, supported by good abutments, in preference to more numerous piers, which unnecessarily interrupt the water-way. In a case where a long series of small arches was required, he has made them so flat, and the piers so slight, that a single pier would be incapable of withstanding the thrust of its arch: but in order to avoid the destruction of the whole fabric in case of an accident, he has intermixed a number of stronger piers, at certain intervals, among the weaker ones. Where several arches, of different heights, were required, he commonly recommended different portions of the same circle for all of them; a mode which rendered the lateral thrust nearly equal throughout the fabric, and had the advantage of allowing the same centre to be employed for all, with some little addition at the ends to adapt it to the larger arches. He records the case of Old Walton bridge, in which the wooden superstructure had sunk two feet, so as to become part of a circle 700 feet in diameter, and the thrust, thus increased, had forced the piers considerably out of their original situation: a striking proof that the principles of the pressure of arches must not be neglected, even when frames of carpentry are concerned.

Mr Smeaton particularly describes the inconveniences arising from the old method of laying the foundations of piers, which was introduced soon after the Conquest, and which is particularly exemplified in London Bridge. The masonry commences above low water mark, being supported on piles, which would be exposed to the destructive alternation of moisture and dryness, with the access of air, if they were not defended by other piles, forming projections partly filled with stone, and denominated sterlings; which, in their turn, occasionally require the support and defence of new piles surrounding them, since they are not easily removed when they decay; so that, by degrees, a great interruption is occasioned by the breadth of the piers, thus augmented, requiring, for the transmission of the water, an increase of velocity, which is not only inconvenient to the navigation, but also carries away the bed of the river under the arches, and immediately below the bridge, making deep pools or excavations, which require from time to time to be filled up with rubble stones; while the materials, which have been carried away by the stream, are deposited a little lower down in shoals, and very much interfere with the navigation of the river. From these circumstances, as well as from the effects of time and decay, it has happened, according to late reports, that the repairs of London Bridge have often amounted, for many years together, to L. 4000 a year, while those of Westminster and Blackfriars Bridges have not cost so many hundreds. It is true, that the fall produces a trifling advantage in enabling the London water-works to employ more of the force of the tide in raising water for the use of the city; and this right, being established as a legal privilege, has long delayed the improvements, which might otherwise have been attempted, for the benefit of the navigation of the river. The interest of the proprietors of the water-works has been valued at L. 125,000; and it has been estimated that L. 50,000 would be required for the erection of steam-engines to supply their place; while, on the other hand, it is said that from thirty to forty persons, on an average, have perished annually from the dangers of the fall under the bridge. (Plate XLIII. fig. 7, 8.)

But Mr Smeaton, as well as his predecessor Mr Labelye, appears sometimes to have gone into a contrary extreme, and to have been somewhat too sparing in the use of piles. It is well known that the opening of Westminster Bridge was delayed for two years on account of the failure of a pier, the foundation of which had been partly undermined by the incautious removal of gravel from the bed of the river, in its immediate neighbourhood; a circumstance which would scarcely have occurred if piles had been more freely employed in securing the foundation. The omission, however, did not arise from a want of a just estimate of the importance of piles in a loose bottom, but from a confidence, founded on examination as the work advanced, that the bed of the river was already sufficiently firm. Mr Smeaton directed the foundations of Hexham Bridge to be laid, as those of Westminster Bridge had been, by means of caissons, or boxes, made water-tight, and containing the bottom of the pier, completed in masonry well connected together, and ready to be deposited in its proper place by lowering the caissons, and then detaching the sides, which are raised for further use, from the bottoms, which remain fixed as a part of the foundations immediately resting on the bed of the river, previously made smooth for their reception, and sometimes also rendered more firm by piles and a grating of timber. By a careful examination of the bottom of the river at Hexham, Mr Smeaton thought he had ascertained that the stratum of gravel, of which it consisted, was extremely thin, and supported by a quicksand, much too loose to give a firm hold to piles, while he supposed the gravel strong enough to bear the weight of the pier, if built in a caisson. The bridge was a handsome edifice, with elliptical arches, and stood well for a few years; but an extraordinary flood occurred, which caused the water to rise five feet higher above than below the bridge, and to flow through it with so great a velocity, as to undermine the piers, and cause the bridge to divide longitudinally, and fall in against the stream; a circumstance so much the more mortifying to the eminent engineer who had constructed it, as it was the only one of his works that, "in a period of thirty years," had been known to fail. It was observed that some of the piers,

which had been built in coffer-dams, with the assistance of some piles, withstood the violence of the flood; and it is remarkable, that the whole bridge has been rebuilt by a provincial architect with perfect success, having stood without any accident for many years.

It seems, therefore, scarcely prudent to trust any very heavy bridge to a foundation not secured by piles, unless the ground on which it stands is an absolute rock; and in this case, as well as when piles are to be driven and sawed off, it is generally necessary to have recourse to a coffer-dam. In the instance of the bridge at Harraton, for example, where the rock is nine feet below the bed of the river, Mr Smeaton directs that the piles forming the coffer-dam be rebated into each other, driven down to the rock, and secured by internal stretchers, before the water contained within them is pumped out. In some cases, a double row of piles, with clay between them, has been employed for forming a coffer-dam; but in others it has been found more convenient to drive and cut off the piles under water, by means of proper machinery, without the assistance of a coffer-dam.

Piles are employed of various lengths, from 7 to 16 feet or more, and from 8 to 10 inches in thickness, and they are commonly shod with iron. Smeaton directs them to be driven till it requires from 20 to 40 strokes of the pile driver to sink them an inch, according to the magnitude of the weight, and the firmness required in the work. He was in the habit of frequently recommending the piles surrounding the piers to be secured by throwing in rubble stone, so as to form an inclined surface, sloping gradually from the bridge upwards and downwards. In the case of Coldstream Bridge, it was also found necessary to have a partial dam, or artificial shoal, thrown across the river a little below the bridge, in order to lessen the velocity of the water, which was cutting up the gravel from the base of the piles. But all these expedients are attended with considerable inconvenience, and it is better to avoid them in the first instance by leaving the water-way as wide and as deep as possible, and by making the foundations as firm and extensive as the circumstances may require.

The angles of the piers, both above and under water, are commonly rounded off, in order to facilitate the passage of the stream, and to be less liable to accidental injury. Mr Smeaton recommends a cylindrical surface of 60° as a proper termination; and two such surfaces, meeting each other in an angle, will approach to the outline of the head of a ship, which is calculated to afford the least resistance to the water gliding by it.

We find that, in the year 1769, the earth, employed for filling up the space between the walls of the North Bridge in Edinburgh, had forced them out, so as to require the assistance of transverse bars and buttresses for their support. In the more modern bridges, these accidents are prevented by the employment of longitudinal walls for filling up the haunches, with flat stones covering the intervals between them, instead of the earth, or the more solid materials which were formerly used, and which produced a greater pressure both on the arch and on the abutments, as well as a transverse thrust against the side walls. For the inclination of the road passing over this bridge, Mr Smeaton thought a slope of 1 in 12 not too great; observing that horses cannot trot even when the ascent is much more gradual than this, and that if they walk, they can draw a carriage up such a road as this without difficulty: and, indeed, the bridge at Newcastle appears, for a short distance, to have been much steeper. But it has been more lately argued, on another occasion, that it is a great inconvenience in a crowded city, to have to lock the wheel of a loaded waggon; that this is necessary at all times on Holborn Hill, where the slope is only 1 in 18; while in frosty weather this street is absolutely impassable for such carriages: and the descent of Ludgate Hill, which is only 1 in 36, is considered as much more desirable, when it is possible to construct a bridge with an acclivity so gentle.

Section V.—*Improvements of the Port of London.*

From the study of Mr Smeaton's diversified labours, we proceed to take a cursory view of the Parliamentary Inquiry respecting the improvement of the Port of London, which has brought forwards a variety of important information, and suggested a multiplicity of ingenious designs. The principal part of that which relates to our present subject is contained in the Second and Third Reports from the Select Committee of the House of Commons, on the improvement of the Port of London; ordered to be printed 11th July 1799, and 28th July 1800.

We find in these Reports some interesting details respecting the history of London Bridge, which appears to have been begun, not, as Hume tells us, by William Rufus, who was killed in 1100, but in 1176, under Henry II.; and to have been completed in 33 years. The piles are principally of elm, and they have remained for six centuries without material decay; although a part of the bridge fell, and was rebuilt about 100 years after it was begun. Rochester, York, and Newcastle Bridges were also built in the twelfth century, as well as the Bridge of St Esprit at Avignon. About 50 years ago, the middle pier of London Bridge was removed; the piles were drawn by a very powerful screw, commonly used for lifting the wheels of the water-works; and a single arch was made to occupy the place of two. In consequence of this, the fall was somewhat diminished, and it was necessary partially to obstruct the channel again, in order that the stream should have force enough for the water-works; but it was very difficult to secure the bottom from the effects of the increased velocity under the arch. Several strong beams were firmly fixed across the bed of the river, but only two of them retained their situations for any length of time; and the materials carried away had been deposited below the middle arch, so as to form a shoal, which was only 16 inches below the surface at low water. The Reports contain also much particular information respecting Blackfriars Bridge, the piles for which were driven under water, and cut off level with the bed of the foundations, by a machine of Mr Mylne's invention. The expense of Blackfriars Bridge, including the

Bridge.

purchase of premises, was about L. 260,000; that of the building only was L. 170,000. Westminster Bridge, built in the beginning of the century, cost about L. 400,000.

The committee had received an immense variety of plans and proposals for docks, wharfs, and bridges, and many of these have been published in the Reports, together with engraved details on a very ample scale. They finally adopted three resolutions respecting the rebuilding of London Bridge.

"1. That it is the opinion of this Committee, that it is essential to the improvement and accommodation of the port of London, that London Bridge should be rebuilt upon such a construction as to permit a free passage, at all times of the tide, for ships of such a tonnage, at least, as the depth of the river would admit of, at present, between London Bridge and Blackfriars Bridge.

"2. That it is the opinion of this Committee, that an iron bridge, having its centre arch not less than 65 feet high in the clear, above high-water-mark, will answer the intended purpose, and at the least expense.

"3. That it is the opinion of this Committee, that the most convenient situation for the New Bridge, will be immediately above St Saviour's Church, and upon a line from thence to the Royal Exchange."

In a subsequent Report, ordered to be printed 3d June 1801, we find a plan for a magnificent iron bridge of 600 feet span, which had been submitted to the Committee by Messrs Telford and Douglas. Mr Telford's reputation in his profession as an engineer deservedly attracted the attention of the Committee; but many practical difficulties having been suggested to them, they circulated a number of queries relating to the proposal, among such persons of science, and professional architects, as were the most likely to have afforded them satisfactory information. But the results of these inquiries are not a little humiliating to the admirers of abstract reasoning and of geometrical evidence; and it would be difficult to find a greater discordance in the most heterodox professions of faith, or in the most capricious variations of taste, than is exhibited in the responses of our most celebrated professors, on almost every point submitted to their consideration. It would be useless to dwell on the numerous errors with which many of the answers abound; but the questions will afford us a very convenient clue for directing our attention to such subjects of deliberation as are really likely to occur in a multiplicity of cases; and it will perhaps be possible to find such answers for all of them, as will tend to remove the greater number of the difficulties which have hitherto embarrassed the subject.

Questions respecting the construction of a cast iron bridge, of a single arch, 600 feet in the span, and 65 feet rise. (Plate XLII. fig. 7.)

1. *What parts of the bridge should be considered as wedges, which act on each other by gravity and pressure, and what parts as weight, acting by gravity only, similar to the walls and other loading, usually erected upon the arches of stone bridges. Or does the whole act as one frame of iron, which can only be destroyed by crushing its parts?*

Bridge.

The distribution of the resistance of a bridge may be considered as in some measure optional, since it may be transferred from one part of the structure to another, by wedging together most firmly those parts which we wish to be most materially concerned in it. But there is also a natural principle of adjustment, by which the resistance has a tendency to be thrown where it can best be supported; for the materials being always more or less compressible, a very small change of form, supposed to be equal throughout the structure, will relieve those parts most which are the most strained, and the accommodation will be still more effectual when the parts most strained undergo the greatest change of form. Thus, if the flatter ribs, seen at the upper part of the proposed structure, supported any material part of its weight, they would undergo a considerable longitudinal compression, and being shortened a little, would naturally descend very rapidly upon the more curved, and consequently stronger parts below, which would soon relieve them from the load improperly allotted to them; the abutment would also give way a little, and be forced out, by the greater pressure at its upper part, while the lower part remained almost entirely unchanged.

It is, however, highly important that the work should, in the first instance, be so arranged as best to fulfil the intended purposes, and especially that such parts should have to support the weight as are able to do it with the least expense of lateral thrust, which is the great evil to be dreaded in a work of these gigantic dimensions, the materials themselves being scarcely ever crushed, when the arch is of a proper form; and the failure of an iron bridge, by the want of ultimate resistance of its parts to a compressing force, being a thing altogether out of our contemplation; and it is obvious that the greater the curvature of the resisting parts, the smaller will be the lateral thrust on the abutments.

We may, therefore, sufficiently answer this question, by saying, that the whole frame of the proposed bridge, so far as it lies in or near the longitudinal direction of the arch, may occasionally cooperate in affording a partial resistance if required; but that the principal part of the force ought to be concentrated in the lower ribs, not far remote from the intrados.

But it is by no means allowable to calculate upon a curve of equilibrium exactly coinciding with the intrados; since, if this supposition were realized, we should lose more than three-fourths of the strength of our materials, and all the stability of the joints independent of cohesion, so that the slightest external force might throw the curve beyond the limits of the joint, and cause it to open. Nor can we always consider the curve of equilibrium as parallel to the intrados: taking, for example, the case of a bridge like Blackfriars, the curve of equilibrium, passing near the middle of the arch-stones, is, and ought to be, nine or ten feet above the intrados at the abutment, and only two or three feet at the crown; so

that the ordinates of this curve are altogether different from the ordinates which have hitherto been considered by theoretical writers. It may be imagined that this difference is of no great importance in practice; but its amount is much greater than the difference between the theoretical curves of equilibrium, determined by calculation, and the commonest circular or elliptical arches.

With respect to the alternative of comparing the bridge with masonry or with carpentry, we may say, that the principles on which the equilibrium of bridges is calculated, are altogether elementary, and independent of any figurative expressions of strains and mechanical purchase, which are employed in considering many of the arrangements of carpentry, and which may indeed, when they are accurately analysed, be resolved into forces opposed and combined in the same manner as the thrusts of a bridge. It is, therefore, wholly unnecessary, when we inquire into the strength of such a fabric, to distinguish the thrusts of masonry from the strains of carpentry, the laws which govern them being not only similar but identical; except that a strain is commonly understood as implying an exertion of cohesive force, and we have seen that a cohesive force ought never to be called into action in a bridge, since it implies a great and unnecessary sacrifice of the strength of the materials employed. If, indeed, we wanted to cross a mere ditch, without depending on the firmness of the bank, we might easily find a beam of wood or a bar of iron strong enough to afford a passage over it, unsupported by any abutment, because, in a substance of inconsiderable length, we are sure of having more strength than we require. But to assert that an iron bridge of 600 feet span "is a lever exerting a vertical pressure only on the abutments," is to pronounce a sentence from the lofty tribunal of refined science, which the simplest workman must feel to be erroneous. But, in this instance, the error is not so much in the comparison with the lever, as in the inattention to the mode of fixing it: for a lever or beam of the dimensions of the proposed bridge, lying loosely on its abutments, would probably be at least a hundred times weaker than if it were firmly connected with the abutments as a bridge is, so as to be fixed in a determinate direction. And the true reason of the utility of cast iron for building bridges, consists not, as has often been supposed, in its capability of being united so as to act like a frame of carpentry, but in the great resistance which it seems to afford to any force tending to crush it.

Question II. *Whether the strength of the arch is affected, and in what manner, by the proposed increase of its width towards the two extremities or abutments, when considered vertically and horizontally. And if so, what form should the bridge gradually acquire?*

The only material advantage, derived from widening the bridge at the ends, consists in the firmness of the abutments; and this advantage is greatly diminished by the increase of horizontal thrust which is occasioned by the increase of breadth; while the curve of equilibrium is caused to deviate greatly from a circular or parabolic arc, in consequence of the great inequality of the load on the different parts; and there seems to be no great difficulty in forming a firm connexion between a narrow bridge and a wider abutment, without this inconvenience. The lateral strength of the fabric, in resisting any horizontal force, would be amply sufficient, without the dilatation at the ends. Perhaps the form was suggested to the inventor by the recollection of the partial failure of an earlier work of the same kind, which has been found to deviate considerably from the vertical plane in which it was originally situated: but in this instance there seems, if we judge from the engravings which have been published, to have been a total deficiency of oblique braces; and the abutments appear to have been somewhat less firm than could have been desired, since one of them contains an arch and some warehouses, instead of being composed of more solid masonry. (Plate XLIII. fig. 9.)

Question III. *In what proportions should the weight be distributed from the centre to the abutments, to make the arch uniformly strong?*

This question is so comprehensive, that a complete answer to it would involve the whole theory of bridges; and it will be necessary to limit our investigations to an inquiry whether the structure, represented in the plan, is actually such as to afford a uniform strength, or whether any alterations can be made in it, compatible with the general outlines of the proposal, to remedy any imperfections which may be discoverable, in the arrangement of the pressure.

There is an oversight in some of the official answers to this question, from quarters of the very first respectability, which requires our particular attention. The weight of the different parts of the bridge has been supposed to differ so materially from that which is required for producing an equilibrium in a circular arch of equable curvature, that it has been thought impossible to apply the principles of the theory in any manner to an arch so constituted, at the same time that the structure is admitted to be tolerably well calculated to stand, when considered as a frame of carpentry. The truth is, that it is by no means absolutely necessary, nor often perfectly practicable, that the mean curve of equilibrium should agree precisely in its form with the curves limiting the external surfaces of the parts bearing the pressure, especially when they are sufficiently extensive to admit of considerable latitude within the limits of their substance. It may happen in many cases, that the curve of equilibrium is much flatter in one part, and more convex in another, than the circle which approaches nearest to it; and yet the distance of the two curves may be inconsiderable, in comparison with the thickness of the parts capable of cooperating in the resistance. The great problem, therefore, in all such cases, is, to determine the precise situation of the curve of equilibrium in the actual state of the bridge; and when this has been done, the directions of the ribs, in the case of an iron bridge, and of the joints of the arch-stones, in a stone bridge, may be so regulated as to afford the

Bridge.

greatest possible security; and if this security is not deemed sufficient, the whole arrangement must be altered.

Considering the effect of the dilatation at the ends in increasing the load, we may estimate the depth of the materials causing the pressure at the abutments as about three times as great as at the crown; the plan not being sufficiently minute to afford us a more precise determination; and it will be quite accurate enough to take $w = a + bx^2$ (Prop. S.) for the load, w becoming $= 3a$ when x is 300 feet, whence $90{,}000\, b = 2a$, and $b = \frac{1}{45{,}000} a$; we have then $my = \frac{1}{2} ax^2 + \frac{1}{540{,}000} ax^4$ for the value of the ordinate. Now the obliquity to the horizon being inconsiderable, this ordinate will not ultimately be much less than the whole height of the arch; and its greatest value may be called 64 feet; consequently when $x = 300$, we have $64\, m = \frac{1}{2} a \times 90{,}000 + \frac{1}{6} a \times 90{,}000$, and the radius of curvature at the vertex $r = \frac{m}{a} = 937.5$ feet, while the radius of the intrados is 725 feet, and that of a circle passing through both ends of the curve of equilibrium, as we have supposed them to be situated, 735 feet. Hence, y being $= \frac{1}{1875} x^2 \left(1 + \frac{1}{270000} x^2\right)$, we may calculate the ordinates at different points, and compare them with those of the circular curves.

Distance x.	Versed sine of the intrados.	Versed sine of the circular arc.	Ordinate y.
50	1.73	1.71	1.34
100	6.94	6.82	5.38
150	15.66	15.43	13.00
200	28.13	27.70	24.50
250	44.42	43.81	41.01
300	65.00	64.00	64.00

Hence it appears that, at the distance of 200 feet from the middle, the curve of equilibrium will rise more than 3 feet above its proper place; requiring a great proportion of the pressure to be transferred to the upper ribs, with a considerable loss of strength, for want of a communication approaching more nearly to the direction of the curve. If we chose to form the lower part of the structure of two series of frames, each about 4 feet deep, with diagonal braces, we might provide amply for such an irregularity in the distribution of the pressure; but it would be necessary to cast the diagonals as strong as the blocks, in order to avoid the inequality of tension from unequal cooling, which is often a cause of dangerous accidents; it would, however, be much better to have the arch somewhat elliptical in its form, if the load were of necessity such as has been supposed.

Question 4. *What pressure will each part of the bridge receive, supposing it divided into any given number of equal sections, the weight of the middle section being given. And on what parts, and with what force, will the whole act upon the abutments?*

It appears from the preceding calculations, that the weight of the "middle section" alone is not sufficient for determining the pressure in any part of the fabric; although, when the form of the curve of equilibrium has been found, its radius of curvature at the summit must give at once the length of a similar load equivalent to the lateral thrust; and by combining this thrust with the weight, or with the direction of the curve, the oblique thrust at any part of the arch may be readily found. Thus, since at the abutment $w = a + bx^2 = 3a$, and $bx^2 = 2a$, we have $y = \frac{1}{2}\frac{a}{m}x^2 + \frac{1}{12}\frac{b}{m}x^4$, and $\frac{dy}{dx}$, the tangent of the inclination, becomes $= \frac{a}{m}x + \frac{1}{3}\frac{b}{m}x^3 = \frac{ax}{m} + \frac{2}{3}\frac{ax}{m} = \frac{5}{3}\frac{x}{r} = \frac{5}{3}\cdot\frac{300}{937.5} = \frac{8}{15} = .5333$; consequently the horizontal thrust will be to the weight of the half arch as 15 to 8, and to that of the whole arch as 15 to 16. Now the arch is supposed to contain 6500 tons of cast iron, and together with the road, will amount, according to Professor Robison's estimate, to 10,100 tons; so that the lateral thrust on each abutment is 9470 tons; and since this is equal to the weight of 937.5 feet in length, of the thickness of the crown, the load there must be about 10 tons for each foot of the length. Hence, it appears, that although the thrust, thus calculated, is greater than the weight of a portion of equal length with the apparent radius at the crown, it is less than would be inferred from the angular direction of the intrados at the abutment: the inclination of the termination of the arch being 24° 27′, while that of the true curve of equilibrium is 28° 4′; that is, about one-tenth greater.

As a further illustration of the utility of this mode of computation, we may take the example of an arch of Blackfriars Bridge. The radius of curvature, as far as four-fifths of the breadth, is here 56 feet; and we may suppose, without sensible error, the whole load to be that which would be determined by the continuation of the same curve throughout the breadth. Now, the middle of the arch stones, at the distance of 50 feet from the middle of the bridge, that is, immediately over the termination of the abutment, is about 12 feet above that termination, and at the crown about three feet above the intrados, so that we have only 31 feet for the extreme value of y, while the whole height of the arch is 40; and a being 6.58 feet, we find (Prop. U.) $my = 13{,}510 = 31m$, whence $m = 436$, and $\frac{m}{a} = r = 66\frac{1}{4}$; we also obtain the values of the ordinates of the curve as in the annexed table.

Distance x.	Ordinate y.	Middle of the Arch-Stones.
10 FEET	.76	.90
20	3.12	3.72
25	5.13	6.12
30	7.71	8.75
40	15.81	16.81
50	31.00	31.00

Hence it appears that the greatest deviation is about 30 feet from the middle, where it amounts to a little more than a foot. But if we suppose this deviation divided by a partial displacement of the curve at its extremities, as it would probably be in reality, even if the resistance were confined to the arch-stones, it would be only about half as great in all three places; and even this deviation will reduce the strength of the stones to two-thirds, leaving them however still many times stronger than can ever be necessary. The participation of the whole fabric, in supporting a share of the oblique thrust, might make the pressure on the arch-stones somewhat less unequal, and the diminution of their strength less considerable; but it would be better that the pressure should be confined almost entirely to the arch-stones, as tending less to increase the horizontal thrust, which is here compressed by $m = 436$, implying the weight of so many square feet of the longitudinal section of the bridge; while, if we determined it from the curvature of the intrados, it would appear to be only $56a = 368$.

In this calculation, the oblique direction of the joints, as affecting the load, has not been considered; but its effect may be estimated by merely supposing the specific gravity of the materials to be somewhat increased. Thus, since the back of each arch-stone is about one-eighth wider than its lower end, the weight of the materials pressing on it will be about one-sixteenth greater than would press on it, if it were of uniform thickness; and this increase will be very nearly proportional to w, the whole load at each part; so that it will only affect the total magnitude of the thrust, which, instead of 436, must be supposed to amount to about 463. If also great accuracy were required, it would be necessary to appreciate the different specific gravities of the various materials constituting the load; since they are not altogether homogeneous; but so minute a calculation is not necessary in order to show the general distribution of the forces concerned, and the sufficiency of the arrangement for answering all the purposes intended.

QUESTION 5. *What additional weight will the bridge sustain, and what will be the effect of a given weight placed upon any of the before mentioned sections?*

When a weight is placed on any part of a bridge, the curve of equilibrium must change its situation more or less, according to the magnitude of the weight; and the tangent of its inclination must now be increased by a quantity proportional to the additional pressure to be supported, which, if the weight were placed in the middle of the arch, would always be equal to half of it; but when the weight is placed at any other part of the arch, if we find the point where the whole thrust is horizontal, the vertical pressure to be supported at each point of the curve must obviously be equal to the weight of the materials interposed between it and this new summit of the curve. Now, in order to find where the thrust is horizontal, we must divide the arch into two such portions, that their difference, acting at the end of a lever of the length of half the span, that is, of the distance from the abutment, may be equivalent to the given weight, acting on a lever equal to its distance from the other abutment, to which it is nearest; consequently this difference must be to the weight as the distance of the weight from the end to half the span; and the distance of the new summit of the curve from the middle must be such, that the weight of materials intercepted between it and the middle shall be to the weight as the distance of the weight from the end to the whole span; and the tangent of the inclination must everywhere be increased or diminished by the tangent of the angle at which the lateral thrust would support the weight of this portion of the materials; except immediately under the weight, where the two portions of the curve will meet in a finite angle, at least if we suppose the weight to be collected in a single point.

If, for example, a weight of 100 tons, equal to that of about 10 feet of the crown of the arch, be placed half-way between the abutment and the middle; then the vertex of the curve, where the thrust is horizontal, will be removed $2\frac{1}{2}$ feet towards the weight; but the radius being 937.5 feet, the tangent of the additional inclination will be $\frac{2.5}{937.5} = \frac{1}{375}$, and each ordinate of the curve will be increased $\frac{1}{375}$ of the absciss, reckoning from the place of the weight to the remoter abutment; but between the weight and the nearest abutment, the additional pressure at each point will be $10 - 2.5 = 7.5$ feet, consequently the tangent will be $\frac{1}{125}$, and the additions to the ordinates at the abutments will be $\frac{450}{375}$ and $\frac{150}{125}$, each equal to $1\frac{1}{5}$ foot, and at the summit $\frac{150}{375} = \frac{2}{5}$, which, being deducted, the true addition to the height of the curve will appear to be $\frac{4}{5}$. But the actual height will remain unaltered, since the curve is still supposed to be terminated by the abutments, and to pass through the middle of the key-stone; and we have only to reduce all the ordinates in the proportion of 64.8 to 64. Thus, at 200 feet from the summit, the ordinate, instead of 24.50 $+ \frac{200}{375} = 25.03$, will be 24.72, so that the curve will be brought $2\frac{1}{2}$ inches nearer to the intrados, which, in the proposed fabric, would by no means

diminish its strength; while, on the opposite side, immediately under the weight, the ordinate $13 - \frac{150}{375} = 12.6$ will be reduced to 12.45, and the curve raised between six and seven inches, which is a change by no means to be neglected in considering the resistances required from each part of the structure. We ought also, if great accuracy were required, to determine the effect of such a weight in increasing the lateral thrust, which would affect in a slight degree the result of the calculation; but it would not amount, in the case proposed, to more than one-eightieth of the whole thrust.

It is obvious that the tendency of any additional weight, placed near the middle of a bridge, is to straighten the two branches of the curve of equilibrium, and that, if it were supposed infinite, it would convert them into right lines; provided, therefore, that such right lines could be drawn without coming too near the intrados at the haunches, the bridge would be in no danger of giving way, unless either the materials were crushed, or the abutments were forced out. In fact, any bridge well constructed might support a load at least equal to its own weight, with less loss of strength than would arise from some such errors, as have not very uncommonly been committed, even in works which have on the whole succeeded tolerably well.

QUESTION 6. *Supposing the bridge executed in the best manner, What horizontal force will it require, when applied to any particular part, to overturn it, or press it out of the vertical plane?*

If the bridge be well tied together, it may be considered as a single mass, standing on its abutments; its mean breadth being about 80 feet, and its weight 10,100 tons; and such a mass would require a lateral pressure at the crown of the arch of about 7000 tons to overset it. Any strength of attachment to the abutments would, of course, make it still firmer, and any want of connexion between the parts weaker; and since the actual resistance to such a force must depend entirely on the strength of the oblique connexion between the ribs, it is not easy to define its magnitude with accuracy: but, as Professor Robison has justly remarked, the strength would be increased by causing the braces to extend across the whole breadth of the half arch. The single ribs, if wholly unconnected, might be overset by an inconsiderable force, since they stand in a kind of tottering equilibrium; and something like this appears to have happened to the bridge at Wearmouth. Dr Hutton, indeed, mentions some "diagonal iron bars" in this bridge; but these were perhaps added after its first erection, to obviate the "twisting," which had become apparent, since they are neither exhibited in the large plates of the bridge, nor mentioned in the specification of the patent.

QUESTION 7. *Supposing the span of the arch to remain the same, and to spring ten feet lower, What additional strength would it give the bridge? Or, making the strength the same, What saving may be made in the materials? Or, if, instead of a circular arch, as in the plates and drawings, the bridge should be made in the form of an elliptical arch, What would be the difference in effect, as to strength, duration, convenience, and expenses?*

The question seems to suppose the weight of the materials to remain unaltered, and the parts of the structure, that would be expanded, to be made proportionally lighter; which could not be exactly true, though there might be a compensation in some other parts. Granting, however, the weight to be the same under both circumstances, if the ordinate y at the end be increased in the proportion of 64 to about 73, the curvature at the vertex will be increased, and the lateral thrust diminished in the same ratio, the 9470 tons being reduced to 8300. The additional thrust occasioned by any foreign weight would also be lessened, but not the vertical displacement of the curve derived from its pressure; and since the whole fabric might safely be made somewhat lighter, the lightness would again diminish the strain. The very least resistance that can be attributed to a square inch of the section of a block of cast iron, is about 50 tons, or somewhat more than 100,000 pounds. It is said, indeed, that Mr William Reynolds found, by accurate experiments, that 400 tons were required, to crush a cube of a quarter of an inch, of the kind of cast iron called gun-metal, which is equivalent to 6400 tons for a square inch of the section. But this result so far exceeds any thing that could be expected, either from experiment or from analogy, that it would be imprudent to place much reliance on it in practice; the strength attributed to the metal being equivalent to the pressure of a column 2,280,000 feet in height, which would compress it to about four-fifths of its length, since the height of the modulus of elasticity (Prop. G.) is about 10,000,000 feet. The greatest cohesive force, that has ever been observed in iron or steel, does not exceed 70 tons for a square inch of the section, and the repulsive force of a homogeneous substance has not been found, in any other instance, to be many times greater or less than the cohesive. There cannot, however, be any doubt that the oblique thrust, which amounts to 10,730 tons, would be sufficiently resisted by a section of 215 square inches, or, if we allowed a load amounting to about one-third only of the whole strength, by a section of 600 square inches; and since each foot of an iron-bar, an inch square, weighs three pounds, and the whole length of the arch nearly a ton, the 600 square inches would require nearly as many tons to be employed in the ribs affording the resistance, upon this very low estimate of the strength of cast iron. The doubts here expressed respecting Mr Reynolds's results, have been fully justified by some hasty experiments, which have been obligingly made by the son of a distinguished architect: he found that two parallelepipeds of cast iron, one eighth of an inch square, and a quarter of an inch long, were crushed by a force of little more than a ton. The experiments were made in a vice, and required considerable reductions for the friction. The mode of calculation may deserve to be explained, on account of its utility on other similar occasions. Supposing the friction to be to the pressure

Bridge. on the screw as 1 to m, and the pressure on the screw to the actual pressure on the substance as n to 1, calling this pressure x, the pressure on the screw will be nx, and the friction $\frac{nx}{m}$; but this resistance will take from the gross ultimate pressure f a force, which is to the friction itself, as the velocity of the parts sliding on each other is to the velocity of the part producing the ultimate pressure, a proportion which we may call p to 1; and the force remaining will be the actual pressure; that is, $f-\frac{pnx}{m}=x$, and $x=\frac{m}{m+pn}f$. In these experiments, the gross force f, as supposed to be exerted on the iron, was 4 tons; the friction $\frac{1}{m}$, was probably about $\frac{1}{4}$, the screw not having been lately oiled; the distance of the screw from the centre of motion was to the length of the whole vice as 3 to 4, whence n was $\frac{4}{3}$, and p was 8.44, the middle of the screw describing 4.22 inches, while the cheek of the vice moved through $\frac{1}{2}$ an inch: consequently $\frac{m}{m+pn}$ was $\frac{4}{4+11.25}=\frac{1}{3.81}$, and the corrected pressure becomes $\frac{4}{3.81}$. In several experiments made with still greater care, and with an improved apparatus of levers, the mean force required to crush a cube of a quarter of an inch was not quite $4\frac{1}{2}$ tons, instead of 400.

Calcareous freestone supports about a ton on a square inch, which is equal to the weight of a column not quite 2000 feet in height: consequently an arch of such freestone, of 2000 feet radius, would be crushed by its own weight only, without any further load; and for an arch like that of a bridge, which has other materials to support, 200 feet is the utmost radius that it has been thought prudent to attempt; although a part of the bridge of Neuilly stands, cracked as it is, with a curvature of 250 feet radius; and there is no doubt that a firm structure, well arranged in the beginning, might safely be made much flatter than this, if there were any necessity for it.

An elliptical arch would certainly approach nearer to the form of the curve of equilibrium, which would remain little altered by the change of that of the arch; and the pressure might be more equably and advantageously transmitted through the blocks of such an arch, than in the proposed form of the structure. The duration would probably be proportional to the increased firmness of the fabric, and the greater flatness at the crown might allow a wider space for the passage of the masts of large ships on each side of the middle. There might be some additional trouble and expense in the formation of portions of an elliptical curve; but even this might be in a great measure avoided by employing portions of three circles of different radii, which would scarcely be distinguishable from the ellipsis itself.

Those who have imagined that a circular arch must in general be "stronger than an elliptical arch of the same height and span," have not adverted to the distinction between the apparent curvature of the arch, and the situation of the true curve of equilibrium, which depends on the distribution of the weight of the different parts of the bridge, and by no means on the form of the arch-stones only; this form being totally insufficient to determine the true radius of curvature, which is immediately connected with the lateral thrust, and with the strength of the fabric.

QUESTION 8. *Is it necessary or advisable to have a model made of the proposed bridge, or any part of it, in cast iron. If so, what are the objects to which the experiments should be directed; to the equilibration only, or to the cohesion of the several parts, or to both united, as they will occur in the intended bridge?*

Experiments on the equilibration of the arch would be easy and conclusive; on the cohesion or connexion of the parts, extremely uncertain; the form and proportion of the joints could scarcely be imitated with sufficient accuracy; and since the strength of some of the parts concerned, would vary as the thickness simply, and that of others as the square or cube of the thickness, it would be more difficult to argue from the strength of the model upon that of the bridge, than to calculate the whole from still more elementary experiments. Some such experiments ought, however, to be made, on the force required to crush a block of the substance employed; and the form calculated to afford the proper equilibrium, might be very precisely and elegantly determined, by means of the method first suggested by Dr Hooke, that of substituting for the blocks, resting on each other and on the abutments, as many similar pieces forming a chain, and suspended at the extremities. It would, however, be important to make one alteration in the common mode of performing this experiment, without which it would be of little or no value; the parts corresponding to the blocks of the arch, should be formed of their proper thickness and length, and connected with each other and with the abutments by a short joint or hinge in the middle of each, allowing room for a slight degree of angular motion only; and every other part of the structure should be represented in its proper form and proportion and connexion, that form being previously determined as nearly as possible by calculation; and then, if the curve underwent no material alteration by the suspension, we should be sure that the calculation was sufficiently correct; or, if otherwise, the arrangement of the materials might be altered, until the required curve should be obtained; and the investigation might be facilitated by allowing the joints or hinges, connecting the block, to slide a little along their surfaces, within such limits as would be allowable, without too great a reduction of the powers of resistance of the blocks.

QUESTION 9. *Of what size ought the model to be made, and what relative proportions will experiments, made on the model, bear to the bridge when executed?*

The size is of little importance, and it would be unsafe to calculate the strength of the bridge from

any general comparison with that of the model. There is an *Essay* of Euler in the *New Commentaries of the Royal Academy of Petersburgh* (Vol. XX. p. 271.), relating expressly to the mode of judging of the strength of a bridge from a model; but it contains only an elementary calculation, applicable to ropes and simple levers, and by no means comprehending all the circumstances that require to be considered in the structure of an arch.

QUESTION 10. *By what means may ships be best directed in the middle stream, or prevented from driving to the side, and striking the arch; and what would be the consequence of such a stroke?*

For the direction of ships, Professor Robison's suggestion seems the simplest and best, that they might be guided by means of a small anchor, dragged along the bottom of the river. The stroke of a ship might fracture the outer ribs, if they were too weak, but could scarcely affect the whole fabric in any material degree, supposing it to be firmly secured by oblique bars, crossing from one side of the abutment to the other side of the middle; and if still greater firmness were wanted, the braces might cross still more obliquely, and be repeated from space to space.

A ship moving with a velocity of three miles in an hour, or about four feet in a second, would be stopped by a force equal to her weight, when she had advanced three inches with a retarded motion; and the bridge could not very easily withstand, at any one point, a force much greater than such a shock of a large ship, if it were direct, without being dangerously strained. But we must consider that a large ship could never strike the bridge with its full force, and that the mast would be much more easily broken than the bridge. The inertia of the parts of the bridge, and of the heavy materials laid on it, would enable it to resist the stroke of a small mass with great mechanical advantage. Thus the inertia of an anvil, laid on a man's chest, enables him to support a blow on the anvil, which would be fatal without such an interposition, the momentum communicated to the greater weight being always less than twice the momentum of the smaller; and this small increase of momentum being attended by a much greater decrease of energy or impetus, which is expressed by the product of the mass into the square of the velocity, and which is sometimes called the ascending or penetrating force, since the height of ascent or depth of penetration is proportional to it, when the resistance is given. And the same mode of reasoning is applicable to any weight falling on the bridge, or to any other cause of vibration, which is not likely to call forth in such a fabric any violent exertion of the strength of the parts, or of their connections. We must also remember, in appreciating the effect of a stroke of any kind on an arched structure, that something of strength is always lost by too great stiffness; the property of resisting velocity, which has sometimes been called resilience, being generally diminished by any increase of stiffness, if the strength, with respect to pressure, remains the same.

QUESTION 11. *The weight and lateral pressure of the bridge being given, can abutments be made in the proposed situation for London Bridge, to resist that pressure?*

Since this question relates entirely to the local circumstances of the banks of the Thames, the persons, to whom it has been referred, have generally appealed to the stability of St Saviour's Church, in a neighbouring situation, as a proof of the affirmative. And it does not appear that there have been any instances of a failure of piles well driven, in a moderately favourable soil. Professor Robison, indeed, asserts that the firmest piling will yield in time to a pressure continued without interruption; but a consideration of the general nature of friction and lateral adhesion, as well as the experience of ages in a multitude of structures actually erected, will not allow us to adopt the assertion as universally true. When, indeed, the earth is extremely soft, it would be advisable to unite it into one mass for a large extent, perhaps as far as 100 yards in every direction, for such a bridge as that under discussion, by beams radiating from the abutments, resting on short piles, with cross pieces interspersed; since we might combine, in this manner, the effect of a weight of 100,000 tons, which could scarcely ever produce a lateral adhesion of less than 20,000, even if the materials were semifluid; for they would afford this resistance, if they were capable of standing in the form of a bank, rising only one foot in five of horizontal extent, which any thing short of an absolute quicksand or a bog would certainly do in perfect security. The proper direction of the joints of the masonry may be determined for the abutment exactly as for the bridge, the tangent of the inclination being always increased, in proportion to the weights of the successive wedges added to the load; and the ultimate inclination of the curve is that in which the piles ought to be driven; being the direction of the result, composed of the lateral thrust, combined with the joint weight of the half bridge, and the abutment.

QUESTION 12. *The weight and lateral pressure of the bridge being given, can a centre or scaffolding be erected over the river, sufficient to carry the arch, without obstructing the vessels which at present navigate that part?*

There seems to be no great difficulty in the construction of such a centre. When the bridge at Wearmouth was erected, the centre was supported by piles and standards, which suffered ships to pass between them without interruption, and a similar arrangement might be made in the present case with equal facility.

QUESTION 13. *Whether would it be most advisable to make the bridge of cast and wrought iron combined, or of cast iron only? And if of the latter, Whether of the hard white metal, or of the soft grey metal, or of gun metal?*

A bridge well built ought to require no cohesive strength of ties, as Mr Southern has justly observed in his answer to the eighth question; and for repulsive resistance, in the capacity of a shore, cast iron is probably much stronger than wrought. It has also the advantage of being less liable to rust, and of expanding somewhat less by heat than wrought iron. But wherever any transverse strain is unavoidable, wrought iron possesses some advantages, and it is generally most convenient for bolts and other fastenings. The kind of iron called gun metal, is decidedly preferred by the most experienced

judges, as combining, in the greatest degree, the properties of hardness and toughness; the white being considered as too brittle, and the grey as too soft. Dr Hutton, however, and Mr Jessop, prefer the grey; and if we allow the strength of the gun metal to be at all comparable to that which Mr Reynolds attributes to it, we must also acknowledge that a much weaker substance would be amply sufficient for every practical purpose, and might deserve to be preferred, if it were found to possess a greater degree of tenacity.

QUESTION 14. *Of what dimensions ought the several members of the iron work to be, to give the bridge sufficient strength?*

See the Answers to Questions 7 and 11.

QUESTION 15. *Can frames of cast iron be made sufficiently correct to compose an arch of the form and dimensions shown in the drawings, so as to take an equal bearing as one frame, the several parts being connected by diagonal braces, and joined by an iron cement, or other substance?*

Professor Robison considers it as indispensable that the frames of cast iron should be ground to fit each other; and a very accurate adjustment of the surface would certainly be necessary for the perfect co-operation of every part of so hard a substance. Probably, indeed, any very small interstices that might be left, would in some measure be filled up by degrees, in consequence of the oxydation of the metal, but scarcely soon enough to assist in bearing the general thrust upon the first completion of the bridge. The plan of mortising the frames together is by no means to be advised, as rendering it very difficult to adapt the surfaces to each other throughout any considerable part of their extent. They might be connected either as in the bridge at Wearmouth, by bars of wrought iron let into the sides, which might be of extremely moderate dimensions; or, as in some still more modern fabrics, by being wedged into the grooves of cross plates, adapted to receive them, which very effectually secure the co-operation of the whole force of the blocks, and which have the advantage of employing cast iron only.

QUESTION 16. *Instead of casting the ribs in frames, of considerable length and breadth, would it be more advisable to cast each member of the ribs in separate pieces of considerable lengths, connecting them together by diagonal braces, both horizontally and vertically?*

No joint can possibly be so strong as a single sound piece of the same metal; and it is highly desirable that the curve of pressure should pass through very substantial frames or blocks, abutting fully on each other, without any reliance on lateral joints; but for the upper parts of the work, single ribs, much lighter than those which form the true arch, would be sufficiently firm.

QUESTION 17. *Can an iron cement be made, which shall become hard and durable, or can liquid iron be poured into the joints?*

Mr Reynolds has observed, that a cement, composed of iron borings and saline substances, will become extremely hard; and it is probable that this property depends on the solidity which is produced by the gradual oxydation of the iron. It would certainly be injurious to the strength of the fabric to interpose this cement between perfectly smooth and solid surfaces; but it might be of advantage to fill up with it any small interstices, unavoidably left between the parts. To pour melted iron into the joints would be utterly impracticable.

QUESTION 18. *Would lead be better to use in the whole or any part of the joints?*

Lead is by far too soft to be of the least use; and a saline cement would be decidedly preferable.

QUESTION 19. *Can any improvement be made in the plan, so as to render it more substantial and durable, and less expensive? And if so, what are these improvements?*

The most necessary alterations appear to be the omission of the upper and flatter ribs; the greater strength and solidity of the lower, made either in the form of blocks or of frames with diagonals; a curvature more nearly approaching to that of the curve of equilibrium, and a greater obliquity of the cross-braces.

It would be necessary to wedge the whole structure very firmly together before the removal of the centres, a precaution which is still more necessary for stone bridges, in which a certain portion of soft mortar must inevitably be employed, in order to enable the stones to bear fully on each other, and which has been very properly adopted in the best modern works. In this manner we may avoid the inconvenience pointed out by Professor Robison, who has remarked, that the compressibility of the materials, hard as they appear, would occasion a reduction of three inches in the length of the bridge, from the effect of the lateral thrust, and a consequent fall at the crown of 15; a result which will not be found materially erroneous, if the calculation be repeated from more correct elements, derived from later experiments and comparisons. For obviating the disadvantageous effects of such a depression, which he seems to have supposed unavoidable, as well as those of a change of temperature, which must in reality occur, though to a less considerable extent, Professor Robison suggested the expedient of a joint in the middle of the bridge, with an intermediate portion, calculated to receive the rounded ends of the opposite ribs, somewhat like an interarticular cartilage; but it is impossible to devise any kind of joint, without limiting the pressure, during the change of form, to a very small portion of the surfaces, which could not bear fully on each other throughout their extent, if any such liberty of motion were allowed, unless all friction between them were prevented; and a similar joint would be required at the abutment, where it would be still more objectionable, as extending to a wider surface.

The arrangement of the joints between the portions of the ribs, in one or more transverse lines, would be a matter of great indifference. Some have recommended to break the joints, as is usual in masonry, in order to tie the parts more firmly together; others to make all the joints continuous, as a safer method, on account of the brittleness of the materials; but if the fabric were well put together, there would be neither any want of firm connexion, nor any danger of breaking from irregular strains, in whatever way the joints might be disposed.

QUESTION 20. *Upon considering the whole cir-*

cumstances of the case, agreeable to the Resolutions of the Committee, as stated at the conclusion of their Third Report, is it your opinion, that an arch of 600 *feet in the span, as expressed in the drawings produced by Messrs Telford and Douglas, or the same plan, with any improvement you may be so good as to point out, is practicable and advisable, and capable of being made a durable edifice?*

The answers that have been returned to this question are almost universally in the affirmative, though deduced from very discordant and inconsistent views of the subject. The only reasonable doubt relates to the abutments; and with the precautions which have been already mentioned in the answer to the 11th question, there would be no insuperable difficulty in making the abutments sufficiently firm.

QUESTION 21. *Does the estimate, communicated herewith, according to your judgment, greatly exceed or fall short of the probable expense of executing the plan proposed: specifying the general grounds of your opinion?*

The estimate amounts to L. 262,289; and it has generally been considered as below the probable expense. The abutments are set down at L. 20,000; but they would very possibly require five times as much, to be properly executed; while some other parts of the work, by a more judicious distribution of the forces concerned, might safely be made so much lighter, as considerably to lessen the expense of the whole fabric, without any diminution either of its beauty or of its stability.

SECTION VI.—*Modern History of Bridges.*

The whole series of the questions, which we have been considering, are fully as interesting at the present moment, as they were at the time when they were circulated by the Committee of the House of Commons. The practice of building iron bridges has been progressively gaining ground, ever since its first introduction in 1779, by Mr Abiah Darby of Colebrook Dale. Mr Wilson, indeed, who assisted Mr Burdon in the erection of the bridge at Wearmouth, mentions in his answers, an iron bridge which has stood secure for ninety years: but it must have been on a very small scale, and has not been at all generally known. Of most of the later iron bridges we find a concise account in Dr Hutton's elaborate Essay on Bridges, which has been reprinted in the first volume of his valuable collection of Tracts: but there are some still greater edifices of this kind which still remain to be completed.

Mr Darby's construction is not remarkably elegant (Plate XLII. fig. 8.), but it is by no means so objectionable as several late authors have seemed to think it. The span is 100 feet 6 inches: the weight $178\frac{1}{2}$ tons. The curvature of the exterior concentric arches, which assist in supporting the roadway, though it may be somewhat too great for the most favourable exertion of their resistance, leaves them still abundantly strong for the purpose intended; nor is it correct to say that every shore supporting a pressure should be straight; for if its own weight bears any considerable proportion to that which it has to support, the curvature ought to be the same with that of a chain of the same weight, suspending a similar load in an inverted position: and the parts of the bridge in question seem to differ only about as much from such a form in excess of curvature, as a straight line would differ from it in defect. The partial failure, which accidentally occurred, rather bears testimony to the merits than to the demerits of the bridge, as they would be estimated in any other situation: for the lateral thrust, which it is generally desirable to reduce as much as possible, was here actually too small, and the abutments were forced inwards, by the external pressure of the loose materials, forming the high banks, against which the abutments rested.

Mr Paine's iron bridge, exhibited in London, and intended to have been erected in America, was a professed imitation of a catenarian curve: it was a good specimen of that ideal something, which a popular reformer generally has in view: a thing not ill imagined, and which might possibly succeed very well under very different circumstances; but which, when closely examined, proves to be wholly unfit for the immediate purpose to which the inventor intends to apply it.

The bridge at Wearmouth was completed in 1796, in great measure through the exertions of Mr Burdon, both as architect and as principal proprietor of the undertaking. It is remarkable for springing 70 feet above low water mark; and the arch rises 30 feet, leaving a height of 100 feet in the whole for the passage of ships in the middle of the stream: the span is 240. The abutments are founded on a solid rock, but their own internal solidity appears to be somewhat deficient. The weight of iron is 250 tons; 210 of them being of cast iron, and 40 of wrought. (Plate XLII. fig. 9.)

A bridge was finished in the same year at Buildwas, near Colebrook Dale (Plate XLII. fig. 10.), under the direction of Mr Telford; 130 feet in span, weighing 174 tons; and rising only 17 feet in the roadway, but furnished on each side with a stronger arch, of about twice the depth, which extends to the top of the railing, and assists in suspending the part of the road which is below it by means of king-posts, and in supporting the part nearer the abutments by braces and shores. The breadth is only 18 feet; and the construction would not be so easily applicable to a wider bridge, unless the road were divided in the middle by an additional elevated arch with its king-posts, like the celebrated wooden bridge at Schafhausen, which was burnt down by one of the French armies. A third iron bridge was also erected in 1796 on the Parrot at Bridgewater, by the Colebrook Dale Company. It consists of an elliptic arch, of 75 feet span, and 23 feet height, and somewhat resembles the bridge at Wearmouth in the mode of filling the haunches with circular rings: a mode not very advantageous for obtaining the greatest possible resistance from the materials, and consequently throwing a little too much weight on the parts of the arch which support them; although it is probable that no great inconvenience has actually arisen from this cause.

An attempt was also made, about the same time, to throw an iron bridge over the river Tame in Herefordshire; but it fell to pieces as soon as the centre was removed. A similar failure occurred some time

afterwards in a bridge of about 180 feet span, which was erected on the Tees at Yarm. In 1802 or 1803, an elegant iron bridge, of 181 feet span, and $16\frac{1}{2}$ rise, was erected at Staines. Its general form resembled that of the bridge at Wearmouth, but the mode of connexion of the parts was somewhat different. In a short time after its completion, it began to sink, and some of the tranverse pieces broke, in consequence of the change of form. Upon examination it was found that one of the abutments had given way: and when this was repaired and made firmer, the other failed. The abutment was pushed outwards horizontally, without any material derangement of its form or direction; a circumstance which could not have happened if its weight had been sufficiently great: but the architect seems to have trusted to the firmness of the iron, and the excellence of the workmanship, and to have neglected the calculation of the lateral thrust, which it is of so much importance to determine.

Mr Rennie has executed several iron bridges with success in Lincolnshire; one at Boston, over the Witham, of which the span is 86 feet, and the rise $5\frac{1}{2}$ only: but the abutments being well constructed, it has stood securely, notwithstanding the fracture of some of the cross pieces of the frames, which had been weakened by the unequal contraction of the metal in cooling. At Bristol, Messrs Jessop erected two iron bridges, of 100 feet span, rising 15; each of them contains 150 tons of grey iron; and the expense of each was about L.4000. The construction appears to be simple and judicious. (Plate XLII. fig. 11.)

Mr Telford has been employed in the construction of several aqueduct bridges on a considerable scale. One of these was cast by Messrs Reynolds, and completed in 1796, near Wellington in Shropshire: it is 180 feet long, and 20 feet above the water of the river, being supported on iron pillars. Another, still larger, was cast by Mr Hazledine, for carrying the Ellesmere canal over the river Dee, at Pontcysylte, in the neighbourhood of Llangollen. It is supported, 126 feet above the surface of the river, by 20 stone pillars, and is 1020 feet in length, and 12 feet wide. (Plate XLII. fig. 12.)

In France, a light iron bridge, for foot passengers only, was thrown across the Seine, opposite to the gate of the Louvre, in 1803. It is supported by stone piers, which are too narrow to withstand the effect of an accident happening to any part of the fabric, and leaving the lateral thrust uncompensated: nor is there any immediate reason to apprehend that any inconvenience should arise from this deficiency of strength; since it is highly improbable than any partial failure should occur, in such a situation, supposing the bridge originally well constructed. (Plate XLIII. fig. 1.)

But all these works have been far exceeded, in extent and importance, by the three new bridges, lately built and now building over the Thames. The Vauxhall Bridge was completed and opened in August 1816: it consists of nine arches of cast iron, each of 78 feet span, and between 11 and 12 feet rise. The breadth of the roadway is 36 feet clear. The architect was Mr Walker. The form of the arches considerably resembles that of Messrs Jessop's bridges at Bristol; but it is somewhat lighter and more elegant, and it has the advantage of a greater solidity in the blocks supporting the principal part of the pressure. (Plate XLIII. fig. 2, 3.)

This advantage characterizes also very strongly the masterly design of Mr Rennie for the structure about to be erected at the bottom of Queen Street, Cheapside, opposite to Guildhall, under the name of the Southwark Bridge. It exhibits an excellent specimen of firmness of mutual abutment in the parts constituting the chief strength of the arch, which has been shown in this essay to be so essential to the security of the work, and which the architect has probably been in great measure induced to adopt from his practical experience of the comparative merits of different arrangements. A plan of the bridge was in February last made public in the Repertory of Arts; a work which amply deserves the encouragement of all those who wish to promote the diffusion of useful information: and the magnitude of the object is such, as to justify our entering into some details of calculation respecting the pressure and strength of the different parts of the fabric, founded on a particular account of their weights and dimensions, which has not yet been made public. (Plate XLIII. fig. 4, 5, 6.)

An act of Parliament for the erection of this bridge was passed in 1811; but it was not begun till 1814; the act having directed that no operations should be commenced, until L. 300,000, out of the required L. 400,000, should be raised by subscription. The subscribers are allowed to receive ten *per cent.* annually on their shares, and the remainder of the receipts is to be laid by, and to accumulate, until it shall become sufficient to pay off to the proprietors the double amount of their subscriptions, and after this time the bridge is to remain open, without any toll. A considerable part of the iron work is already cast, by Messrs Walkers of Rotherham. The middle arch is to be 240 feet in span, the side arches 210 feet each. The abutment is of firm masonry, connected by dowels, to prevent its sliding; and resting on gratings of timber, supported by oblique piles. The piers stand on foundations nine or ten feet below the present bed of the river, in order to provide against any alterations which may hereafter take place in its channel, from the operation of various causes: and they are abundantly secured by a flooring of timber, resting on a great number of piles.

Weight of half of the middle arch of Southwark Bridge.

Span 240 feet. Rise 24. Depth of the blocks or plates at the crown 6 feet; at the pier 8 feet.

It is evident from the inspection of this statement of the weights, that their distribution is by no means capable of being accurately expressed by any one formula; but it will be amply sufficient for the determination of the thrust, to employ the approximation founded on the supposition of a parabolic curve (Prop. T.); and if we afterwards wished to find the effect of any local deviation from the assumed law of the weight, we might have recourse to the mode of calculation exemplified in the answer to the fifth Question. But, in fact, that answer may of itself be considered as sufficient to show, that the effect of a variation of a few tons, from the load appropriate to each part, would be wholly unimportant.

We must, therefore, begin by finding the weight of a portion of the arch corresponding to a quarter of the span; and the whole angle, of which the tangent is $\frac{24}{120} = .2$, being $11^\circ\ 18\frac{1}{2}'$, its sine is .1961; and the angle, of which the sine is .09805, being $5^\circ\ 37\frac{1}{2}$, we have to compute the weight of $\frac{337.5}{678.5}$, or $\frac{1}{2.01}$, of the angular extent, beginning from the middle of the arch. And this will be $48\frac{12}{20} + 88\frac{6}{20} + 95\frac{12}{20} + (87\frac{6}{20}) \times .7345 = 297$ tons. Now, the weight of the covering-plates, cornice, palisades, roadway, and pavement, are distributed throughout the length, without sensible inequality, making 879 tons; from which the part immediately above the piers might be deducted; but it will be safer to retain the whole weight, especially as something must be allowed for the greater extent of the upper surface of the wedges. We shall, therefore, have, for the interior quarter, $297 + 439.5 = 736.5$ tons, and for the exterior $1523 - 736.5 = 786.5$, the difference being 50 tons; one-sixth of which, added to 736.5, gives us 744.8 for the reduced weight, which is to the lateral thrust as the rise to the half span. But for the rise we must take 23 feet, since the middle of the blocks next to the piers is a foot more remote from the intrados than that of the blocks at the crown. And the true half span, measured from the same point, will be $4 \times \frac{120}{312}$ greater than that of the intrados, amounting to 121.6. We have, therefore, $23 : 121.6 = 745.8 : 3942$ tons, for m the lateral thrust. And for $\frac{1}{2}ax$, $736.5 - \frac{50}{6} = 728.2$; whence, $\frac{1}{2}a$ being 60.8, $a = 11.98$, and $r = \frac{m}{a} = 329$ feet, the radius of curvature of the curve of equilibrium at the vertex, while that of the middle of the blocks is 334. In order to determine the ordinate y, we have $my = \frac{1}{2}ax^2 + \frac{1}{12}bx^4$; but $\frac{1}{2}ax$ for the whole arch is 728.2, and $\frac{1}{4}bx^3 = 50$; consequently $my = 728.2x + \frac{50}{3}x$, the first portion varying as x^2, and the second as x^4; and the sum y being $23 = 22.49 + .51$, the ordinate at $\frac{1}{4}x$ or 30.4 feet is $\frac{1}{16} \times 22.49 + \frac{1}{256} \times .51 = 1.41$; and, in a similar manner, any other ordinate may be calculated, so that we have,

x.	y.	Middle of the Blocks.
30.2	1.41	1.40
60.8	5.65	5.67
91.0	13.02	12.89
121.6	23.00	23.00

Hence it appears that the curve of equilibrium nowhere deviates more than about two inches from the middle of the blocks, which is less than one fortieth of the whole depth.

The half weight of the smaller arches is probably about 1300 tons, and their lateral thrust 3500; and, since the abutment weighs 11,000 tons, the foundation ought to have an obliquity of $\frac{3500}{12300}$, or more than 1 in 4, if it were intended to stand on the piles without friction; but in reality it rises only 66 inches in 624, or nearly 1 in 9; so that there is an angular difference of 1 in 7 between the direction of the piles and that of the thrust, which is probably a deviation of no practical importance.

It remains to be inquired how far the series of masses of solid iron, constituting the most essential part of the arch, is well calculated to withstand the utmost changes of temperature that can possibly occur to it in the severest seasons (Prop. K.) For this purpose, we may take the mean depth $a = 7$ feet, h being 23; then $1 + \frac{4h}{a} = \frac{99}{7} = 14.14$, and $1 + \frac{16hh}{15aa} = \frac{9199}{735} = 12.52$: consequently the greatest actual compression or extension of such a structure is to the mean change which takes place in the direction of the chord, as 14.14 to 12.52, or as 1.129 to 1; and if, in a long and severe frost, the temperature varied from 52° to 20°, since the general dimensions would contract about $\frac{1}{5000}$, the extreme parts of the blocks near the abutments would vary $\frac{1.129}{5000}$ of their length; and the modulus M being

5

about 10,000,000 feet, this change would produce a resistance equivalent to the weight of a column of the same substance 2258 feet high: that is, to about three tons for each square inch, diminishing gradually towards the middle of the blocks, and converted on the other side into an opposite resistance: so that this force would be added to the general pressure below in case of contraction, and above in case of extension. Now, the lateral thrust is derived from a pressure equivalent to a column about 329 feet high, of materials weighing 1523 tons, while the blocks themselves weigh 357; that is, to a column equal in section to the blocks, and 1400 feet high: it will, therefore, amount to about two tons on each square inch: consequently such a change of temperature, as has been supposed, will cause the extreme parts of the abutments to bear a pressure of five tons, where, in the ordinary circumstances, they have only to support two.

The ingenious architect proposes to diminish this contingent inconvenience, by causing the blocks to bear somewhat more strongly on the abutments at the middle than at the sides, so as to allow some little latitude of elevation and depression, in the nature of a joint: and, no doubt, this expedient will prevent the great inequality of pressure which might otherwise arise from the alternations of heat and cold. But it cannot be denied that there must be some waste of strength in such an arrangement, the extreme parts of the abutments, and of the blocks near them, contributing very little to the general resistance; and when we consider the very accurate adjustment of the equilibrium throughout the whole structure, we shall be convinced that there is no necessity for any thing like so great a depth of the solid blocks, especially near the abutments; and that the security would be amply sufficient if, with the same weight of metal, they were made wider in a transverse direction, preserving only the form of the exterior ones on each side, if it were thought more agreeable to the eye. In carpentry, where there is often a transverse strain, and where stiffness is frequently required, we generally gain immensely by throwing much of the substance of our beams into the depth; but in a bridge perfectly well balanced, there is no advantage whatever from depth of the blocks: we only want enough to secure us against accidental errors of construction, and against partial loads from extraneous weights; and it is not probable that either of these causes, in such a bridge, would ever bring the curve of equilibrium six inches, or even three, from its natural situation near the middle of the blocks.

We cannot conclude our inquiries into this subject with a more striking example, than by applying the principles of the theory to the magnificent edifice which is now nearly finished, by the same judicious and experienced architect, and which is destined to bear the triumphant appellation of Waterloo Bridge; a work not less pre-eminent among the bridges of all ages and countries, than the event which it will commemorate is unrivalled in the annals of ancient or modern history. It consists of nine elliptical arches, each of 120 feet span, and 35 feet rise. The piers are 20 feet thick, the road 28 feet wide, besides a foot pavement of seven feet on each side. The arches and piers are built of large blocks of granite, with short counterarches over each pier. The haunches are filled up, as is usual in the most modern bridges, by spandrils, or longitudinal walls of brick, covered with flat stones, and extending over about half the span of the arch; the remainder being merely covered with earth or gravel, which is also continued over the stones covering the spandrils. The hollow spaces between the walls are carefully closed above, and provided with outlets below, in order to secure them from becoming receptacles of water, which would be injurious to the durability of the structure. The mean specific gravity of the materials is such, that a cubic yard of the granite weighs exactly two tons, of the brick work one ton, and of the earth a ton and an eighth. Hence, the weight of the whole may be obtained from the annexed statement. (Plate XLIV. fig. 1, 2, 3.)

Contents of the materials in half an arch of Waterloo Bridge, from the middle of the pier to the crown, beginning from the springing of the arch.

	Cubic Feet.

Balusters 72, 151 cwt. -	102
Coping, E. and W. - -	142

From this statement, and from a consideration of the arrangement of the materials, exhibited in the plate, we may infer that the half arch, terminated where the middle line of the arch-stones enters the pier, is equivalent in weight to about 34,000 cubic feet of granite; its inner half containing in round numbers 13,000, and its outer 21,000, whence we have 14,333 for the reduced weight of the quarter arch (Prop. T.). The extreme ordinate will be about 21 feet; the middle of the blocks being somewhat more than 16 feet above the springing of the arch, and the key-stone being four feet six inches deep; consequently the horizontal thrust will be expressed by $14{,}333 \times \frac{60}{21} = 40{,}952$ cubic feet, weighing 3033 tons. But $\frac{1}{2}ax$ being 11667, and $\frac{1}{2}x = 30$, $a = 389$, and $\frac{m}{a} = r = \frac{40952}{388} = 105$ feet; while the radius of curvature of the ellipsis at the crown is $\frac{60 \times 60}{35} = 103$ feet. It is obvious,

therefore, that the curve of equilibrium will pass everywhere extremely near to the middle of the blocks, and there can be no apprehension of any deficiency in the equilibrium. It is true that, as it approaches to the piers, it acquires an obliquity of a few degrees to the joints; but the disposition to slide would be abundantly obviated by the friction alone, even if the joints were not secured by other precautions.

In building the arches, the stones were rammed together with very considerable force, so that, upon the removal of the centres, none of the arches sunk more than an inch and a half. In short, the accuracy of the whole execution seems to have vied with the beauty of the design, and with the skill of the arrangement, to render the Bridge of Waterloo a monument, of which the metropolis of the British Empire will have abundant reason to be proud, for a long series of successive ages.

EXPLANATION OF THE PLATES.

Plate XLII. fig. 1. If AB represent the distance of any two particles of matter, and BC, DE, FG the repulsive forces at the distances AB, AD, AF respectively, and BC, DH, FI, the corresponding cohesive forces, then GI must be ultimately to EH as FB to BD. (Sect. I. Prop. A.)

Fig. 2. The block will support twice as great a pressure applied at A as at B. (Prop. B.)

Fig. 3. It is obvious that $ABC - ADE = ABC - CFG$, HI being $=$ HK, and $HG = HA$; and the difference ABFHA is always equal to $DB \times KH$. (Prop. C.)

Fig. 4. It is evident that AB is to CD as AE to CE, or as $z + \frac{1}{2}a$ to z. (Prop. E.) It is also obvious that as z or CE is to CD, so is EF to FG. (Prop. F.)

Fig. 5. Supposing the arch AB to be so loaded in the neighbourhood of C as to require the curve of equilibrium to assume the form ADCEB, the joints in the neighbourhood of D will be incapable of resisting the pressure in the direction of the curve CD, and must tend to turn on their internal terminations as centres, and to open externally. (Prop. Y.)

BRISSON (MATHURIN JAMES), a zoologist and natural philosopher, born at Fontenay le Comte, 3d April 1723, the son of Mathurin Brisson and Louisa Gabrielle Jourdain.

He was originally intended for the church, but he had acquired at an early age a taste for natural history, which was particularly encouraged by the advantage that he enjoyed of passing his holidays with the justly celebrated Réaumur, who had an estate near Fontenay. At the age of twenty-four, he had made great progress in his theological studies, and had fully qualified himself for the rank of a subdeacon; but his courage failed him at the time appointed for taking orders, and he then determined to confine himself to the study of physical sciences. Réaumur had the direction of the Chemical Laboratory of the Academy of Sciences, and had given up the salary attached to it to several young men in succession, whom he appointed as his assistants, and of whom Pitot and Nollet became afterwards the most distinguished. He now chose Brisson for the situation, which served him, as it had done his predecessors, rather as a step in his advancement with respect to general science, than in enabling him to pursue any objects more immediately chemical; and he followed his passion in attaching himself, almost exclusively, to natural history. The collection of Réaumur furnished him with ample materials for his studies, and with the principal subjects described in his works on the *Animal Kingdom*. The first of these was published in 1756, containing quadrupeds and cetaceous animals. It consists of simple descriptions of the different species, together with synonyms in various languages, more in the nature of a prodromus than of a complete history. His *Ornithologie* appeared in 1760, forming six volumes, and containing a number of well-executed plates. But upon Réaumur's death, the collection having been added to the Royal Cabinet, Messrs Buffon and Daubenton, the Directors of that Cabinet, not affording him all

the accommodations that he expected, he discontinued the work, and altogether renounced the study of natural history in favour of natural philosophy.

M. Brisson had been chosen a Member of the Academy of Sciences in 1759: he soon afterwards associated himself with the Abbé Nollet in delivering lectures on experimental physics, and obtained the reversion of his appointments of Professor in the College of Navarre, and Instructor of the royal family in Natural Philosophy and Natural History. The subject of electricity was at this time warmly debated between Nollet and Franklin; and M. Brisson had a difficult task to perform, in discussing the merits of a mistaken friend and an overbearing opponent; but, in fact, this department of science was at that time too little understood to make it disgraceful for Nollet to be in error with respect to the utility of conductors, or for Brisson to remain neuter upon this and other similar questions. He seems, however, by no means to have adhered to the character of neutrality in his anonymous *Translation* of Priestley's *History of Electricity*, published in 1771, and accompanied by notes, which exhibit a spirit of acrimonious criticism, not at all calculated to enhance the merit of the work, which he wished to introduce to the notice of his countrymen. He also attempted, in an *Essay on Waterspouts*, published in the Memoirs of the Academy, to explain a variety of electrical phenomena, by means of the different currents of fluid imagined by Nollet, but certainly with very little success.

He afterwards undertook a course of experiments on the *Specific Gravity of Alcohol and Water*, mixed in different proportions, which led him to a conjecture, at that time somewhat singular, that water was not a homogeneous substance. He assisted M. Trudaine, and other observers, in the experiments which they made on *Heat and Light* with the powerful lens of Bernière; and, in conjunction with M. Cadet, he endeavoured to disprove the opinion of Beccaria, that electricity has a power of reviving the *Metallic oxyds*. He also made experiments on the *Refractive powers* of fluids which might be substituted for flint glass, in the object glasses of telescopes; on the utility of different kinds of *Steel for magnetical purposes;* and on the mode of renewal of the *Shells of some species of Snails.*

In 1772, M. Brisson published a memoir on the *Specific Gravities of Metals*, a subject which, in all its extent, occupied a great portion of his attention during twenty years of his life. The results of his experiments, on a great variety of substances, were collected into a single volume of *Tables of Specific Gravities*, which was published in 1787. It was principally for the use of students who attended his lectures, that he published his *Traité de Physique*, and his *Dictionnaire;* both of them containing elementary and popular information, rather calculated exclusively for the immediate purpose which they were intended to serve, than for being of permanent utility in the promotion of the sciences. At a late period of his life, he renewed his attention to the subject of chemistry, when the discoveries of his junior contemporaries had given greater certainty and precision to its laws; and his last work was an *Elementary Treatise* on that science, intended for the use of his pupils in the central school.

His whole life was occupied in his studies, and the history of his various works comprehends the history of every thing that is to be recorded concerning him. After eighty years of uninterrupted activity of mind, an attack of apoplexy reduced him to a state of second childhood, and effaced from his memory even all traces of his native language, except a few words of the dialect of Poitou, which he had spoken when he was a boy. He died the 23d June 1806; and his place in the Academy was filled by M. Gay Lussac. (Delambre, *Mém. Inst.* Par. VII. *Hist.* p. 189.) (T. U.)

BRISSOT (John Peter), the chief of the *Brissotine* or pure republican party in France, during the early stages of the Revolution, was born at the village of Ouaroille, near Chartres, in the Orleannois, on the 14th of January 1754. His father, who was a pastry-cook, gave his son a liberal education, and Brissot became an author when he had scarcely left College. He exhibited a decided predilection for politics, and displayed an early zeal for republican principles. The boldness of his writings against the inequality of ranks excited the displeasure of the Government, and subjected him to a prosecution and imprisonment in the Bastile. Having been restored to liberty through the influence of the Duke of Orleans, at the solicitation of Mad. de Genlis, he married one of the Duchess's women, and soon afterwards went to England, with secret instructions, it is said, from the Lieutenant of the police. Others assert that he came over to London, to avail himself of the freedom of the press in conducting a periodical publication, the design of which was to enlighten the people of France on the subject of civil liberty. It is certain that he endeavoured to maintain himself in London by his literary talents; but the failure of this attempt subjected him to embarrassments from which he was relieved by the liberality of a friend, and he then returned to his native country.

Having again rendered himself obnoxious to the government by an attack on the administration of the Archbishop of Sens, he escaped a second imprisonment by a journey to Holland. During a temporary residence at Mecklin, he published a periodical paper, called *Le Courier Belgique*. In the beginning of the year 1788, he repaired to America; but, on the approach of the revolution, he returned to Paris, resolved to take an active part in the scenes which were just preparing. He commenced his revolutionary career in 1789, by the publication of some pamphlets, and particularly of a Journal, entitled *Le Patriote François*. He belonged to the *Representation des Communes*, which was formed in the capital a short time previous to the memorable 14th of July. On the storming of the Bastile, the keys were deposited with him. He was elected President of the Jacobin Club; and, in consequence of his zeal and activity in the revolutionary cause, he was appointed by his colleagues a Member of the *Comité des Recherches*, which served as the model of all those Committees which were afterwards successively formed, under similar denominations, and with similar objects; such as the *Comités de Surveil-*

Brissot.

lance, de Sureté Generale, de Salut Public, &c. Of this Committee Brissot was the president; and, while in this situation, he acquired a number of enemies. A French writer of the name of Morande published at Paris, in 1791, a periodical pamphlet, under the title of *Argus,* in which he assailed the character of Brissot with great bitterness, representing his conduct in the most odious colours, and even accusing him of robbery,—an accusation which, there is reason to believe, was utterly calumnious.

On the flight of the royal family, in 1791, Brissot, in concert with the Chevalier de Laclos, drew up the famous petition of the *Champ de Mars,* demanding the abdication of the king, which became the signal for a dangerous insurrection, that was with difficulty quelled, by the interposition of the National Guard. This circumstance is said to have been the occasion of his quarrel with M. de Lafayette, to whom he had previously been zealously attached. At this period, the republican faction began to assume a consistent form, and to utter their sentiments with freedom and boldness. Brissot, who had been one of its first and most zealous apostles, was returned a Member to the National Assembly, in spite of the opposition of the Court, to whom he had become extremely formidable; and from this time he displayed an implacable enmity to the king. The National Assembly, attributing to Brissot talents which he does not appear to have possessed, appointed him a Member of the Diplomatic Committee, of which he became the habitual organ; and in this capacity he was the constant advocate of the most violent public measures, and never ceased to demand a declaration of war against all the powers of Europe. In order to attain this object, it was necessary to remove the ministers, whose dispositions were favourable to peace. Brissot, accordingly, attacked them all, but particularly M. Delessart, who was at the head of the department of foreign affairs; and, by repeated denunciations, he at length succeeded in obtaining a decree of accusation against him. His place was supplied by Dumouriez, under whose administration war was declared against the Emperor of Germany, on the 20th of April 1792. From this period, however, the political influence of Brissot began to decline. Robespierre, with whom he had previously been intimately connected, now declared himself his enemy, denounced him at the Jacobin Club as a traitor to his country, and an enemy of the people, and continued to persecute him with unrelenting rancour, until he finally effected his destruction. Alarmed at the storm which was gathering around him, Brissot, in concert with the other leaders of his party, attempted to form a reconciliation with the constitutional royalists; but this attempt having proved abortive, he reverted to his former opinions and line of conduct, and continued to denounce to popular vengeance all those whom he knew to be attached to the king. But although his writings may naturally be supposed to have excited those dispositions among the people which gave rise to the atrocities of the times, he had no direct influence on the revolution of the 10th of August, which appears to have been planned and directed by Danton, and the ferocious leaders of the Orleans faction. He was chosen a Deputy to the National Convention for the department of the Eure, where he played only an inferior part, and was continually exposed to the rancorous attacks of Robespierre. It was Brissot, however, who, as the organ of the diplomatic committee, obtained the declaration of war against England and Holland, on the 1st of February 1793. This may be considered as the last act of his political life; for, from thenceforth, he was only occupied in defending himself against his numerous enemies.

Brissot.

The party distinguished by the name of the *Mountain* had now acquired a complete ascendancy, and meditated the destruction of their opponents, the *Girondists,* to which latter party Brissot was attached. Having at length been proscribed, after the revolution of the 31st of May, he was arrested at Moulins, while attempting to make his escape into Switzerland, sent to Paris, subjected to a mock-trial before the revolutionary tribunal, and beheaded on the 31st of October 1793, at the age of thirty-nine.

Brissot was somewhat below the middle size, a little deformed, and of a feeble constitution. His countenance was pale and melancholy, and he affected an extreme simplicity in his dress. With regard to his intellectual character, his talents appear to have been much beneath his reputation, and he certainly possessed more zeal than judgment. Notwithstanding, however, the violence of his writings, declamations, and public conduct, he was not deficient in humanity; and, in the intercourse of private life, his manners are said to have been mild and accommodating. As an author, Brissot has not much merit; his style is monotonous, verbose, and tedious; and, upon the whole, it is wonderful, that, with such slender abilities, he should have acquired so great an ascendancy in public opinion. The best articles of his journal are said to have been written by his secretary, Dupré. The following are the principal productions of his pen:

1. *Moyens d'Adoucir la Rigueur des Lois Penales en France,* Chalons, 1781, 8vo. 2. *Un Independant de l'Ordre des Avocats sur la Décadence du Barreau en France,* 1781, 8vo. 3. *De la Vérité, ou Meditations,* &c. 1782, 8vo. 4. *Le Philadelphien à Geneve,* 1783, 8vo. 5. *Theorie des Lois Criminelles,* 1781, 2 vols. 8vo. 6. *Bibliotheque Philosophique du Legislateur, du Politique, du Jurisconsulte,* 1782–1786, 10 vols. 8vo. 7. *Tableau de la Situation Actuelle des Anglais dans les Indes Orientales,* &c. 1784–85, 8vo. 8. *Journal du Lycée de Londres,* &c. published in monthly numbers, 1784, 8vo. 9. *Un Défenseur du Peuple à l'Empereur Joseph II., sur son Reglement concernant l'Emigration,* &c. 1785, 12mo. 10. *Examen Critique des Voyages dans l'Amérique Septentrionale, par le Marquis de Chatellux,* 1786, 8vo. 11. *Voyages en Europe, en Asie, et en Afrique,* translated from the English, with notes, 1786, and 1790, 2 vols. 8vo. 12. *Nouveau Voyage dans les Etats-Unis de l'Amerique Septentrionale,* 1791, 3 vols. 8vo. To the first volume of this work was prefixed the life of Brissot, which was translated into English, and published separately in 1794. Besides these works, Brissot wrote a variety of pamphlets, and

articles inserted in periodical publications, which it is unnecessary to enumerate. See the Life of Brissot, above-mentioned, and the *Biographie Universelle.* (H.)

BRITAIN. The history of ENGLAND and SCOTLAND is given under these separate heads in the *Encyclopædia*, down to the Union of the Crowns in the person of James VI.; from which period the history of the two countries is brought down to the rupture of the peace of Amiens, under the article BRITAIN. In order to afford more time to digest a comprehensive account of the great and important events which have succeeded, and of which Britain was the prime mover, we shall defer the continuation of the history till we reach the word ENGLAND.

BROCKLESBY (RICHARD), a Physician of considerable reputation, was born in Somersetshire, on the 11th of August 1722; and was descended from a respectable and opulent Irish family, belonging to the sect of Quakers. He received his grammatical education at the Academy of Ballytore, in the north of Ireland, and afterwards pursued his medical studies at Edinburgh, and at Leyden; at which latter University he graduated, in 1745, choosing for the subject of his thesis, *De Saliva sana et morbosa.* In the following year, he fixed his residence in London, with a view to practice; and in 1751 was admitted a Licentiate of the Royal College of Physicians, of which he afterwards became a fellow; after having received honorary degrees of Doctor in Medicine from the Universities of Dublin and of Cambridge. The first publication by which he became known to the world, was his *Essay on the Mortality of the Horned Cattle,* which appeared in 1746, and gained him considerable reputation; and his practice extended itself with that gradual and steady progress, which affords the surest prospect of permanent and distinguished success. His benevolent attention to his poorer patients, and the general suavity of his manners, soon brought him into notice, and procured him the esteem of a wide circle of friends, especially among his professional brethren. In consequence of their recommendation of him to Lord Barrington, he was appointed, in 1758, Physician to the Army; in which capacity he served in Germany during the greater part of the seven years' war; and in the course of it was chosen Physician to the Hospitals for British Forces. The results of his observations during this period were published in 1764, under the title of *Economical and Medical Observations, from 1738 to 1763, tending to the improvement of Medical Hospitals,* in one volume 8vo. He had already, however, given to the public many proofs of the activity of his mind, and the variety of his attainments. The *Transactions of the Royal Society* for 1747 (Vol. XLIV.) contain a letter of his *On the Indian Poison sent over by Don Antonio de Ulloa;* and the succeeding volume for 1747-8, a paper *On the Poisonous Root lately found mixed with the Gentian.* In the *Transactions* for 1755 (Vol. XLIX.) are inserted his *Experiments on the Sensibility and Irritability of the several parts of Animals.* He also published, in different volumes of the *Medical Observations,* the following papers, viz. *The Case of a Lady labouring under Diabetes,* in Vol. III.—*Experiments relative to the Analysis of Seltzer Water;* and *Case of an Encysted Tumour in the Orbit of the Eye;* in Vol. IV. His *Dissertation on the Music of the Ancients* appeared in 1749; and his *Oratio Harveiana* in 1760.

Dr Brocklesby was appointed, by his patron and friend the Duke of Richmond, Physician-General to the Royal Regiment of Artillery and Corps of Engineers; an appointment that connected him much with the laboratory of Woolwich, which he always visited with pleasure. It was by his advice, indeed, that a Professorship of Chemistry was added to the establishment of the College; and it was also by his recommendation that the celebrated Dr Adair Crawford was nominated the first Professor in this new chair.

The life of a medical practitioner, absorbed in the laborious duties of his profession, is seldom diversified with much incident; and Dr Brocklesby was now arrived at that period when the approaching infirmities of age demand some relaxation from labour, and an exchange of the anxieties and fatigue of practice, for the tranquil amusements of literature, and the solace of cheerful society. The frugal use which he had made of means originally slender, but progressively augmenting by the increase of his professional emoluments, by the addition of a pension from the Duke of Richmond, his half pay from the army, and an estate which devolved to him on the death of his father, had placed him in circumstances not only independent, but affluent, and enabled him to derive from retirement all the advantages he had contemplated. His society was courted on all sides; and the circle of his friends comprehends some of the most distinguished literary men of the age. He was, during the whole of his life, intimate with Burke. His acquaintance with this extraordinary man, began at the school where they both were educated, and soon ripened into the most warm and most durable friendship. He was also in terms of close intimacy with Dr Johnson, and attended him in his last illness with the assiduity and kindness of a friend. Dr Brocklesby is characterized in Boswell's *Life of Dr Johnson,* as a man whose reading, knowledge of life, and good spirits, supplied him with a never-failing source of conversation; and several letters, addressed to him from Dr Johnson, are preserved in that entertaining work. One trait, however, is omitted, which does him great honour. Understanding that Dr Johnson wished, in the latter part of his life, to remove to the continent for the recovery of his health, Dr Brocklesby immediately made him an offer of an annuity of L. 100 during the remainder of his life; and when this offer was declined, pressed him to reside in his house, as more suited to his health than the one in which he then lived. The same generous disposition was manifested in his conduct to Burke, to whom he transmitted L. 1000, as a legacy he had intended leaving him, but which he thought would be of more use to him at the present time. Dr Brocklesby was, indeed, the survivor of Burke, though only for a few months; for on his return from a visit which he paid to his widow at Beaconsfield, after dining with his two

Brocklesby || Broker.

nephews Dr Thomas Young and Mr Beeby, of whose education he had taken the principal charge, he expired suddenly a few minutes after retiring to bed, without the least pain or previous illness. He left his fortune, which was considerable, between his two nephews, with the exception of a few legacies to friends and distant relations. (W.)

BROKER, an agent or intermediate person appointed for the transactions of special business for another, somewhat different from an ordinary factor in functions and responsibility. Of this class, there are various descriptions, exercising employments without the smallest analogy, though all are brought under the general name of brokers; and of these, the principal are, Exchange-Brokers, whose province is to ascertain the rates and relation of exchange between countries; Stock-Brokers, who negociate transactions in the public funds; Insurance-Brokers, who effect insurances on lives or property; and Pawn-Brokers. It is to the last that our attention shall here be chiefly directed.

Pawn-broker.

Pawn-Brokers are a kind of bankers who advance money at a peculiar rate of interest, on goods impledged for security of the capital; and in case of failure to redeem the goods within a limited time, they may be sold to indemnify the lender.

Nature of the Trade.

A part of the population of every flourishing country consists of necessitous people, those frequently belonging to a class whose skill contributes to its prosperity; but whose income, often slender and precarious, cannot keep pace with the times, or support the demands of an increasing family. Exposed also to sudden disappointments and losses, they are forced, from the want of pecuniary capital, to seek a temporary relief, by impledging their property for a certain sum, while they pay interest on the advance. But this advance, in general, bears a very inconsiderable proportion to the value of the property, whence its confiscation, by the increasing difficulties of the owner, or of not being claimed on account of death or removal, proves most advantageous to the holder; for, in the one case, he may become the absolute proprietor himself, and, in the other, he secures a high rate of interest originally stipulated. Thus, a pawnbroker has an infinite superiority over an ordinary banker; the latter calculates only on the credit of his debtor, which is frequently nominal; the former never makes an advance without being put in possession of what exceeds it in value; his rate of interest is much greater, and the credit of his debtor is of no importance. Nay it is rather better that his circumstances should be desperate. It thence results, that, like other trades, the number of pawnbrokers will increase with the necessities of the people requiring their aid, and, on that account, giving them employment, just as bankers, whose issues increase when the calls of the public require a more ample supply of a circulating medium. Thus a strong inducement is continually held out to commence the profession of a pawnbroker; for all that is required, is comprised in a licence of L. 10 yearly to Government, a small capital, and an empty warehouse. On such an establishment, business may be done to a great extent in a very short time; because the securities increase in a much greater ratio than the debts, while the latter are void of any risk. We find in the city of London, that the number of pawnbrokers lately amounted to no less than about 240, and it was calculated, that the property of necessitous persons in their possession, probably amounted to a million Sterling. Their numbers also had suddenly augmented, and they are still augmenting. In Edinburgh, on the contrary, which is not above a tenth part of the size of the metropolis. there was scarcely one a few years ago, and now the number does not exceed a dozen. Therefore the number is not one half in proportion to the population of the two different places, which indicates fewer necessitous people by a half in Edinburgh; arguing, either that the inhabitants are more industrious and more easily maintained, or less exposed to losses and fluctuations.

Broker.

But the temptations held out to those who, in this manner, obtain possession of the property of others to such an amount, and with so little reference to its value, combined with the natural propensity of mankind to take advantage of the necessities of their neighbours, long ago rendered legislative interference necessary in regulating the duties and interests of pawnbrokers. Besides, it was of great consequence to check the facilities with which stolen goods might be impledged with, and sold by them. Omitting, however, the older enactments on these branches, we shall limit ourselves to those of more recent date.

Statutory Rates of Pawning.

By the 99th chapter, of 39th and 40th George III., it is provided, that for every pledge on which a sum, not exceeding two shillings and sixpence, shall have been advanced, it shall be lawful to take one halfpenny *per* month, as interest and indemnification for warehouse room; one penny for five shillings; three halfpence for seven shillings and sixpence; twopence for ten shillings; and if the loan does not exceed forty shillings, the pawnbroker may take at the rate of fourpence for every kalendar month, including that which is current. For any sum exceeding forty shillings and not above ten pounds, he may take at the rate of threepence monthly *per* pound Sterling. But these sums, though apparently inconsiderable, are in fact high per centages, and far surpassing the legal rate of interest.

The pawner may redeem his goods within seven days after the expiry of the first month, without paying any thing as interest to the pawnbroker on these seven days; and also, if the goods are redeemed before expiry of the first fourteen days of the second month, the profits or interest of one month and a half only are due. But if he fail to redeem them until after the lapse of these fourteen days of the second month, the pawnbroker may demand the profits of the whole second month; and the like regulation is in force for every kalendar month subsequent.

Should the sum advanced on the goods in pawn exceed five shillings, it is enacted that a description of the pledge shall be entered in a book by the pawnbroker, and a note or ticket, an extract copy or duplicate of the same, be delivered gratis to the impledger. If the sum advanced be above five and under ten shillings, the pawnbroker is entitled to a halfpenny for this duplicate; if above ten and under twenty, to one

oker. penny; and for a copy of the entry of goods pawned for five pounds or more, fourpence may be taken, but nothing higher. Further, an account of the amount of profits shall be written on this duplicate when the goods are redeemed; and pawnbrokers are bound always to produce their books when required. They must likewise exhibit a table of their profits in conspicuous characters in the place where they carry on their business, and register their name and profession over their doors, under a penalty of ten pounds.

… when …ned …ds may …old.

By the seventeenth section of the statute, it is declared that all goods and chattels which are pawned or impledged, shall be deemed to be forfeited, and may be sold at the expiration of a year, from the date of pawning. But the impledger is, to a certain degree, protected by another clause, prohibiting pawnbrokers from purchasing goods in their own custody. If any sum above ten shillings, and not exceeding ten pounds, has been lent, the goods shall be sold by public auction after expiration of the year, under strict regulations in respect to previous advertisement, and publication of catalogues, specifying, in addition to their description, the month in which they were impledged, as also the name and place of abode of the pawnbroker. But it is provided that pictures, prints, books, bronzes, statues, busts, carvings in ivory and marble, cameos, intaglios, musical, mathematical and philosophical instruments, and china, shall be sold only at four times in the year; namely, the first Monday of January, April, July, and October, and on the following day if the number of articles render it necessary. Thus the impledger may redeem his goods at any time within a year, on payment of the statutory profits on the money lent, but, on his failure, they may be sold. Should he give notice to the pawnbroker before the year closes, of his intention to redeem, the sale must be postponed until three months subsequent to its termination. When the sale has actually taken place, the pawnbroker is entitled to appropriate only so much of the price received as shall cover his own advances, the statutory profits and costs, and must pay the residue to the owner on demand, within three years, under high penalties in event of refusal.

…ctments …event …ses and …ds.

Pawnbrokers are prohibited from lending money to persons below twelve years of age, or to those who are intoxicated; nor may they receive any goods in pawn before eight in the morning, or after nine at night, between Michaelmas and Lady-Day; nor before seven in the morning and after ten at night, during the remainder of the year; but with some exceptions which the statutes explain.

A great many enactments are comprised in the statute 39th and 40th Geo. III., respecting the penalties of unlawfully pawning goods the property of another, and those of forging any notes or memorandums regarding them; likewise as to the apprehension and punishment of persons offering goods to pawn who cannot give a good account of themselves. The facility with which loans might be obtained from pawnbrokers on stolen goods, had previously rendered it an object of anxiety with the Legislature to detect offenders. Hence an act was passed in the 29th of Geo. II. cap. 30, after many preceding ones, annexing the pain of transportation, for fourteen years, to the reset of stolen goods: and by a statute of the preceding year, it was made lawful for a pawnbroker, or other dealer, his servants or agents, to whom any goods should be offered to be pawned, exchanged, or sold, which he suspected to be stolen, to seize and detain the person offering the same, for the purpose of being examined by a justice, who was empowered, if he saw any reason to suppose that the goods had been unlawfully obtained, to commit the persons offering the same to prison, for a period not exceeding six days. Nevertheless all prohibitions are found ineffectual in practice; and although pawnbrokers, in the metropolis, are entitled to carry on their trade only on taking out an annual licence of L.10, and of L.5 if in any other part of the kingdom, nothing is liable to greater abuses. It is not uncommon for sharpers and swindlers to obtain such licences, and, taking advantage of the necessitous or unwary, to exercise all possible deceptions on them. Such persons are invariably the receivers of stolen goods, on which advances are made without scruple, from well-knowing that no one will ever return to reclaim them; and, besides, the goods may safely be sold, for the same reason, before the statutory period expires. Without any regard to reputation or integrity, it has proved so easy to be established a pawnbroker, that, it is alleged, persons confined to the hulks on the Thames have even been able to obtain licences to carry on a trade in the very place of their punishment.

Broker.

Evils inseparable from Pawning.

However lucrative the business of pawnbrokers may be to those who follow it, doubts are entertained whether the toleration of them be not an evil to the public. They are, indeed, temporarily useful, to persons in the most necessitous circumstances; but as it is impossible, by any Legislative interference, to bring them under that control which would be desirable,—as their interests are always at variance with the interests of their employers,—and as mankind, under the pressure of necessity, are restrained by no sacrifice in seeking momentary relief, ultimate considerations are too often overlooked. Hence the first resort for aid frequently leads to a second, and then to others successively, while the property originally impledged remains unredeemed, and all the rest belonging to the owner gradually diminishes, until he is left destitute. It is the poor and necessitous only who avail themselves of raising supplies on their goods, to ward off some impending evil, and it is surprising how low such transactions are carried. Nay, the statute itself illustrates the nature of this miserable traffic more forcibly than could be done in other terms. It is enacted, that if, at the period of redeeming the goods impledged, there shall be a certain sum due of interest and profit, of which the lowest denomination shall be a farthing, and the redeemer "shall not be able to produce and pay to the Pawnbroker a current farthing, which shall be to the satisfaction and liking of such person or persons as are to receive the same, but shall, in lieu thereof, tender to such person or persons to receive the the same, one halfpenny, in order to discharge the said remaining farthing so due, as aforesaid, the said

Pawnbroker or Pawnbrokers, his, her, or their servant or agent, to whom such tender of a halfpenny shall be made, shall, in exchange thereof, deliver unto such person or persons so redeeming goods as aforesaid, one good and lawful farthing of the current coin of this kingdom, or, in default thereof, shall wholly abate the said remaining farthing from the total sum to be received" from the redeemer. But it is not only in the view of the indigent yielding to the pressure of necessity, in parting with their property for an inconsiderable value, that society suffers an injury. The thoughtless and depraved here find ready means of gratifying their propensities, by the assistance of the pawnbroker's shop, and thousands part with their apparel and furniture for what is, the next moment, wasted in intoxication. Besides, the facility of obtaining the reception of stolen goods, is attended with the most pernicious consequences, and the most powerful encouragement to theft. Notwithstanding the law anxiously endeavours to secure property to its owners, by imposing penalties on those who offer it in pawn, and in ordaining it to be restored by the pawnbroker, cases innumerable may be figured, where the pawnbroker cannot discriminate what is the genuine property of any individual in particular, and where it is not only difficult, but may prove impossible, to bring an offender to justice. In the present year (1817), an association, more immediately resulting from the pressure of the times, has been formed in Edinburgh, for the purpose of aiding those with advice and information who have dealings with pawnbrokers. Its special object, we believe, is, to warn the ignorant of the laws under which their property is protected.

The banks called *Savings' Banks* may probably prove a beneficial substitute for resort to the pawnbroker. Sums amounting to a shilling and upwards are received, and bear interest at 4 *per cent.* when accumulated to twelve shillings; thus enabling the labourer, or mechanic, or artisan, to preserve the remnant of his weekly wages, and convert it to advantage. Loans, not exceeding L. 5, are made, free of interest, to the necessitous under temporary pressure, whereby their little property may remain entire. Banks of this description are, at the present moment, rapidly disseminating throughout the different parishes and towns of Scotland, and their outset has been attended with one decided benefit, in diminishing the resort to alehouses, where the earnings of labour, too small to form an object for preservation, quickly disappeared. In some towns of Italy we have understood there are charitable institutions of a mixed nature between pawnbroking and banking. There, an advance seems to be made on goods impledged at a certain rate of interest by some, and by others money is received and returned, with 7 *per cent.*, at the termination of a year. The transactions of these institutions, however, are not completely explained, either as to the security given or the advantage derived. (s.)

BRONZING. A combination of metals which has received the name of bronze was employed by the ancients in the fabrication of different utensils, and in casting busts, statues, and other subjects, either larger or smaller than life. The Egyptians, Greeks, and Romans, nations which subsisted long and were familiar with the most refined state of the arts, used this compound metal in the greater part of the decorations of those magnificent temples and palaces, whose ruins only have remained to later eras. But amidst the general wreck there are still some fragments preserved, which indicate the perfection which was attained in the employment of bronze. The wealth of some ancient cities was estimated by the number of their brazen statues; and Delphos, Athens, and Rhodes, are reported to have each possessed three thousand. Some distinguished Romans adorned the public edifices of their city in this manner; and so strong a propensity was excited for multiplying such works, that an observation became current, that, "in Rome, the people of brass were not less numerous than the Roman people." It has been remarked, that the works which we now execute in iron or steel were little known to the ancients; that their arms and armour were usually of brass, or the compound now alluded to; and a set of surgeons' instruments consisting entirely of bronze was found not long ago at Pompeii.

Bronze is extremely hard, sonorous, more brittle than brass, and more fusible than copper, from which, and its not being liable to tarnish, it is peculiarly adapted for casts of statues. Various nations have compounded the metals employed in different proportions. The Egyptians are said to have taken two-thirds brass and one-third copper. According to Pliny, the bronze of the Grecians was formed in the same way, with the addition of one-tenth part of lead and a twentieth of silver; which proportions were adopted by the Romans. In modern times, bronze is generally composed of two-thirds of copper and one-third of brass, and sometimes small quantities of lead and zinc have been added. These latter render the cast more compact and brilliant; and the combination of different substances occasions the readier fusibility of the whole than when separate. The ancient bronzes, however, present a difference in appearance and composition from those executed by the moderns, and the fact is ascertained in respect to the metallic proportions by skilful chemists on analysis. An illustration of this fact is sometimes given in the four celebrated horses of bronze, supposed to be the work of Lysippus, a Greek artist; which were brought from Venice, by command of Bonaparte, to the Thuilleries at Paris.

The casting of bronze statues is a nice and difficult art, requiring long experience and the judicious management of a great apparatus. An exact model must be made of the subject to be cast, and nicely coated over with wax not less than an inch thick, on which the artist works the impression meant to be taken. A mould is then formed, consisting of several hollow pieces of wood or other resisting substance, filled with a mixture of clay and sand, which is applied to the model, in order that its outline may be received. The mould being united together, is perforated by a number of channels, and the melted metal being discharged from a furnace by means of these into the interior, thus produces the cast. When cold, the external covering is taken off, and the subjects appear as if covered with spines, which are the

Bronzing. channels filled with metal; they are removed by saws, files, and chisels, and any imperfections on the surface being corrected, the whole is completed. But this in detail is a tedious, laborious, and expensive process; and the difficulty of producing beautiful works in bronze, conspires to give them a high value in the estimation of the lovers of the arts. In general, the natural colour of the composition remains unaltered, and with the lapse of time, tends to black, or particular shades of green; but some artists render it black artificially, or give it a green colour from the first. It is the delicacy of the workmanship, however, that constitutes the value of bronzes, not the colour, because it is the former alone which constitutes the difficulty, and calls for the skill of the artist. Colossal figures are sometimes obtained in bronze; but more usually, when of very large dimensions, they are formed by the union of several pieces, and are hollow within; as is also the case with some of those of smaller size. Considerable premiums have been offered by the *Society for the Encouragement of Arts*, for promoting the execution of bronze figures in England, but few have been claimed. Nevertheless, British artists have produced several very creditable works, if we take the low condition of sculpture in view; but either from want of skill or practice, neither the bronzes of this Island nor of the Continent rival the masterpieces of antiquity. Perhaps it is only the best specimens which are preserved, and many of inferior note have been allowed to decay, or cease to attract attention; and in this way we may partly account for our own inferiority.

Art of Bronzing. The substances on which bronzing is employed are either metals, wood, ivory, clay, or plaster; but more general preference is given to wood or plaster. The colours are of various shades and intensity; their composition and application being in a great measure arbitrary, according to the will of the artist. This art is nothing but a species of painting, far from the most delicate kind; and, when applied to plaster figures, may be done either with or without cement, the latter rendering it more durable. One principal ingredient in bronzing is gold-powder, for the preparation of which the following receipt is given. A quantity of leaf-gold is ground with virgin honey on a stone, until the texture of the leaves be completely broken, and their parts divided to the most minute degree. The mixture of gold and honey is then removed from the stone, and put into a basin of water, whereby the honey may be melted, and the gold freed from it; and the basin is allowed to stand at rest until the gold subsides. When it does so, the water is poured off, and fresh quantities are added, until the honey be entirely washed away; after which, the gold is put in paper, and dried for use. This is the true gold-powder; besides which, there is another, called German gold, in common use; and also a third, called *aurum mosaicum* or musicum, greatly employed in bronzing, and is thus prepared. A pound of tin, seven ounces of flour of sulphur, half a pound of purified quicksilver, and the same quantity of sal ammoniac, are taken as the necessary ingredients. The tin being melted in a crucible, the quicksilver is added to it; and, when this mixture is cold, it is reduced to powder, and ground with the sal ammoniac and sulphur until the whole be thoroughly mixed. They are then to be calcined in a mattrass, and the sublimation of the other ingredients leaves the tin converted into the *aurum mosaicum*, which is found at the bottom of the glass like a mass of bright flaky gold-powder. Should any black or discoloured particles appear, they must be removed. The sal ammoniac used here must be very white and clean, and the mercury quite pure, and unadulterated with lead. These colours are commonly employed in bronzing; but when a shade more of a red, resembling copper, is required, it can easily be obtained by grinding a very small quantity of red lead along with them. Copper powder may be procured by dissolving filings or slips of that metal with nitrous acid in a receiver. When the acid is saturated, the slips are to be removed; or, if filings be employed, the solution is to be poured off from what remains undissolved. Small iron bars are then put in, which will precipitate the copper from the saturated acid, in a powder of the peculiar appearance and colour of copper; and the liquid being poured from the powder, this is to be washed clean off the crystals by repeated levigations. In addition to these compounds, we may name gold size, which is of particular use in bronzing, and several other branches of the arts. This is prepared from a pound of linseed-oil, with four ounces of gum animi. The latter is gradually supplied in powder to the oil, while boiling, and it is necessary that it should be stirred with every successive dose, until the whole be dissolved and incorporated with the oil. The mixture is still allowed to continue boiling, until a small quantity, when taken out, appears of a thicker consistence than tar, and the whole being then strained through a coarse cloth, is put aside. When used, it must be ground with as much vermillion as will render it opaque, and, at the same time, diluted with such a quantity of oil of turpentine as will bring it to a proper consistence for working freely with the pencil.

In regard to the operation of bronzing itself, if a cement is to be used, the powders now described may be mixed with strong gum water or isinglass, and laid on the subject with a brush or pencil; in doing which, some artists recommend beginning at the bottom, and proceeding upwards. By a different process, gold size, prepared with a due proportion of turpentine, may be taken, and the subject covered with it; then being allowed to dry very nearly, but still preserving a certain clamminess, a piece of soft leather wrapped round the finger is dipped in the powder, and rubbed over the work; or, what is judged preferable, it may be spread with a soft camel-hair pencil. The whole, now covered, must be left to dry, and the loose powder then cleared away by a hair pencil also. Here the principal nicety consists in ascertaining the proper period of dryness for applying the powder, as much of the effect depends on it. But this method of bronzing is esteemed better, because the gold size binds the powders to the ground, without any hazard of their scaling or rubbing off, which sometimes happens

when gum or isinglass are employed. The precise tint of bronzing is regulated by taste; and, indeed, a very perceptible difference appears both in ancient and modern statues, resulting either from age or the metallic proportions.

Bronzing on wood may be effected by a particular process, somewhat varying from the general rules. Prussian blue, patent yellow, raw umber, lamp-black, and pipe-clay, are ground separately, with water, on a stone, and as much of them as will make a good colour put into a small vessel three-fourths full of size, not quite so strong as what is called Clean Size in gilding. This mixture is found to succeed best on using about half as much more pipe-clay as of the rest; but this depends on taste and fancy in preferring a peculiar tint. The wood being previously cleaned and smoothed, and coated with a mixture of clean size and lamp-black, receives a new coating with the preceding ingredients, twice successively, having allowed the first to dry; afterwards the bronze-powder is to be laid on with a pencil, and the whole burnished or cleaned anew, observing to repair the parts which may be injured by this operation. Next, the work must be coated over with a thin lather of Castile soap, which will take off the glare of the burnishing, and afterwards carefully rubbed with a woollen cloth. The gangrenous appearance of the cavities is effected by slightly wetting them with a camel-hair pencil dipped in the lather, and then sprinkling them with a little dust of verditer gum. The superfluous powder may be rubbed off when dry.

In bronzing iron, the subject should be heated to a greater degree than the hand can bear, and German gold, mixed with a small quantity of spirit of wine varnish, spread over it with a pencil. Should the iron be already polished, it is necessary to heat it well and moisten it with a linen rag wet in vinegar, on purpose to obscure the glare, that the bronze-powder may be sufficiently incorporated with the surface. There are other methods of accomplishing the same object, as by employing some coloured mordant, when the iron is not to be exposed to heat, and spreading the bronze over the mordant, when half dry, with a pencil.

Bronze is injured by humidity; and it is said not to preserve its proper quality beyond ten years; but it may be renewed, in which case the subject must be completely cleaned.

There is an analogous method of silvering casts of plaster of Paris, and other substances, which is also called Bronzing, and conducted after the manner above described, but it is not in general repute.

Conjectures have been entertained, that artists originally resorted to bronzing solely for the purpose of correcting the glare of colours; but this is exceedingly improbable, and it is certainly unnecessary to seek farther than the inducement of easily imitating metallic figures esteemed by the curious. This art has, of late years, come into very general use, and has received many improvements. (S.)

BROSSES (Charles de), first President of the Parliament of Burgundy, was born at Dijon, on the 17th of February 1709. He studied law, with a view to the magistracy, but without neglecting literature and the sciences, to which he discovered an early and decided attachment. His study of the Roman history excited in him a strong desire to visit Italy, which he accordingly traversed in 1739, in company with his friend M. De Sainte-Palaye. On his return to France, he published his *Lettres sur l'etat Actuel de la Ville Souterraine d'Herculaneum*, Dijon, 1750, 8vo,—the first work which had appeared upon that interesting subject. A Collection of Letters, written during his Italian tour, entitled *Lettres Historique et Critique*, in 3 vols. 8vo, was published at Paris after his death without the consent of his family. In 1760 he published a dissertation *Sur le Culte des Dieux Fetiches*, 12mo, which was afterwards inserted in the *Encyclopédie Methodique*. At the solicitation of his friend Buffon, De Brosses undertook his *Histoire des Navigations aux Terres Australes*; which was published in 1756, 2 vols. 4to, with maps, by Robert de Vaugondy. It was in this work that De Brosses first laid down the geographical divisions of Australasia and Polynesia, which were afterwards adopted by Pinkerton, and succeeding geographers. In 1765 appeared his *Traité de la formation Mechanique des Langues*; a work distinguished by much research, and containing many ingenious hypotheses; but, at the same time, marked by that love of theory which is so apt to imbue the cultivators of etymological science.

De Brosses had been occupied, during a great part of his life, in making a translation of Sallust, and in attempting to supply the chasms in that celebrated historian. At length, in 1777, he published *l'Histoiré du 7e Siècle de la Republique Romaine*, 3 vols 4to,—a work which would probably have met with great success, had the style corresponded with the interest of the subject, and with the author's historical sagacity, and depth of research. To the history is prefixed a learned life of Sallust, which was reprinted at the commencement of the translation of that historian by De Lamalle. After the death of De Brosses, a Supplement was added to this work, from his MSS. containing the various readings, fragments, and an Index of the authors from whom they are taken. This Supplement, which should be placed at the end of the third volume, is wanting in some copies.

These literary occupations did not prevent De Brosses from discharging with ability his official duties, nor from carrying on a constant and extensive correspondence with the most distinguished literary characters of his time. During the leisure afforded him by the suspension of the Parliaments, in the year 1771, he applied himself with greater vigour to literature. In 1758, he succeeded the Marquis de Caumont in the *Academie de Belles Lettres*; but was never admitted a member of the French Academy, in consequence, it is said, of the opposition of Voltaire, who entertained a dislike to him.

De Brosses died on the 7th of May 1777. He was a man no less distinguished for ease and vivacity in the general intercourse of society, than for the extent and variety of his literary attainments. Besides the works we have already mentioned, he wrote

several memoirs and dissertations in the collections of the Academy of Inscriptions, and in those of the Academy of Dijon. He also contributed a number of articles to the *Dictionnaire Encyclopedique*, on the subjects of Grammar, Etymology, Music, &c. and he left behind him several MSS. which were unfortunately lost during the Revolution. See the *Biographie Universelle*. (H.)

BROUSSONET (Pierre Marie Auguste), a distinguished French Naturalist, born at Montpellier, February 28, 1761. His father was a respectable schoolmaster in that town, who, perceiving the avidity with which he received instruction of every kind, took pains to store his mind with knowledge at an early age. It appears from his writings that he was at first educated for the medical profession. The opinion entertained in the university of the success with which he pursued his studies, was proved by his being appointed to fill a Professor's chair when he was only eighteen years of age. So great, indeed, was the reputation he had acquired, that when he offered himself as candidate, a few years after, for a seat in the Academy of Sciences, he was elected a member by an unanimous vote; a circumstance which had hitherto been without example since the foundation of that learned body. Botany seems to have been the science to which he was at first chiefly devoted; and he laboured with much zeal to establish the system of Linnæus in France. In pursuit of this great object, and with a view of extending his knowledge of the science, he visited Paris, and studied every museum and collection from which he could derive instruction in the different branches of natural history. He next came to England, where he was admitted, in 1782, an Honorary Member of the Royal Society. It was also at this period that he published his work on *Fishes*, describing the most rare species of this class of animals, under the title of *Ichthyologia, sistens Piscium Descriptiones et Icones*. London. On his return to Paris, he was appointed perpetual Secretary to the Society of Agriculture, an office which the Intendant Berthier de Sauvigny purposely resigned, that it might be filled by Broussonet.

A life thus dedicated to the pursuits of science, was not likely to be chequered by any remarkable vicissitude. But the Revolution, which soon broke out in France, and for a long time unhinged all the ordinary relations of society, had already involved in its vortex, not only the ambitious and the turbulent spirits of the nation, but also the peaceful votaries of science. In 1789, he was nominated a Member of the Electoral College of Paris, an office which required him to serve as Magistrate, whenever his colleagues were in need of assistance in the exercise of their functions. On the first day when he was called upon this duty, as he was proceeding to the Hotel de Ville, he had the misfortune to see his friend and protector, Berthier, barbarously murdered by the populace. His own life was frequently exposed to great danger during the tumults that ensued, and when he had the charge of superintending the supply of provisions for the capital. In 1791, he had a seat in the Legislative Assembly; but, disgusted with politics, he quitted Paris the year following, and repaired to his native city. Persecution followed him in his retreat, and he was glad to effect his escape to Madrid, after encountering many dangers. But though well received and liberally assisted by the Literati of that city, the malignity of the French emigrants, who could not pardon his having held any office under the Revolutionary Government, still pursued him, and drove him from Spain, and afterwards from Lisbon, where he had sought another asylum. He at last went out as physician to an embassy which the United States sent to the Emperor of Morocco. He was furnished with the means of equipping himself by the generous assistance of Sir Joseph Banks, who, informed of his distresses, nobly sent him a credit for L. 1000. After residing for some time at Morocco, during which he lost no opportunity of pursuing his favourite science, he obtained from the French Directory permission to return to France; and he was appointed by them Consul at the Canaries, in which capacity he resided for two years at Teneriffe. On his return, in 1796, he was chosen Member of the Institute, and was reinstated in his botanical Professorship at Montpellier, with the direction of the botanical garden. He was afterwards elected a Member of the Legislative Body, and died of apoplexy, July 27, 1807. France is indebted to him for the introduction of the Merino sheep and Angola goats.

Besides the work on fishes, already noticed, the following are his principal productions: 1. *Variæ positiones circa respirationem*, Montpellier, 1788. 2. *Essai sur l'Histoire naturelle de quelques especes de Moines, décrite à la manière de Linnée*, 8vo. 1784, which is a translation of a Latin Satire on the monks, the original of which appeared in Germany in 1783. 3. *Année rurale, ou Calendrier à l'usage des Cultivateurs*, in 2 vols. 12mo. Paris, 1787-8. 4. *Notes pour servir à l'histoire de l'Ecole de Medecine de Montpellier pendant l'an* VI. 8vo. Montpellier, 1795. He was also a conductor, conjointly with Parmentier, Dubois, and Lefebure, of *La feuille du Cultivateur*, in 8 vols. 4to, published in 1788, and the following years. (W.)

BRUCKER (James), Theologian, Historian, Philologer, and Biographer, was born at Augsburgh on the 22d of January 1696. His father, who was a respectable burgher, destined him for the church, and his own inclinations according with his father's wishes, he was sent, at the usual age, to pursue his studies in the University of Jena. Here he took the degree of Master of Arts in 1718; and in the following year he published his *Tentamen Introductionis in Historiam doctrinæ de Ideis*, in 4to; a work which, having afterwards amplified and completed, he republished under the title of *Historia Philosophica doctrinæ de Ideis*, at Augsburgh in 1723. He returned to his native city in 1720; but here his merit having attracted envy rather than recompence, he was induced to accept of the office of Parish Minister of Kaufbevern in 1724. In the same year he published a memoir, *De Vita et Scriptis Cl. Etingeri*, Augs. 8vo. His reputation having been at length established by these learned works, in 1731 he was elected a Member of the Academy of Sciences of Berlin, and soon thereafter he was in-

Brucker.

vited to Augsburgh to fill the honourable situation of Pastor, and senior Minister of the church of St Ulric. He published, in the same year, three dissertations relating to the history of philosophy, under the title of *Otium Vindelicum, sive Meletematum Historico-philosophicorum triga*, Augsburgh, 1731, 8vo. Besides several smaller dissertations on *Biography* and *Literary History*, printed at different times, and which he afterwards collected in his *Miscellanea*, he published at Ulm, in 1737, *Neue Zusaetze verschiedner Vermehrungen*, &c. *zu den kurtzen Fragen aus der Philosophischen historie*, 7 vols. 12mo. This work, being a history of philosophy in question and answer, contains many details, especially in the department of literary history, which he has chosen to omit in his greater work on the same subject. He was forced, by the booksellers, in opposition to his own opinion, to adopt the erotematic method, which at that time had been rendered popular by the writings of Hubner and Rambach.

In 1741, at Leipsic, appeared the first volume of his great work, *Historia Critica Philosophiæ, a mundi incunabulis ad nostram usque ætatum deducta.* Four other ponderous quartos, completing the first edition of this elaborate history, followed in 1744. Such was the success of this publication, that the first impression, consisting of four thousand copies, was exhausted in twenty-three years, when a new and more perfect edition, the consummation of the labours of half a century devoted to the history of philosophy, was in 1767 given to the world in six volumes quarto. The sixth volume, consisting entirely of supplement and corrections, is applicable to the first as well as to the second edition. Of the merits of this work, we shall speak in the sequel.

His attention, however, was not wholly occupied by this stupendous undertaking: the following books would of themselves have been sufficient to exhaust the industry of any ordinary author. *Pinacotheca Scriptorum nostra ætate literis illustrium*, &c. Augsburgh, 1741-55, folio, in five decads. *Ehren Tempel der Deutschen Gelehr samkeit in welschen die Bildnisse gelehrter Maenner unter den Deutschen aus dem XV. XVI. and XVII. Jahrhundert aufgestellet, und ihre Geschichte*, &c. *outworfen sind*, Augsburgh, 1747-49, 4to, five decads: *Institutiones Historiæ Philosophicæ*, Leipsic, 1747, 8vo, a second edition, ibid. 1756; and a third has been published since Brucker's death, with a continuation by Professor Born of Leipsic, in 1790: *Miscellanea Historiæ Philosophicæ Literariæ criticæ olim sparsim edita nunc uno fasce collecta*, Augsburgh, 1748, 8vo: *Erste Anfangsgrunde der Philosophischen Geschichte, als ein Auszug seiner grossern Werke. Zweyte Ausgabe*, Ulm. 1751, 8vo. He likewise superintended and corrected an edition of Luther's translation of the *Old* and *New Testament*, with a Commentary extracted from the writings of the English Theologians, Leipsic, 1758-70, folio, six parts. His death ensued before this work was finished, which has since been accomplished by Teller. He died at Augsburgh in 1770; and he may be added to the catalogue of Huetius, to prove that literary labour is not incompatible with sound health and longevity. See *Saxii Onomasticon.—Biographie Universelle.*—Gesner's *Isagoge.*

It is only by his writings on the history of Philosophy that Brucker is now known in the literature of Europe. In this study, his great work forms an important æra, and even at the present day it is the most extensive and elaborate upon the subject. It is, however, a work of which the defects are great, and its errors have been important in their consequences, in proportion to the authority it has acquired. We shall, therefore, hazard a few general observations on the defects which chiefly detract from the perfection and utility of the *Critical History of Philosophy.*

If Brucker had carried into this study a penetration equal to his diligence; and had his general comprehension of the scope and nature of the subject been correspondent to the elaborate minuteness of his details: he would have left us a work which might have had some pretensions to be considered as a rational history of human opinion. He lived, however, at a period when these different qualities were only beginning to be conjoined; and when as yet the history of Philosophy had been written merely as a chronicle of the passing theories of individuals and sects. To give to the science of history a regular and connected form, and to arrange the narrative of successive events, and still more of successive opinions, according to the relation they bear to principles of established influence, was an attempt of which few in that age had any conception, and of which Brucker certainly had none. In civil history, it was then believed, that the historian had fulfilled all the duties of his office, if he strung together the events which were known, or believed to have occurred, in good language, and garnished them occasionally by a few general reflections on the absolute motives of human action. A very different notion is now held of the functions of the historian. He who at present attempts to write the history of any country, must reflect before he begin, what were the chief occurrences in that history, and what were the revolutions which the manners and constitution of that particular nation have undergone. He must bear with him, from the commencement to the conclusion of his labours, a constant impression that every occurrence should be more or less considered, not only as it took place, and as it bore an influence on contemporary affairs, but as it may remotely have contributed to the events, and the opinions, and the character of succeeding times. But if this be true in regard to the histories of particular nations, it is evident, that by how much the traces of opinions are more light and evanescent than those of events,—by how much the speculations of philosophers, whose writings have either perished or come down to us mutilated and obscure, are more difficult to be appreciated in their causes, and connections, and consequences, than the actions of warriors and statesmen; by so much the more is it necessary in philosophical than in civil history, to combine reasoning with erudition, and to substitute the researches of the philosopher for the details of the chronicler. History and philosophy are two different things; and he who

would write the history of philosophy must excel in both. Bacon had long ago required this union, and had pointed out the manner in which the historian of literature should endeavour to establish those principles of connection, which constitute the soul and charm of such a history; how by detecting the union of effects and causes, he might be enabled to determine the circumstances favourable or adverse to the sciences; and how, in short, by a species of enchantment, he might evoke the literary genius of each different age. The fulfilment of this plan was, however, far beyond the capacity of Brucker; and was an undertaking of which he had even no conception. Better qualified by nature and education for amassing than arranging materials, he devoted his principal attention to a confused compilation of facts, leaving to others their application, the discovery of their mutual connections, and the formation of the scattered fragments into a whole.

The merit of his great work consists entirely in the ample collection of materials. The reader who would extract any rational view of the progress of opinion, must peruse it with a perpetual commentary of his own thoughts. He will find no assistance from his author, in forming any general views, or in tracing the mutual dependencies of the different parts of the subject. Brucker has discovered the fountains of history; but he has made us drink of them without purifying the draught. Even in this respect, his merit has been greatly overrated. Vast as is the body of materials which he has collected, we are always missing those very things which we might reasonably have expected would have been the first objects of a rational inquirer, and we are continually disappointed of the information we are most anxious to acquire. The idle and slavish attention which he has bestowed on previous compilers, has frequently diverted him from the study of the original authors themselves. Quoting the passages of the ancients from others, or trusting, perhaps, to the reference of an index, he has frequently overlooked those very testimonies which could have given us the most authentic knowledge of the opinions or characters of ages and individuals. He has often presented the authorities he has adduced, mutilated or misapplied; and this either from not having sufficiently studied these passages in their general connection with the system they illustrate, or from having been unable to withdraw them from the obscurity in which they were involved. He has shown no critical sagacity in distinguishing the spurious from the authentic, or in balancing the comparative weight of his authorities. He has frequently transcribed, where he ought to have explained, the words of the original authors; and, without taking into account the different value of the same term in different nations and ages, he has left us to apply a doubtful or erroneous meaning to words which might have been easily rendered by other expressions, and to suppose a distinction in the sense, where there only existed a difference in the language. The glaring errors, even, which occasionally occur in his expositions of the Grecian philosophy, while they are inconsistent with any critical knowledge of the tongue, would make us suspect that he was in the habit of relying on the treacherous aid of translations. In short, if we knew nothing more of the ancient philosophers than what we acquire from Brucker, we should be often obliged to attribute to them opinions, so obscure or so absurd, that we must either believe ourselves wrong in the interpretation, or be unable to comprehend the cause of all the admiration and reverence they have received.

He has discovered little skill in his analyses of the different Systems of Philosophy; and the confusion of what is essential and principal with what is accidental and subordinate, clearly evinces, that these abridgments were thrown together while acquiring, in detail, a knowledge expressly for the purpose, instead of being the consummation of a long and familiar meditation on the subjects in all their modifications and dependencies. He has dwelt with the most irksome minuteness on every unimportant and doubtful circumstance in the lives of the Philosophers; but he has too often overlooked the particular and general causes that produced an influence on the destinies of their philosophy. The aphoristic method which he has adopted, prevents him from following a consecutive argument throughout its various windings. The most convincing reasoning, in his hands, loses much of its demonstration and beauty; and every ingenious paradox comes forth from his alembic a mere *caput mortuum*,—a residue from which every finer principle has been expelled. Where the genius of the Philosopher is discovered more in the exposition and defence, than in the original selection and intrinsic stability of his tenets, Brucker has not found the art of doing justice both to the Philosopher and his opinions, or in conveying to the reader any conception of the general value of the original. This last defect, it must, however, be acknowledged, is, more or less, inseparable from every abstract of opinions, where it is always necessary to separate, in some degree, what is essential to the subject from what is peculiar to the man. He has relieved the sterility of his analyses by none of the elegancies of which the subject was susceptible. Without any pretension to purity, his diction is defective even in precision; and his sentences, at all times void of harmony and grace, are abrupt, and often intricate in their structure.

The person, therefore, who would attempt to write a history of Philosophy, without the imperfections of that of Brucker, must draw from obscurity many important facts hitherto omitted; he must arrange and combine these in a more perspicuous order; and, above all, he must review the opinions he shall thus relate and methodise with a more accurate criticism. He ought not to write of Peripatetics like a disciple of Aristotle, of Platonists like a pupil of Proclus, nor of the doctrines of the Porch like a follower of Zeno. Still less must he compare the tenets of one sect by the principles of another; or endeavour to estimate doctrines, dubious in themselves, by reference to a standard equally arbitrary and contingent. He must place himself, to use the language of Lucretius, upon the highest pinnacle of the temple of science, from whence he may look calmly back, and

compare and study the doctrines of all these departed sages, without being himself involved in the partialities of particular sects or opinions,—

Despicere unde queat alios, passimque videre,
Errare, atque viam palanteis quærere veri.

He must honour the genius of all alike; and believe that all are deserving of commendation, although all are more or less subject to error. He ought, in short, to be a Philosopher superior even to the prejudices of philosophy.

If we take a survey of what has been attempted since the death of Brucker, in accomplishing a more perfect history of philosophy, we shall find that more has been done in illustrating the philosophical tenets of particular sects, or the progress of particular portions of science, than in giving a comprehensive view of the general history of thought. In France, in Italy, and in our own country, those who have laboured in this work, far from being able to correct the errors of Brucker, have, in general, through defect of erudition, been wholly indebted to his industry for their materials, and been content to rely on his accuracy with more than Pythagorean faith. If we except some ingenious speculations, which are more of the nature of philosophical essays on the history of philosophy, and which endeavour rather to illustrate the general spirit, than to detail the particular opinions of the philosophers, there is nothing valuable on this subject to be found in the literature of these countries. Among the learned of his own country, Brucker has never enjoyed a very distinguished reputation; and the Germans, while they were the most capable of discovering his defects, have had the honour of most sedulously and successfully endeavouring to supply them. We are indebted to them, especially, for many valuable treatises on the history of particular portions of philosophy, in which we find, at length, a profound reasoning united to an extensive and original erudition. The works of Meiners, Fulleborn, Tiedmann, and perhaps Buhle, deserve especially to be distinguished. An undertaking, however, which, from the extent of its plan, as well as the ability of its execution, claims particular notice, is the *History of Philosophy*, by Professor Tenneman of Jena. This work, as far as it is completed, affords us the most accurate, the most minute, and the most rational view we yet possess, of the different systems of philosophy, in their intrinsic and relative bearings. The author has not only given us a minute analysis of each system, the result of a profound and familiar study of the original Philosopher, but he has also displayed to us his philosophy, divested of its peculiarities, and compared with others by a general and impartial review. The main defect of this work, at least in reference to readers not German, is, that, like Buhle and the other disciples of Kant, he has taken the Critical philosophy as the vantage-ground from whence to make his survey of all former systems. Thus the continual reference to the peculiar doctrines of the school of Kant, and the adoption of its language, render it frequently impossible for those who have not studied the dark works of this modern Heraclitus, to understand the strictures of Tenneman on the systems even of Aristotle or Plato. (KK.)

BRYANT (Jacob), a profound scholar, mythologist, and sacred historian, born at Plymouth in 1715. His father had a place in the Customs, and was afterwards stationed in Kent, where his son was first sent to a provincial school, from which he was removed to Eton. Here he appears to have remained till 1736, the date of his election to King's College, Cambridge, and he took his degrees of Bachelor and Master of Arts in 1740 and 1744. He returned to Eton in the capacity of private tutor to the late Duke of Marlborough, then Marquis of Blandford; and the good taste which his pupil showed through life, in the protection of the fine arts, and in the pursuit of science, sufficiently demonstrated the beneficial influence of his instructor's example. In 1756, he went to the Continent as Private Secretary to the Duke of Marlborough, then Master-General of the Ordnance, and Commander in Chief of the forces in Germany; and he was rewarded, after his return, for his various services to the family, by a lucrative appointment in the Ordnance, which allowed him ample leisure to indulge his literary taste in a variety of refined investigations, and to exercise his zeal for the cause of religion in a multitude of works, calculated for the illustration of the Scriptures, and the demonstration of their authenticity and divine authority.

1. His first publication was entitled *Observations and Inquiries* relating to various parts of Ancient History, containing Dissertations on the wind Euroclydon, and on the Island Melite, together with an Account of Egypt in its most early state, and of the Shepherd Kings, 1767. In this work he attempts to prove that the Melite, on which St Paul was wrecked, was not Malta, but one of the Illyrian islands in the Adriatic, now called Melede; and he endeavours to illustrate several points in the early history of the oriental, and especially of the Aramitic nations.

2. But his most elaborate performance was his *New System or Analysis of Ancient Mythology*, wherein an attempt is made to divest tradition of fable, and to reduce truth to its original purity, 3 vols. 4to, 1774, 1776. In this attempt, the author has equally displayed his deep and extensive learning, and his inventive fancy; but it must be confessed that, on a minute examination, the work exhibits much more of a poetical imagination than of a sound judgment, and that, in endeavouring to substitute etymological for historical evidence, he has been completely unsuccessful. Nothing can afford a more satisfactory kind of proof than etymology taken on a large scale, and considered as a mode of tracing the relations of nations to each other, by the affinities of their languages; since the accumulation of a multitude of probabilities, each weak when taken separately, becomes at last equivalent to a certainty. But nothing, on the other hand, can be more fallacious, or more liable to controversy, than single etymological inferences, in particular cases, when one of these slight resemblances is magnified into a striking likeness, and even an identity, which is then made the foundation of a magnificent superstructure in mythology or in history.

Bryant. Bryant || Buat.

Mr Richardson has shown, in the Preface to his *Dictionary*, how much Mr Bryant was mistaken in some of his reasoning respecting the signification and derivation of particular words; and even if he had been more correct in these instances, the conclusions, which he has deduced from his etymologies, would by no means have been perfectly legitimate. Jablonsky seems to have exhibited one of the strongest examples of this dangerous abuse of learning; in which he has been followed not only by Mr Bryant, but by several other modern writers equally visionary, who have commonly been very imperfectly acquainted with the languages on which their conjectures have depended, and have been still more deficient in that sort of common sense, and correct feeling, confirmed by experience, which constitutes the most essential part of the qualifications of a critic, and the want of which can never be compensated by the most unwearied labour of a mere mechanical commentator.

3. Some remarks, which had been made on particular passages of Mr Bryant's work, led him to publish *A Vindication of the Apamean Medal;* of the inscription ΝΩΕ; and of another coin, in the *Archaeologia*, Vol. IV. Art. 21, 22, 23. 4. He deviated somewhat more widely from the usual objects of his researches, and apparently without any very decided advantage over his adversary, in *An Address to Dr Priestley*, on the doctrine of philosophical necessity, 8vo, 1780. 5. He also published in the same year *Vindiciæ Flavianæ*, or a vindication of the testimony given by Josephus concerning our Saviour, 8vo.

6. Unfortunately for the credit of his critical discrimination in matters of old English literature, Mr Bryant was the author of *Observations on the Poems of Thomas Rowley*, in which the authenticity of these poems is ascertained, 2 vols. 12mo, 1781. If there could be any excuse for the commission of forgeries like that of Chatterton, it would be found in their serving as a valuable test of the degree of confidence, which it is justifiable to place, in the decrees of the most powerful critics, respecting other questions of a more ambiguous nature.

7. Mr Bryant contributed to the publication of the *Duke of Marlborough's Collection of Gems*, the Latin explanations contained in the first volume, fol. 1783. 8. He inserted in the *Archaeologia*, VII. 387, some *Collections on the Zingara or Gipsey Language;* which has been since sufficiently proved to be one of the many derivatives of the old Sanscrit. 9. Sometime afterwards, he published an anonymous *Treatise on the Authenticity of the Scriptures*, and the truth of the Christian religion, 1792. 10. This was succeeded by his *Observations upon the Plagues* inflicted upon the Egyptians, 8vo, 1794.

11. His opinions respecting the existence of the city of Troy, and the veracity of Homer as a historian, raised up against him a host of powerful adversaries; and in a question of this nature, upon which the decisions of mankind are so manifestly influenced by their sensibility to poetical beauty, and their early habits and attachments, a much more cautious attempt to innovate might easily have been unsuccessful. Whatever learning and talents may have been exhibited in this controversy, it will hardly be believed by an impartial judge, reasoning on the general probabilities of the case, that Homer intended the actions of his heroes, any more than their genealogies, to be historically correct; but, at the same time, it will readily be admitted, that he was much more likely to take, for the scene of his poem, a town that had really existed, and, for its subject, a traditional report of a war which had actually been carried on, than to have invented a fabulous city and an imaginary warfare, without any historical foundation whatever. Mr Bryant published on this subject *Observations on a Treatise*, entitled, *Description of the Plain of Troy*, by Mr de Chevalier, 4to, 1795. 12. *A Dissertation concerning the War of Troy*, and the expedition of the Greeks, as described by Homer; showing that no such expedition was ever undertaken, and that no such city in Phrygia existed, 4to, 1796. 13. *Observations on the Vindication of Homer*, written by J. B. S. Morritt, Esq. 4to, 1799.

14. He had, in the meantime, not discontinued his theological studies, and had published an Essay on *The Sentiments of Philo Judaeus* concerning the word of God, 8vo, 1797. His last work was a volume of *Dissertations on Various Subjects in the Old Testament*, which had been nearly completed thirty years before. The subjects which had particularly attracted his attention, were the histories of Balaam, Sampson, and Jonah; and besides Philo Judaeus and Josephus, he had endeavoured to illustrate some controverted passages of Justin Martyr, as well as many other departments of religious and historical discussion.

The habits of Mr Bryant's maturer life were in general completely sedentary; although, in his youth, he had taken his full share in the cultivation of the manly exercises common to Etonians, and had once the good fortune to save, by his proficiency in swimming, the life of Dr Barnard, afterwards Provost of Eton. His conversation was elegant and animated; his manners mild but firm; he exerted himself to please others, and was himself easily pleased. He was much courted in society, and his residence, at Cypenham, near Windsor, was not unfrequently visited by persons of the highest possible rank. He never married. He died in his 89th year, the 14th November 1804, from the immediate consequence of an accidental blow. He left his library to King's College, having, however, previously made some valuable presents out of it to the King, and to the present Duke of Marlborough. He also bequeathed L. 2000 to the Society for the Propagation of the Gospel, and L. 1000 for the use of the superannuated collegers of Eton School. [*Gentleman's Magazine*, LXXIV. p. 1080. 1165. Nichols's *Literary Anecdotes*, IV. 667. 8vo, Lond. 1812. Aikin's *Biographical Dictionary*, X. *Supplement.*] (N. A.)

BUAT-NANCAY (LOUIS GABRIEL, COUNT DU), was born of an old family in Normandy, on the 2d of March 1732. At an early age, he entered into the Order of Malta; and, by a fortunate accident, he became acquainted with the Chevalier Folard, author of the *Commentaries on Polybius*, who received him into his house, and superintended his education.

Buat || Buckinghamshire.

Folard had a nephew, who was Minister for France at different German Courts, and under whom Buat studied History and Diplomacy. He was successively Minister for France at Ratisbon and Dresden; but afterwards, becoming disgusted with this career, he retired from public life, in the year 1776. He died at Nançay, in Berry, on the 18th of September 1787.

Buat was a man of some talents, and considerable literary attainments, but possessing little knowledge of the world; which circumstance seems to have, in a great measure, disqualified him for public employment. He appears to have written with great facility; but his style is very unequal. His works are: 1. *Tableau du Gouvernement actuel de l'Empire d'Allemagne*, translated from the German of Schmauss, with notes historical and critical. Paris, 1755, 12mo. 2. *Les Origines, ou l'Ancien Gouvernement de la France, de l'Italie, et de l'Allemagne*, published at the Hague, 1757, 4 vols. 12mo. 3. *Histoire Ancienne des Peuples de l'Europe*, Paris, 1772, 12 vols. 12mo. This is the largest, and perhaps the best work of Buat. 4. *Les Elémens de la Politique, ou Recherches sur la vrais Principes de l'Economie Sociale*, 1773, 6 vols. 8vo. 5. *Les Maximes du Gouvernement Monarchique, pour servir de suite aux Elemens*, 4 vols. 8vo. There is also ascribed to Buat a work entitled *Remarques d'un Français, ou Examen impartial du livre de M. Necker sur les Finances*, Geneva, 1785, 8vo. In his youth he had composed a tragedy, entitled *Charlemagne, ou le Triumphe des Lois*, published at Vienna, 1764, 8vo. He likewise contributed several articles to the journals of his time, on different points of history, literature, and political economy; in particular, some excellent observations on the character of Xenophon, &c., inserted in the fourth volume of the *Variétés Litteraires*. See *Biographie Universelle*. (II.)

Boundaries.

BUCKINGHAMSHIRE is divided from Berkshire by the river Thames, during a course of about 28 miles, from about a mile to the north of Henley Bridge to the conflux of the farthest stream of the Colne: for a course of about 14 miles, the Colne is the eastern boundary between this county and Middlesex. The Thame, in its course from the town of that name, is, for a very few miles, the boundary between Buckinghamshire and Oxfordshire. The Ouse first becomes a boundary between this county and Northamptonshire, near Brackley; and for a few miles beyond Westbury, it divides it from Oxfordshire; after it passes Thornton, it again becomes, for a few miles, the boundary between Buckinghamshire and Northamptonshire; and just before it quits the county, it forms the boundary between it and Bedfordshire. The Ousel is the boundary between these two counties, from Eaton Bray to Linchlade.

Form and Extent.

The figure of this county approaches to that of a crescent, but its outline is rendered very irregular by projections and indentations. From the south-eastern to the north-western extremity, it measures nearly 50 miles; but its greatest breadth is scarcely 18: it is about 138 miles in circumference. According to the *Report to the Board of Agriculture*, it contains 518,400 acres; but, according to the returns to Parliament, of the poor's rates, only 478,720; and Dr Beeke, in his *Observations on the Income-Tax*, calculates the number of acres at 461,729.

Divisions.

The parishes, according to the Parliamentary returns respecting the poor's rates, amount to 223, and not 185, as stated in the *Encyclopædia*. The fourteen Members for Parliament are returned,—two for the county; two for Buckingham; two for Aylesbury; two for Wycombe; two for Amersham; two for Wendover; and two for Marlow. There are seven deaneries in it. Though in the diocese of Lincoln, four parishes are in the peculiar jurisdiction of the Archbishop of Canterbury, and four others are in the diocese of London, and in the jurisdiction of the Archdeacon of St Albans. The great tithes of ninety-two parishes are in lay hands, and most of the remainder are held by lay leases. The Summer Assizes are held at Buckingham,—the Lent Assizes at Aylesbury. The Quarter-Sessions are always held at Aylesbury. This county contains many magnificent seats; among which the most celebrated are Stowe, the seat of the Marquis of Buckingham,—Bulstrode, formerly belonging to the Rutland family, but lately purchased by the Duke of Somerset,—Dropmore, the seat of Lord Grenville,—Taploe House, the seat of the Marquis of Thomond,—Wycombe Abbey, of Lord Carrington.

Soil.

The southern part of Buckinghamshire, beyond the Thames, is principally occupied by the Chiltern Hills. The soil of these is chalk, intermixed with flints. They stretch across the country from Bedfordshire to Oxfordshire, forming a part of that great chain which extends from Norfolk to Dorsetshire. On the west side of the county, adjoining Oxfordshire, is a range of hills of calcareous stone. In that part of the county which borders on Bedfordshire, about Wavendon, Broughton, and the Brick-hills, the soil is a deep sand. The Vale of Aylesbury, of proverbial fertility, which lies under the Chiltern Hills, and occupies the middle of the county, is formed of a rich black loam, on a calcareous subsoil. In the northern parts of the county, the soil is chiefly clay; but, on the Bedfordshire border, the surface rises into gentle sand-hills. The whole of the Chiltern district is said formerly to have been a forest; the western part, occupied by the forest of Bernwood, was disforested in the reign of James I. At present, the chief woodlands lie to the south of the Chiltern Hills. On a tract of land, extending across the parish of Little Kimble into that of Great Kimble, there are about 100 acres of box-wood, apparently the natural growth of the soil. The black cherry abounds in the neighbourhood of Chesham. The prevailing timber in the southern part of the county is beech; one wood of which, in the parish of Wycombe, is said to contain 700 acres; nearly one-sixth part of the land between the road to Oxford and the Thames, is supposed to be covered with this wood. Whaddon Chace is the principal woodland in the northern part of the county, containing 2200 acres of coppices.

Rivers.

The rivers of note are the Ouse and the Thames; the Ouse enters Buckinghamshire, on the west side, near Water Stratford, which it passes, and then flows in a devious course

Buckinghamshire.

to Buckingham; thence winding to the north, through a rich tract of meadow land, it reaches Stoney Stratford, Newport Pagnell, and Olney; soon afterwards, turning suddenly to the east, it leaves the county near Brayfield. One of the most considerable streams of the Thames, rises near the borders of the county, in Hertfordshire, and flowing through the Vale of Aylesbury, from east to west, receives the waters of several smaller streams, and enters Oxfordshire, near the village of Ickford; its course through Buckinghamshire is about 30 miles. The grand junction canal enters this county near Woolverton, and, running eastward, goes within a mile of Newport Pagnell; thence flowing to the south, it passes Fenny Stratford, Stoke-Hammond, Cinslade, and Ivinghoe, into Hertfordshire. From a branch of the canal at Old Stratford, a cut has been made to Buckingham; and another from Bulbourne to Wendover.

Fuller's-earth.

On the borders of Bedfordshire, are the celebrated fuller's-earth pits, one of which only is now occasionally worked. Mr Pennant thus describes the *strata*: "The beds over the marl are, first, several layers of reddish sand to the thickness of six yards; then succeeds a *stratum* of sandstone, of the same colour, beneath which, for seven or eight yards more, the sand is again continued to the fuller's-earth, the upper part of which being impure, or mixed with sand, is flung aside; the rest taken up for use. The earth lies in layers, under which is a bed of rough white freestone, and under that sand, beyond which the labourers have never penetrated."

Natural History.

A striated species of *Nautilus* is found in great abundance, and frequently of a very large size, in the yellow limestone near Dinton. The only very rare plant known to the botanists as indigenous to this county, is the *Dentaria bulbifera*, which grows abundantly in its south-east corner. The great snail, or *Pomatia*, Mr Pennant was informed, is found in the woods near Gothurst; and he regards this as its most southern residence in England. We have seen it, however, near Ashted in Surrey; and the tradition there, as in Buckinghamshire, is, that it was introduced from abroad for medicinal purposes.

Agriculture.

Formerly, the commons, common fields, and wastes in this county, bore a very large proportion to the whole of its area; but, at present, their whole extent is very inconsiderable, except in the vale of Aylesbury, where the common fields are still numerous. Between the 1st of Queen Anne and the year 1797, there were thirty-one inclosure-acts passed for this county, comprehending 38,457 acres; besides 22 acts, in which the number of acres was not specified; and during the first 40 years of his present Majesty's reign, there were 61 acts of inclosure passed. In other respects, however, the agriculture of this county has not advanced much, principally in consequence of the restrictions in the leases. It has long been remarkable for its produce of corn and cattle. "Buckinghamshire bread and beef," was an old proverb. As far back as the time of Camden, numerous flocks of sheep were fed in the vale of Aylesbury, which yielded great profit from their wool; and Fuller informs us, that, in his time (1660), the largest sheep in England were bred in this vale, and that it was not unusual to give L. 10 or more for a ram. At present, this vale is principally employed in feeding oxen for the Smithfield market, and in furnishing immense quantities of butter to the London dealers. Eight pounds is the average weight of butter produced weekly from each cow in summer, and six the average in winter. In the northern parts of the county, great numbers of calves are bred, which are purchased at Aylesbury market by the farmers of the Chiltern district, and by them fattened for the markets of the metropolis. The skim and butter-milk of the dairies are employed in fattening vast numbers of swine. There is a very small proportion of arable land in the northern division of the county; and not much in any other part, except the Chiltern districts. Here the crops usually cultivated are wheat, barley, oats, beans, and sainfoin. In the neighbourhood of Aylesbury, they are famous for rearing ducks very early in the spring, and sometimes by Christmas; these are sent to London, and sold at a very high price. The ducks are prevented from laying, by artificial means, till October or November. A few weeks before they lay, they are fed highly; the eggs are hatched by hens, which are frequently exhausted to death, by sitting on three broods successively. As soon as the ducklings break the shell, they are nursed with particular care at the side of a fire.

Manufactures.

The only manufactures of consequence in this county are those of bone-lace and paper. The former is principally carried on at Olney, Newport Pagnell, and Hanslope, a village about five miles north-west from Newport Pagnell. In this village, in the year 1801, 800 out of a population of 1275 were employed in this manufacture. The lace made here sells from sixpence to two guineas a yard. But, since lace has been made on the frame at Nottingham, Loughborough, and other places in that neighbourhood, the bone-lace manufacture of Buckinghamshire has been greatly on the decline. The manufacture of paper has been carried on in the neighbourhood of Wycombe for more than a century. On that part of the small river Wyke which passes through this parish, there are fifteen corn and paper-mills. At Amersham, besides the lace manufacture, there is a manufacture of sacking; and one for all kinds of white cotton goods At Marlow are manufactures of paper and black silk lace, large works of copper, brass, and brass-wire, and mills for making thimbles, and for pressing rape and linseed oil. The principal markets in the county are those of Aylesbury, Buckingham, and Wycombe. Marlow fair is much celebrated for its show of horses.

Architectural Antiquities.

The church of Stewkley is one of the most complete specimens of Saxon architecture now remaining; no part of it, externally or internally, having been altered or materially defaced; nor have any additions been made to it, except the porch on the south side, and the pinnacles of the tower. The date of 1106 is said to have been observed on a stone by some workmen who were repairing the roof of the Chancel. The Chancel of the church of Chetwode, supposed to have been founded in the year

Buckinghamshire ‖ Budukshaun.

1244, has lancet-shaped windows, with slender pillars, the capitals of several of which are highly enriched with foliage and figures of animals. Hillesden Church, which was rebuilt about the year 1493, affords a rich specimen of the later Gothic. Some of the most ancient and elegant specimens of stained glass in the kingdom, remain in the chancel of Chetwode Church; as there is little doubt that this glass was coëval with the erection of the church, in 1244, it may be considered as one of the earliest specimens of the kind produced in England. The cross built upon the side of a hill, near the hamlet of Whiteleaf, is supposed to have been erected in the reign of Edward the Elder, to commemorate a battle fought against the Danes; it is about 100 feet high, and 50 broad, tapering to 20.

Poor's Rates.

In the year ending Easter 1803, the total money raised by poor's rates, and other parochial rates, was L. 105,378, 14s. 11¾d.; on the average of the three years 1783, 1784, and 1785, it was L. 48,242, 15s. 3d.; and in the year 1776, it amounted to L. 37,052, 18s. 1d. In the account of the poor's rates for the year ending 25th March 1815, ordered by the House of Commons to be printed 26th February 1816, there are no returns from this county.

Population.

In the year 1377, the number of persons in Buckinghamshire, charged to a poll-tax, from which the clergy, children, and paupers were exempted, was 24,672. In the year 1700, the population amounted to 80,500. In the year 1801, by the returns under the act of Parliament, there were 20,443 inhabited houses, and 543 uninhabited. The total number of inhabitants was 107,444, of whom 52,094 were males, and 55,350 females. Of this total number, 25,083 were employed in agriculture, and 20,138 in trade, manufactures, or handicrafts. In the returns of the population act in 1811, the following results are given:

Inhabited houses - -	21,929
Families inhabiting them -	25,201
Houses building - -	119
Uninhabited houses - -	457
Families employed in agriculture -	13,933
Ditto in trade, &c. - -	8,424
Ditto not comprehended in preceding classes	2,844
Males - - -	56,208
Females - - -	61,442
Total population - -	117,650
Ditto in 1801 - -	107,444
Increase - - -	10,206

BUDUKSHAUN, a mountainous country, or rather range of mountains, in Asia, reaching northwards, from the great ridge of Hindoo Coosh to the source of the Oxus. It forms thus the western boundary of the territory of Kaushkaur. The whole range is covered with snow during the greater part of the year; but there is only one point of perpetual snow, being that from which the Oxus and Kama take their rise. The territory is watered also by a considerable river, called the Koocha, which falls into the Oxus. The mountains contain many valuable mines of silver, iron, antimony, and lapis lazuli. Budukshaun is celebrated also for mines of rubies, situated on the lower hills, near the Oxus; but they are no longer wrought.

Budukshaun ‖ Buenos Ayres.

This country, from its inaccessible situation, has generally maintained its independence against any foreign power. The present chief, Sultaun Mahommed, is said to be absolute over his own subjects. He has a revenue of about L. 60,000, and maintains from 7000 to 10,000 men, armed with matchlocks, in the use of which the Budukshees are said to be peculiarly expert. The capital is Tyzabad, a considerable town situated on the river Koocha. (B.)

BUENOS AYRES, one of the viceroyalties into which the Spanish dominions in South America are divided, and the most extensive of the whole. To the south and north its limits are not exactly defined, as it stretches into extensive deserts inhabited only by savages, and little known. Its southern boundary may be considered to extend from Cape Lobos westward to the Rio Colorado; on the north it is bounded by Amazonia, or the country of those independent Indians who wander about the Amazons and its tributary streams; on the east by Brasil and the Atlantic Ocean; and on the west by the great ridge of the Cordilleras, which separates it from Chili, and further to the north from Peru. From Cape Lobos to the furthest northern settlements on the Paraguay, it extends upwards of 1600 miles; and from Cape St Anthony at the mouth of the Plata, to the ridges that separate it from Chili, 1000 miles. It was erected into a viceroyalty in 1778, and several districts were added to it from Peru and Chili. From the latter those provinces were principally taken which are situated on the eastern declivity of the Andes.

Boundaries.

Divisions.

The viceroyalty of Buenos Ayres is divided into five governments or provinces, namely,

I. Buenos Ayres, or Rio de La Plata, of which the chief towns are Buenos Ayres the capital, Santa Fe, Monte Video, and Maldonado on the opposite shores of the river.

II. Paraguay, of which the chief town is Assumption.

III. Tucuman, of which the chief towns are San Jago del Estero, and Cordova.

IV. Los Charcos, or Potosi, formerly part of Peru, and comprehending the new district of Santa Cruz de la Sierra. The chief towns are La Plata, Potosi, Santa Cruz de la Sierra, and La Paz.

V. Chiquito, or Cuzco, formerly part of Chili, of which the chief towns are Mendoza, and San Juan de la Frontera.

The viceroyalty of Buenos Ayres forms a compact body of land nearly square, lying between the mountains of Brasil on the east, and the Cordilleras of Peru and Chili on the west. Towards the south, from those great ranges of mountains, a considerable tract of elevated country branches into the interior, in which arise all the numerous streams by which the country

is watered; whilst its western and southern parts, descending by gradual slopes, run into extensive, and in some places marshy, plains to the foot of the Cordillera of Chili.

It is chiefly by means of the Rio de la Plata, that those extensive regions are drained of their waters; all the streams which have their rise in the eastern declivity of the Chilian Andes, or that descend from the western ridges of Brasil, being ultimately carried into the channel of this great river. In the upper part of its course, it is known by the name of the Paraguay, and runs nearly in the centre of the American continent, from N. to S., receiving from the mountains of Brasil the two great streams of the Parana and the Uruguay, while from the west it receives the Pilcomayo, the Vermejo, and the Salado, which flow down the eastern declivity of the Andes.

It was called Rio de la Plata, or *River of Silver,* by Sebastian Cabot, from his having taken a considerable booty, in gold and silver, from a body of Indians whom he defeated on its banks, and this imposing title it has ever since retained. This appellation, however, though no doubt intended by its author to apply to the whole of the river, is now confined to the channel by which the Paraguay, the Panana, and the Uruguay, pour their united waters into the ocean. This vast estuary of fresh water, which is without a parallel for width and magnificence, is 150 miles broad at its mouth, from Cape St Maria, on one side, and Cape St Anthony, on the other. Between Monte Video and the Punta de Piedras, which some have considered its proper limits, it is 80 miles in breadth; and at Buenos Ayres, which is 200 miles from its mouth, its breadth is about 30 miles; and, the shores being low, it is seldom that they can be seen from opposite sides. This immense inland sea is, however, rendered dangerous for the purposes of navigation, not only by rocks and sand-banks, which are the terror of mariners, and which greatly detract from its utility; but by tempests of wind which, bursting forth from the south-west, sweep over the boundless plains of the *Pampas*, where they meet with no obstacle to oppose them, and rush down the wide opening of the Plata with unequalled fury. A thunder storm is the general prelude to those destructive blasts, which are known by the name of the *Pamperos;* so that the mariner, being warned of the coming tempest, generally seeks shelter in some of the neighbouring ports.

The greater part of the country included within the viceroyalty of Buenos Ayres, forms, according to Azara, a vast plain, of which the uniform level is hardly ever interrupted by hills of a greater elevation than of 90 toises above their base; and it has been calculated, by barometrical observations, that the great river Paraguay, in its progress southward, does not fall above one foot in perpendicular height between the 18th and 22d parallels of south latitude. In like manner it is asserted, by persons well acquainted with the country, that when the easterly winds occasion the rivers of Buenos Ayres to rise to the height of seven feet above its ordinary level, this rise is perceived in the river Panana at the distance of 60 leagues.

In consequence of this flatness of the country, the rains which fall upon the Cordilleras are stopped when they descend into the plain, and are insensibly evaporated; so that a number of small rivulets which, under a different configuration of the ground, would be collected into rivers, are here checked in their course, and gradually evaporated. Nor can any art or skill ever remedy this physical defect of the country; for the same cause which prevents its superfluous moisture from forcing its way to the ocean, would equally prevent the conveyance of water by means of any artificial canal. In Buenos Ayres, accordingly, and in other places situate on the banks of rivers, it is always found necessary to make use of a pump in order to raise the water to the level of the town.

Lakes.

But this peculiarity is, on the other hand, favourable to the formation of lakes. There being no outlet to the superfluous waters which the soil cannot absorb, they are necessarily collected in the flat parts of the country, where they spread to a great extent, covering an immense space, but of no great depth in any part. Most of the lakes which are to be found in this extensive country are of this description. Of these, the celebrated lake of Los Xarayes is formed by the collected waters which fall during four months from the beginning of November to the end of February in the northern provinces, and in the mountainous districts in which the Paraguay has its sources. This great river, swelled by the tropical rains, soon overflows its banks, and its redundant waters spread to a great extent over the flat country through which it flows. As the quantity of rain which falls in different years varies considerably, the dimensions of Lake Xarayes, which is formed by the overflowing of the river, are liable to great uncertainty. In general, however, it is found to extend beyond the 17th degree of south latitude, and about this point its breadth on the east of the river Paraguay is about 66 miles. It preserves the same breadth for about 300 miles to the north, surrounding with its waters several islands which are covered with lofty trees. On the west side of the river, the breadth of the lake is not so considerable. Its whole length, according to the nearest estimate, may be 330 miles, and its breadth on an average 120 miles. But although it spreads over so large a space, it is not navigable in any part except for canoes and small craft. When the rainy season abates, the waters of this lake subside into the channel of the Paraguay, leaving the whole plain perfectly dry, and covered with weeds and other plants. The number of crocodiles in this lake is immense, and in the vicinity are found tigers, leopards, stags, and monkeys of various kinds; the country also swarms with ants, mosquitoes, and innumerable noxious insects. During the inundation, the Portuguese, from their settlements on the Cuyaba, cross the lake in canoes and small barks. There are various other lakes of the same description in Paraguay, such as that of Aguaracaty in the 25th degree of latitude; those which are found to the south and north of the lake

Buenos Ayres.

of Ypoa, situated in the 26th degree; that of Neembucu at the 27th; all those which lie on the eastern banks of the Paraguay, besides an infinite number of others of more or less extent, on the banks of all the streams and rivulets which run through the vast plains of this level country.

All those more permanent collections of water, which depend not for their existence on the supply from the periodical rains, are in like manner spread over extensive flats, and they have in consequence little depth. Of this sort, there is a great number, both large and small, scattered throughout different parts of the country. The most considerable are the lakes of Mandiha, situated in 25° 20′ of south latitude, that of Ypacarary, situated in 25° 23′, and the Iberi, to the south of the Parana, between the 20th and 29th parallels. This lake is of an irregular figure, nearly 200 miles in length, but little more than 46 in breadth. It gives rise to three rivers which, issuing from its south-west extremity, fall into the Parana, namely, the St Lucia, Batela, and Corrientes, and also to the river Mirinay, which, taking a south-east course, falls into the river Uruguay. It is shallow, and filled with aquatic plants, which greatly obstruct the access into the interior. The immense expanse of its waters is diversified by several islands, which are covered with wood, and abound in deer and other game. It produces a continual supply of fish, which are remarkably sweet and fresh, and abundance of wild fowl are found on its surface. This lake overflows twice a-year; its environs are fertile and beautiful, and they are enlivened by the flourishing settlements, now called Presidencies, which have been established on its shores.

In the late additions which have been made to the viceroyalty of Buenos Ayres, from the kingdom of Peru, the lake Titiaca, or Chucuito, appears to be included. It is situated between the two Cordilleras of Peru, in the north-western part of the province of Los Charcos, and, being formed by the accumulated waters of the surrounding mountains, which have no outlet, it differs entirely from the lakes which are to be found in the flat parts of the country, being in some parts from 70 to 80 fathoms in depth. It is about 240 miles in circumference, and is navigable for the largest vessels, but is subject to storms, owing to the winds which descend in tremendous gusts from the neighbouring mountains. It is frequented by immense flocks of water-fowl; and its shores are covered with flags and rushes, which serve for many purposes of domestic manufacture. It contains several islands, of which the largest is Titiaca, from which this lake derives its name. The banks are crowded with towns and villages, which are considered the most pleasant residences in the country. Helms, who travelled by this route from Buenos Ayres to Lima, mentions, that, after quitting the banks of the Plata, he did not meet with any country, in the whole course of his journey, so pleasant and picturesque, as that which bordered on this lake. The hills and dales appeared agreeably intermixed with the richest meadows, on which were feeding numerous herds of cattle, mules, horses, and sheep.

Buenos Ayres. Immense Plains called Pampas.

The vast plains of which so great a proportion of this viceroyalty consists are many of them fruitful; and, in the vicinity of the Spanish settlements, where they have been cultivated, they yield abundant crops of excellent corn, and other productions, while others afford pasture for numerous flocks of sheep. From the banks of the Paraguay, immense plains extend westward to the limits of the province of Los Charcos, and to the mountains that rise far to the north. These are in general elevated and dry, though traversed by numerous rivers. They are skirted by extensive and ancient forests, which afford shelter to the wild animals of the country, and they are inhabited by scattered tribes of Indians, who roam over their trackless deserts in a state of savage independence. One continued plain, in like manner, extends from the banks of the Plata to Chili, and to the large rivers of Patagonia. These plains are called the *Pampas*, and they present one uniform expanse of waving grass, uninterrupted either by wood or eminence for about 900 miles. The luxuriant herbage of those fertile districts affords pasture to innumerable herds of cattle, which rove about over a great portion of South America, and which are principally sought after by the Spanish hunters for their hides and tallow. The same circumstance has also favoured the multiplication of wild horses, which are so numerous in the plains, that travellers are often surrounded with them for the space of several weeks; and while they are passing them in troops, at full speed, which frequently happens for hours together, the party are in the greatest danger of being run over and trampled down. Here are also found deer, as well as great abundance of ostriches, armadilloes, wild geese, ducks, partridges, and other game, and towards the frontiers, guanacoes and vicunnas are met with in considerable numbers. These regions are not well watered; for, though the rivers Saladillo, Hueque-Leuvu, and the first Desaguadero, otherwise called Rio Colorado, run through them, the country is traversed by no smaller streams running into those main rivers; so that they hold their solitary course through the arid plains; and no water is to be found, except what is collected in the pools when the rain falls.

Mode of travelling across the Pampas.

This country, though neither inhabited by Indians nor Spaniards, is occasionally traversed by both; by the former in hunting or in predatory excursions, and by the latter in journeying from Mendoza to Buenos Ayres, or in hunting expeditions. There is a route across the *Pampas* to Chili; but no stations have been established for the accommodation or protection of travellers, who are exposed, in consequence, to the attacks of the savage Indians. As there is frequently no beaten track for hundreds of miles, nor any traces by which the road can be discovered, the journey across the level country is often pursued by the compass. In travelling, covered carts are made use of, which are constructed with all the accommodations of a house, having doors to shut, windows on each side, and mattresses laid on the floor, on which the travellers sleep for the greater part of the journey. In general, they begin travelling about two hours before sun-set, and continue all night, until an hour after

sun-rise in the morning. In the course of this journey, the party are exposed to many dangers and inconveniencies. Of these the want of water is the most serious evil. It is always necessary to carry a supply with them, both for themselves and their cattle; but when this fails, they suffer the greatest distress, unless fortunately a shower of rain comes to their relief. The excessive heats during the day are also greatly complained of. Against these the caravan affords no adequate shelter, nor does it protect its inmates against the rains, which often fall in excessive quantities. The inconceivable fury of the westerly winds, which sweep across the *Pampas* without any interruption, presents another obstacle to the progress of the traveller. There is a road established across the country from Buenos Ayres to Lima, which is more frequented than the route to Chili. On this road regular stages were established in the year 1748, post-houses were erected, and relays of horses and carriages were provided, for the accommodation of travellers. It is likewise free from all danger of attacks from the Indian tribes, who, in their predatory incursions, seldom advance so far within the precincts of the Spanish territories; and it is only in the first stages that it is thought necessary to place troops at the different stations for the security of travellers. This was the route pursued by Helms, the German Mineralogist, who has published an account of his journey. In traversing the mountainous districts of the Andes, the party were exposed to the most sudden and dangerous vicissitudes of heat and cold, sometimes oppressed by the scorching heat of the deep valleys through which the road winded, and within the space of a few hours shivering in the regions of everlasting ice and snow.

There is a very large tract of country in the extensive plains of South and North America, of which the soil is saturated with fossil salt. In this viceroyalty the saline plains extend about 600 or 700 miles in length, and 150 in breadth. It has been generally observed, that, in all the country westward of the Paraguay, in all that tract which is comprehended under the denomination of the Chaco, and in the country also to the south of the Plata, from Cape St Anthony on the south to the Rio Vermejo on the north, there is not a single rivulet, lake, or well, which is not of a brackish taste during the heats of summer, when a quick evaporation takes place, or during a long course of dry weather, when no rain falls to correct, by its freshness, the natural saltness of the rivers and springs. All the rivers that flow from the western Andes yield excellent water, until they reach the salt territory, after which their waters are not fit to be drunk until they reach the Parana. Even the great rivers the Pilcomayo and the Vermejo have a brackish taste during the dry season, when their waters are low. The rivers and springs are, however, more impregnated with salt in some parts than in others. The fort of Melincue, which is situated about 33° 44′ S. lat. and about 150 miles to the north-west of Buenos Ayres, is almost entirely surrounded with salt lakes, which are frequently dry when there is a scarcity of rain. Azara mentions that, arriving in this quarter in the month of March, he found the surface of the ground, for about a league across, covered to the depth of four inches with Epsom salt.

Buenos Ayres.

Salt Lakes.

To the south-west of Buenos Ayres, about 130 leagues, there is a salt lake always filled with excellent common salt, which is preferred to that of Europe on account of its being entirely free from a slight tincture of bitterness, always supposed, in these countries, to adhere to European salt. In the neighbourhood, at the distance of from 400 to 450 miles, there is an abundance of salt lakes, which produce very fine crystalline-grained salt. These lakes are large and broad. Some of them are surrounded by woods to a considerable distance; and their banks are white with salt, which needs no other preparation than an exposure for some time to the heat of the sun. Journeys are undertaken from Buenos Ayres to this part of the country, for the purpose of procuring salt, and from 200 to 300 carts are annually loaded with it for the supply of this city. Numerous salt-lakes of the same description occur in the neighbourhood of the river Vermejo, and in the Chaco to the west of the Paraguay. At the city of Assumption, situated on the Paraguay, in latitude 24° 47′ south, and longitude 59° 35′ west, a considerable quantity of salt is refined from the earth. Between Santa Fe and Cordova, a still greater quantity is produced, and this quality of the soil reaches to St Jago del Estero, where the whole ground is covered with a white incrustation of salt, and even quite across the barren and desert plain which extends westward to the foot of the Cordillera.

Saltpetre.

Natural saltpetre is also produced in this country in great abundance. After a shower of rain the ground appears white with it, so as to chill the feet excessively. A small quantity, however, is only collected, no more than is sufficient to manufacture fire works for the amusement of the converted Indians, at the religious festivals of the Romish church.

In this country, as in Brasil, and other parts of America, the cattle are accustomed to receive salt as part of their nourishment. In the province of Paraguay, they eat a sort of salted clay which they find in the ditches, and when this fails, which sometimes happens in the eastern cantons of this province, and in the missions on the banks of the Uruguay, numbers of cattle perish in the space of a few months. It is incredible with what avidity they feed upon this singular nutriment, and when they have wanted it for some time, no inducement, not even blows, will tempt them to quit the place where they have found it.

Mountains.

The western parts of this viceroyalty, more especially the provinces which were added from Peru, are generally mountainous, comprehending within their limits some of the highest ridges of the Andes. The province of Los Charcos includes a considerable proportion of the two principal chains that run from north to south along the eastern part of Peru, and between which lie the elevated plains of Cuzco, with the districts of Los Charcos, rugged and barren, but rich in mineral treasures. From the great chain of the Andes, branches diverge in different parts, and extend far into the interior. Of these, the mountains of Cordova and Achala, in the province

of Tucuman, and those of the more westerly province of Cuyo, form secondary ridges; and another ridge of this nature branches off in the latitude of the great river Colorado, which, under the Indian appellation of Casuhati, runs nearly across to the Atlantic. These southern mountains are covered with thick impenetrable woods, and are little known. The eastern mountains, which form the Brasilian ridge, are also of secondary elevation. They are generally covered with thick forests, interspersed with extensive tracts wholly devoid of vegetation. They form a cluster of mountains towards the interior provinces of Minas Geraes and Matto Grosso, by which the tributary streams of the great river of the Amazons are divided from those which run south into the Plata. Different ridges diverge from them to the north and south, and the main chain extends quite across the Continent, taking a north-westerly direction towards Santa Cruz, de la Sierra, and Potosi, and thus uniting with the great ridges of the western Cordillera. In this mountainous district, the summits of the Andes rise above the regions of the clouds, and are covered with eternal snows. In the lower parts of the mountain, where the snow is only occasional, sterile tracts of sandy deserts appear, which are bordered with various kinds of lichen that grow in crevices. To this imperfect vegetation succeeds a wiry kind of grass or rush, the natural food of the guanacos and the vicunnas which haunt those upland deserts. The mountains of secondary elevation are covered with stately forests, and the embosomed vales which are interspersed amongst them, though frequently of a higher elevation than the summits of the Pyrenees, enjoy from their sheltered situation a temperate and favourable climate, which adapts them to the production, in great abundance, of all sorts of European fruits and grain. In many of those valleys, apples, peaches, cherries, plumbs, grow to great perfection. Wheat is cultivated with success, and there are extensive natural pastures, which afford herbage for large herds of cattle and flocks of sheep.

Productions.

In the lower districts of the country, and in the plains, wheat, maize, cocoa, grapes, oranges, citrons, figs, olives, and sugar-canes, are among the most common productions; and the herb paraguay, or matté, which furnishes the favourite beverage of all ranks, with the exception of the European Spaniards, is yielded in great abundance. This herb, which is called the tea of Paraguay, is drunk as an infusion, and the Creoles are so passionately fond of it, that they never travel without a supply of this favourite refreshment. About 100,000 arrobas of this plant, of 25 lbs. each, are annually exported from Paraguay to Peru. The value of each arroba is estimated at L.1, 3s. 4d. Sterling, which makes the annual value of this merchandize sent to Peru equal to L.116,666. There are, besides, great quantities sent to Buenos Ayres from the city of Assumption, of which this herb constitutes one of the principal articles of export.

Roads and Bridges.

The route from Buenos Ayres to Potosi, which is 1617 geographical miles, and from Potosi to Lima, which is an additional 1215 miles, passes over the highest ridge of the Andes, and, according to the account of Helms, who crossed the continent by it to Lima, the traveller who undertakes so arduous a journey must expect to meet with every sort of privation and hardship; not only from being exposed to the utmost extremes both of heat and cold, but from the rugged and impracticable nature of the country through which he has to pass. It is only during the summer that the passage across the Andes can be attempted, and as this is the season when the mountain snows begin to melt, the streams which rush down the declivities of the Cordilleras are swelled to impetuous torrents. And this often happens so suddenly, that the unfortunate traveller has no time to escape from the fury of the stream, but is swept down with his mule, and perishes miserably amid the precipices and dark abysses through which the foaming waters take their rapid course. To facilitate the passage across those rivers, wooden bridges are frequently constructed, of sufficient breadth to admit the passage of a traveller on horseback; but where the river is too broad for the construction of those bridges, other bridges are thrown over of a slighter construction. These are formed of a thin elastic cane, called *bijuco*, and from thence they have received the name of bijuco bridges. Several of these canes are twisted together so as to form a large cable of the length required. Six of these being stretched from one side of the river to the other, two of which are considerably higher than the other four, sticks are laid in a transverse direction over the lower four, and over these branches of trees. The two uppermost ropes are fastened to the others that are lower, so as to serve as rails for the security of the passengers, who would otherwise be in no small danger from the continual oscillation. These bridges are only for men, the mules being taught to swim across the rivers. But where the rapidity of the torrent, and the large stones which it continually rolls down, render it impracticable for mules, a contrivance is adopted for passing them safely across, named a *tarabita*. This consists of two ropes made of bijuco, or of thongs of an ox-hide twisted together to a proper thickness. These ropes, being extended across the river, are fastened on each bank to strong posts, and the animal being slung in a sort of leathern hammock which depends from the ropes, and properly secured by girths round the belly, neck, and legs, is drawn to the opposite shore by means of ropes fastened to the hammock and extending to both sides of the river. For the carrying over men or baggage only one rope is required, and on one side is a winch or wheel by which it may be either tightened or slackened as circumstances may require.

Climate.

In those upper regions heat and cold depend, it is well known, not so much on the geographical position of any particular place, as on its height above the level of the sea. In South America, accordingly, which is distinguished above all other countries by the prodigious elevation of its soil, we find everlasting ice and snow under the rays of a tropical sun; and throughout the whole tract of this elevated country the climate is uniformly modified by the height of the land. In the low country, on the other hand, the distance from the equator fixes the climate; and the extensive and unsheltered plains are ex-

posed to the most scorching heats, more especially those towards the south. At Assumption, the capital of Paraguay, which is situated in 25° 16′ 40″ of south latitude, it is stated by Azara that, in ordinary summer weather, Fahrenheit's thermometer rose, within doors, to 85 degrees; and that, during the greatest heat of the season, it rose so high as 100. During the winter, in weather which would have been called cold, it fell to 45; but in seasons when the cold was unusually severe, such as in the years 1786 and 1789, the water was found frozen in a court adjoining his house. The nature of the weather depends, in a great measure, on the prevailing winds. It is generally remarked, that a south or south-east wind brings cold weather, and that the weather is hot when the wind blows from the north. This last is the most prevailing wind, the southerly wind not blowing, at the most, for more than a twelfth part of the year. The west wind is scarcely ever known, and, if it is sometimes felt, it scarcely continues for two hours together.

At Buenos Ayres, which is situated in south latitude 34° 35′, the weather is, of course, colder than at Assumption; and it is considered as an ordinary winter in which there are only three or four days when water is slightly frozen. Here, and on the coast, the winds are greatly more violent than in the interior. The west winds, which have been already noticed, are more frequent; and those from the south-east, while they always bring rain in winter, are accompanied with clear weather in summer. The violent winds, which prevail both in summer and spring, raise clouds of dust which penetrate into all the apartments of the houses, and greatly incommode the inhabitants. Hurricanes are rare; but they sometimes occur. In the year 1799, the settlement of Atira in Paraguay was thrown down by one of them; thirty-six persons were killed, many carriages were blown away, and various other destructive consequences were experienced. The atmosphere is everywhere filled with moisture, by which the furniture of the houses is injured. At Buenos Ayres, all the apartments which have a southern exposure have the floors continually damp; the walls are also covered with moss, and the roofs with a sort of bushy grass, three feet in height, which must be cleared away every two or three years, to prevent the moisture from sinking down into the house. This moisture of the atmosphere does not appear to be in the least degree prejudicial to the health of the inhabitants. In no country is thunder and lightning more violent. The peals of thunder succeed each other with such rapidity, that there seems hardly an instant between them, and the whole heavens appear as if they were illuminated with one flame. These thunder-storms are frequently fatal to individuals; and in one of them, which happened in January 1793, the lightning struck the town of Buenos Ayres in thirty-seven places, and killed nineteen persons.

The precious metals, which form such an important article of commerce in this viceroyalty, are entirely derived from the western provinces, which lie on the eastern declivity of the Cordillera, and which, in 1778, were separated from Peru. The following enumeration of the mines presently worked was extracted by Helms from the records of the chancery.

Silver Mines of Potosi.

An account of the accidental discovery of the rich mines of Potosi will be found in the *Encyclopædia* under the article PERU. In 1545, the first mine was formally registered. Another was discovered some days afterwards. A third, surpassing the two others in wealth, was distinguished by the name of Rica, which, with a fourth, were soon worked with great activity. The mountain, which at the base is 18 miles in circumference, is pierced everywhere by the operations of the miners. According to Helms, who visited Potosi in 1789, above three hundred pits were at that time worked; but those who directed these works seemed totally ignorant of the first principles of mining. Few of them penetrated to a greater depth than 70 yards, and they were all of them worked as irregularly, as if it had been merely for plunder. Many of the pits were inundated with water; to free them from which, a main conduit had been begun in 1778, which, in the course of nine years, had, at an incredible expence, been carried two miles in length. But so unskilfully had this important work been planned, that even at its mouth the conduit was above the level of the water in many of the mines, after which it rose about one yard in every thirty-two, which rendered it still more inefficacious. Eight new veins were intersected by this conduit, some of them containing very rich silver ores. Another conduit was inspected by Helms and the other German Mineralogists who accompanied him, which was begun about 100 years before, and which led to many rich veins of red and grey silver ore. For want of proper machinery, however, all the pits were filled with water; though, under better management, they might have been

Buenos Ayres.

made to yield a considerable revenue to their proprietors.

The one from which silver is extracted is various in its nature, consistency, and colour. The mountain of Potosi consists chiefly of a yellow, very firm argillaceous slate, full of veins of ferruginous quartz, in which silver ore, and sometimes brittle vitreous ore, are found interspersed. There is also a greyish brown one, in which appear some small grains, and thin branches or veins of silver, running along the layers of stone. This ore is extremely rich, yielding for each caxon, or 50 hundred weight, 20 marcs of silver or about 13 lbs. Some of the ores which are found in other provinces of this viceroyalty appear black, frequently from the admixture of lead. The silver is seen when the ore is scratched. These ores are called *negrillos*, from their colour, and are esteemed very rich, yielding 50 or 60 marcs of silver *per* caxon. They are more valued also on another account, namely, that the silver is extracted from them at a small charge. In place of the usual process of amalgamation with quicksilver, they are merely melted in furnaces, where the lead, being evaporated by the fire, the silver is left pure and clean. There is another sort of rich ore, containing a large proportion of the finest silver, which turns red if it is weted and rubbed against iron. Some of the ores glitter like talc. These yield but little silver; but, being soft, the metal is easily extracted from them. Some are green, from the admixture of copper, which it is found troublesome to separate from the silver. But the most scarce and valuable ore is that which appears in entangled threads of pure silver, so fine that it is called *arana*, from its resemblance to a spider's web.

The veins of silver frequently run through hard rocks, which have to be reduced to a very fine powder before the ore can be fit for the process of amalgamation. In order to render the ore more friable, it is frequently roasted or calcined in an oven. It is afterwards broke to pieces with iron mallets, after which it is carried to the mills, where, being ground to a very fine powder, it is passed through several wire sieves successively, the last being the finest. The rude ores are also frequently broke to pieces by hammers lifted up and down by means of a wheel. These hammers weigh about 200 pounds, and fall with sufficient violence to reduce the hardest stones to powder. This powder is laid in wooden troughs, and is kneaded with quicksilver and water, until the two metals are completely amalgamated, after which the quicksilver is evaporated by distillation, and the metal which remains is cast into ingots.

In some of the smaller rivers, mills with grindstones are used. The ore is ground with water, which makes a liquid mud, that runs into a receiver. The mud is disposed on the floor in square parcels about a foot thick, each of them containing 25 hundred weight of ore. On each of these about 200 weight of sea-salt is thrown, which is moulded and incorporated with the earth for two or three days. After this the quantity of quicksilver which they judge necessary is added to the mass, which is moulded eight times a day, and lime is frequently mixed with it, to accelerate the process of amalgamation. In the elevated and cold regions of Potosi and Lipes, this operation requires a month or six weeks before it is completed. But, in warmer districts, it is finished in eight or ten days.

Low state of the Art of Mining.

The manner in which these and all the other operations are performed, by which the precious metals are extracted from the earth, and afterwards separated from their ores, is censured, in the most unqualified terms, by Helms. After pointing out the ignorance which prevailed in the previous management of the mines, "still greater, if possible (he observes), was the ignorance of the Directors of smelting-houses and refining works at Potosi. By their method of amalgamation they were scarcely able to gain two-thirds of the silver contained in the rude ores; and for every marc of pure silver gained, they destroyed one, and frequently two marcs of quicksilver. Indeed, all the operations at the mines of Potosi, the stamping, sifting, washing, quickening, and roasting the ore, are conducted in so slovenly, wasteful, and unscientific a manner, that, to compare the excellent method of amalgamation invented by Baron Born, and practised in Europe, with the barbarous process used by these Indians and Spaniards, would be an insult to the understanding of my readers."

"The tools of the Indian miner (he continues) are very badly contrived and unwieldy. The hammer, which is a square piece of lead of 20 pounds weight, exhausts his strength,—the iron, a foot and a half long, is a great deal too incommodious, and, in some narrow places, cannot be made use of. The thick tallow candles, wound round with wool, vitiate the air."

The same mismanagement prevailed in the Royal Mint, where every hundred weight of refined copper used for alloy in the gold and silver coin cost the King L. 35 through the ignorance of the overseers, who spent a whole month in roasting and calcining it, and in the course of these tedious operations frequently made it unfit for the purpose to which it was intended. Mr Helms was ordered by the Governor to introduce a more improved process for the refining of the copper, and he accordingly showed, by actual experiment, that copper could be brought to a greater degree of fineness in four hours and a half, and at less than $\frac{1}{20}$th of the expence. The other evils in the management of the mines, he also attempted to reform, in conjunction with another person of skill in the mining art, who accompanied him to South America for the same purpose. In order to free the mines from water, two deep conduits were dug in the mountains; proper machines were erected; amalgamation works were set on foot, and the necessary instructions in metallurgy were given to six pupils, for the purpose of enabling them to reduce this improved system to practice. If the water in the pits can be drained, the mines of Potosi would be in as flourishing a condition as ever. The total want of timber, however, on the naked ridge of mountains in which those mines are situated, tends greatly to retard the progress of the work.

Produce of the Silver Mines.

Respecting the quantity of silver which has been extracted from the mines of Potosi, various accounts have been published. But these have generally been founded on imperfect materials, and their accuracy is therefore liable to doubt. On this point,

Humboldt's invaluable work on the kingdom of New Spain, contains the most complete and satisfactory information. This celebrated traveller was enabled to procure, from official papers, an account of the value of the royal duties paid into the provincial treasury of Potosi, on all the silver brought to the mint between the years 1556 and 1789; and the proportion of those duties to the whole produce being known, the annual amount of the silver extracted from the mines, during this period, with the exception of what was carried away by the contraband traders, can be easily ascertained from these accounts. From the year 1545 to 1556, there are no records of the royal duty, and Humboldt has supplied this defect from such imperfect and accidental information as he could collect in the works of the earlier writers on South America. Ulloa, who proceeds upon the authority of a writer in the 17th century, estimates the silver produced, during those eleven years, when the official records are wanting, to 72,000,000 of marcs, equal to about L. 144,000,000 Sterling. But, according to the more accurate reckonings of Humboldt, this estimate must be greatly above the truth; and he conjectures that the whole produce during this period, cannot have exceeded 15,000,000 of marcs or 127,500,000 piastres, equal, valuing the piastre at 4s. 2½d. to L. 26,328,125 Sterling. He states, however, that little reliance can be placed on the correctness of this estimate.

From the year 1556 to the year 1578, a duty of one-fifth was paid on all the silver brought to the mint of Potosi. These duties amounted, during this period of twenty-three years, to 9,801,906 piastres, which gives a total produce for these twenty-three years, of 49,009,530 piastres, or 5,765,827 marcs of silver, equal to L. 10,312,431.

From the year 1579 to the year 1736, including a period of 158 years, a duty of 1½ *per cent.* was paid, and afterwards the fifth of the remaining 98½ piastres, which amounted to nearly 6½ *per cent.* The produce of this duty for 158 years amounted to 129,417,273 piastres, which gives a total produce of about 610,458,835 piastres, or 71,818,686 marcs, and an annual average produce of 3,888,272 piastres, or of 455,991 marcs, in value equal to something more than L. 8,000,000 Sterling.

From the year 1736 to 1789, 1½ *per cent.* of duty, and the half of the fifth were paid, and, during this period of fifty-three years, the duties amounted to 14,542,684 piastres. The whole produce amounted consequently to 128,129,374 piastres, or 15,074,044 marcs of silver, and the annual average produce to about 281,758 marcs, equal to about L. 490,000.

From 1789 to 1803, there is no account of the royal duties. But, according to the records of the mint, the produce amounted to 46,000,000 of piastres, or to 3,285,710 piastres *per annum.* Helms, who visited Potosi in 1789, states that there were annually coined in the royal mint from 550,000 to 600,000 marcs of silver, and about 2000 marcs in gold.

According to these calculations, the quantity of silver yielded by the mines of Potosi, amounts

	Piastres.	L.
For 11 years, from 1545 to 1556, to - -	127,500,000	26,828,125
For 23 years, from 1556 to 1578, to -	49,009,530	10,312,431
For 158 years, from 1579 to 1736, to -	610,458,835	128,450,713
For 53 years, from 1736 to 1789, to	128,129,374	26,960,554
From 1789 to 1803, to	46,000,000	9,679,166
In this account the piastre is estimated at eight reals, or 4s. 2½d. Previous to the year 1600, it contained 13½ reals de Plata. For this add two-thirds to the produce of these years, about - -	250,000,000	52,604,166
The allowance for contraband is variously estimated at a third, a fourth, and a sixth. Estimating it at one-fourth, it will amount to - -	302,774,434	63,708,780
	1,211,097,739	254,835,155
Add for contraband, one-fourth, .	302,774,434	63,708,780
Total produce, -	1,513,872,173	318,543,935

From this estimate of the produce of these mines, it will be found that they were never more flourishing during the whole period of 233 years, from 1556 to 1789, than from 1585 to 1606. For several successive years, the royal fifth amounted to one and a half million of piastres, which supposes an annual produce of 1,490,000, or 882,000 marcs, according as the piastre of silver is estimated at 13½ or 8 reals.* This is the more surprising, as at this period more than a third of the silver was never registered. Adding this one-third to the annual produce calculated from the royal fifth, the quantity of silver produced at this time, will amount to 10,000,000 of piastres, equal to L. 2,104,166. After the year 1606, the produce began gradually to diminish, although from this time to 1688, it never was below 350,000 marcs *per annum.* From the commencement of the subsequent century, the produce continued decreasing, and from the year 1736, when the royal fifth only amounted to 85,410 piastres till about the year 1748, the annual amount of the duties was never equal to 200,000 piastres. After this period, the produce began to increase, and gradually rose to between 300,000 or 400,000 marcs. This quantity, however, Helms, who had the best opportunities of information, assures his

* This coin, towards the conclusion of the sixteenth century, was reduced to the value of eight reals; and as it is uncertain when this change took place, we cannot exactly ascertain the quantity of silver which was produced at this period. We can only be certain of its highest and lowest quantity.

Buenos Ayres.

readers could be doubled, if the mines were drained of the water with which they are overflowed, and if some other simple improvements, which he suggests, were carried into effect.

In 1545, it is mentioned that ores containing from 80 to 90 marcs *per* quintal of 1600 ounces, were common. The marc is nearly equal to about eight ounces; so that, according to this account, 1600 ounces of ore were found to yield about 600 or 700 ounces of silver. The average produce was, at this period, from eight to nine ounces *per* quintal, which was nearly in the proportion of one ounce in twenty-two or twenty-five. Since the commencement of the eighteenth century, it is stated by Humboldt, that they reckon only on extracting from three to four marcs of silver from the caxon of ore, equal to 5000 lbs. which is only one ounce of silver out of every 2000 or 2500 ounces of mineral. According to experiments made by Helms on 300 specimens of ores, they were found to produce from six to eight ounces of silver for every caxon of 5000 lbs.; although in some ores the silver was in the proportion of 20 marcs to each caxon, which is about one in 384.

The minerals of Potosi are consequently extremely poor, and it is owing to their abundance alone, that they still produce so great a quantity of silver. From 1574 to 1789, the mean quantity of silver afforded by the ores has diminished in the proportion of 170 to one, while the silver extracted from the mines has only diminished in the proportion of four to one. It thus appears that the productiveness of mines does not by any means depend so much on the richness or poverty of the minerals which they contain, as on their abundance, and the facility with which they are worked. It happens, accordingly, that the Mexican mines, which are the richest in the world, contain remarkably poor minerals, the best yielding, on an average, from $4\frac{8}{10}$ to $5\frac{3}{10}$; the middling from $1\frac{8}{10}$ to $2\frac{7}{10}$, and the worst about $1\frac{3}{10}$ ounces of silver for every 1600 ounces of ore. In some of the mines of Germany, on the other hand, of which the produce falls so far short of those of South America, the mean proportion of silver is found to amount to 10 ounces *per* quintal, and in fortunate periods to 15.

From 1545 till 1571, the silver minerals of Potosi were all smelted in portable furnaces contrived by the Indians. These were cylindrical tubes of clay, very broad, and pierced with a number of holes, which, admitting the air, gave the flame a great degree of intensity. About the year 1571, the method of amalgamation with mercury was introduced; and of the 8000 or 10,000 quintals produced by the mine of Guancunelica towards the end of the sixteenth century, above 6000 or 7000 quintals were consumed in the works of Potosi. About the year 1763, the consumption amounted to between 16,000 and 17,000 quintals annually. There are at present 2000 miners engaged in the works at Potosi, who are paid at the rate of 25s. *per* day. Fifteen thousand lamas, and an equal number of asses, are employed in carrying the ore from the mountain of Potosi to the amalgamation works.

Gold Mines.

Gold is found in most of the mountainous districts of this viceroyalty. It is either worked in mines, gathered from the sands, or collected from the streams. Near the town of Mojos, there is a considerable stratum of rich magnetical iron sand, in which are found particles of gold of the size of a lentil, and sometimes as heavy as the quarter of a ducat. The Indians, however, by their unskilful mode of working the sand, lose all the finer particles of the gold, which are carried away by the stream. From the town of Mojos to within a short distance of Potosi, from which it is distant 180 miles, similar alluvial layers occur, and gold is washed from them, especially at the little town of St Jago de Cotagoita, which is distant about 90 miles from Potosi. In the province of Lipes there are gold mines, many of which have been abandoned. But two are now worked, and one of copper, the strata of which are intermixed with gold, silver, iron, and loadstone. In Puno and Oruro, there are several gold mines. But most of them have gone to decay from the inactivity of the inhabitants, or they have been overflowed, and all efforts to drain them have been found unavailing. The most abundant mines are in the province of Cochabamba and Sicasica. The whole of the mountains in this last district, where the Indians collect ore by working, abound in rich gold ore, and when, about a hundred years ago, a projecting part fell down, lumps of pure gold, weighing from two to fifty pounds, were severed from the stone; and, even in the present times, in the layers of sand washed from the mountain by the rain water, pieces of pure gold are found, some of which weigh an ounce. From the ignorance of the inhabitants, however, most of these treasures lie totally neglected.

Animals.

A very brief and general account of the animals of this country, is all that can be attempted within our present limits. The horses and horned cattle, originally imported from Europe, have multiplied amazingly in the extensive plains of South America. Asses, mules, European sheep, stags of different species, foxes, rabbits, goats, and hogs, are numerous, and great numbers of wild dogs are to be met with. These are descended from those of a domestic kind that have left their masters in pursuit of the game, with which the country everywhere abounds. The other wild animals are the puma or American lion, the jaguar and cougar, two species of American tigers, which are strong and ferocious animals, and commit great devastations among the flocks. The jaguar, when full grown, is a large animal, some of them measuring five feet from the nose to the root of the tail, which is two additional feet long, and so strong that they will drag the carcase of a horse or bull which they have killed to the place where they intend to devour it. They are excellent swimmers, and Azara mentions, that he has seen them swimming across a large river loaded with their prey. The Puma is a weak and cowardly animal, and is now become very scarce in the parts inhabited by the Spaniards. The guazuara, called the cougar by Buffon, is 47 inches long, without including the tail, which is 26 inches long. It flies from the human species, but kills calves, sheep, pigeons, and all other smaller animals. It does not stop to eat the flesh, but is contented with licking the blood. Of the other animals, the most remarkable are the anta or danta, which is between the elk and buffalo

species. It is of the size of a large ass, has no horns, and is of singular strength. It is frequently found in the forests and plains of Paraguay, but has been so much hunted both for its skin and flesh, that it is scarce both in Tucuman and Buenos Ayres. The armadillos are very numerous all over South America, and are of various species, differing in size, and in the nature of the armature with which they are covered. The tamandua, or nurumi, or ant-eater, is $53\frac{1}{2}$ inches long, without reckoning the tail, which is in length $22\frac{1}{2}$ inches, besides a thick bunch of hair at its end, 11 inches long. Azara enumerates various other small animals, which are generally carnivorous, preying upon birds, reptiles, or other inferior quadrupeds. The chibi-guazu, which he considers to be the jaguar of New Spain, or the tiger-cat of other countries, is 34 inches, and the tail 13 inches. Wild cats are found of various sorts. There are also several animals which have the form of the martin, the pole-cat, and the ferret, but which are much larger and stronger. The sarigue or the fecundo, is a small animal peculiar to America, which preys upon pigeons, mice, insects, eggs, &c. It has a long triangular and pointed face; its eyes are oblique and jutting out. Its mouth is large, and well furnished with teeth. Its tail is long, thick, and covered with scales, which it uses to climb up trees and walls when the surface is in any degree rough. It has long whiskers, and its ears are round, naked, and transparent.

Of the domestic animals, those most worthy of note are the lama and the paco, both natives of the mountainous parts of Peru, and inhabiting the higher districts of the Tucuman, and the provinces of Los Charcos, and Santa Cruz de la Sierra. The lama is a most useful animal, and is capable of carrying heavy burdens in the most rugged and dangerous roads. It is about four feet high; the body, including the neck, is five or six feet long. This animal bears a great resemblance to a camel, excepting that it has no hunch on its back. The paco, or vicunna, is a species of subordinate animal to the lama, in the same manner as the ass to the horse. Their wool is fine and long, and is a valuable article of merchandise. The natural colour of it is that of a dried rose-leaf; and while every kind of clothing manufactured of it possesses a peculiar degree of genial warmth, it is at the same time most beautifully silky and light. The lama and the paco inhabit the highest mountain-deserts amid perpetual ice and snow; and the cold, far from being unfavourable to them, seems to invigorate and refresh them. The tapir, though more abundant in Brasil, is also found on the banks of the Parana and Paraguay. It is of the size of a small cow, but has neither horns nor tail.

Of birds, the emu, which is generally known by the name of the American ostrich, and the well-known bird of prey the condor, are the most remarkable. The emu is bred in the *Pampas*. It is generally six feet high, measuring from the head to the feet; and it runs with such swiftness that the fleetest dogs are thrown out in the pursuit. Carrion vultures, which fly in large flocks, are also very common, and feed upon numerous carcases of the cattle slaughtered for the sake of their hides.

Fish.

The rivers abound in great varieties of fish; and of amphibious animals, there are on the coast turtles, seals, and sea-lions; while alligators or caymans, of a large size, and very voracious, swarm in all the rivers. The interior of the country is infested by innumerable tribes of reptiles and insects, which are brought into life in the damp forests, and on the rank soil on the borders of rivers. Serpents also abound in these parts, among which the most remarkable is the enormous boa constrictor, which is chiefly found in the marshy places of the forests.

Commerce.

In regulating the colonial trade, Spain has uniformly proceeded upon the principle of sacrificing the colony for the supposed advantage of the mother country; and, with this view, such restraints were imposed on the commerce of her South American provinces, as forced them to depend entirely on the parent state, both for the supply of their wants, and for the sale of their produce. They were not only entirely debarred from trading with Europe, or with any other country, in their own vessels, but their intercourse with each other was either entirely prohibited or obstructed by many severe restrictions. Under this system, the commerce of Spain with her colonies centered entirely in the port of Seville; and the cargo of every ship destined for the colonies was inspected by a board appointed for the purpose, before she could receive a licence to make the voyage. In 1720 this commerce was transferred to Cadiz, as being a more convenient port; and the commerce was carried on by means of annual fleets, which sailed periodically, and which consisted of two squadrons, known under the respective appellations of the galleons and the flota. These expeditions were made exclusively to the Gulf of Mexico; and it was through the ports of Porto-Bello and Vera Cruz alone that the colonies of Spain were either supplied with European commodities or found a vent for their own productions. Owing to this limited intercourse, the produce of America was exchanged for that of Europe on terms extremely disadvantageous. Her markets were always imperfectly supplied with the commodities of Europe, which bore, in consequence, a very high price; while her own productions, being restricted to particular ports, were always liable to arrive at a market already overstocked. The Spanish colonies languished under those harassing restrictions; and Buenos Ayres, whose territorial resources consisted neither in gold, silver, indigo, cochineal, nor in any of those precious products which are easily exported, but in bulky and perishable commodities requiring the constant command of shipping, remained for a long time in a state of obscurity and depression.

But the operation of this system was eventually counteracted by its extreme violence and injustice; in consequence of which it was found impossible, in cases where it prohibited the colonies from being supplied with articles of the first necessity, to carry it into strict execution. Salutary evasions were, therefore, connived at, and, in process of time, a contraband trade was established, which was found so beneficial, that it flourished in spite of all the expedients adopted to prevent it. The legitimate

Buenos Ayres.

commerce was proportionably diminished, and the annual squadron gradually dwindled away from 15,000 to 2000 tons of shipping.

Those encroachments on the monopoly of the colonial trade plainly suggested the necessity of relaxing the restraints by which the colonies were oppressed, and of devising some method for ensuring to them a constant and adequate supply of European produce. In the year 1740, a considerable part of the American trade was permitted to be carried on by register ships, which, on purchasing a licence from the Council of the Indies, were allowed to sail at any time, and which, in the year 1748, finally superseded the galleons and flota, after they had been in use for two centuries. By means of this intercourse, the American market was more regularly supplied with the productions of Europe, and Buenos Ayres was benefited, along with the other colonies, by these regulations.

Other relaxations of the system of restraint soon followed. In 1774, a free intercourse was opened between several of the American provinces; and, in 1778, seven of the principal Spanish ports, to which, in 1788, five others were added, were permitted to engage in a free trade with Buenos Ayres, and with the ports of the South Sea. These regulations, together with the erection of Buenos Ayres into an independent viceroyalty in 1778, gave it importance and stability; and, from this period, its imports and exports have progressively increased. Previous to the year 1778, not more than 12 or 15 registered vessels were engaged in the colonial trade of South America, and these seldom performed more than one voyage in three years. But, in that year, their number increased to 170 vessels, the value of whose cargoes amounted to L.1,958,676. For the further encouragement of the trade of Buenos Ayres, salted meat and tallow were allowed, in the year 1793, to be exported duty-free; and, by this and other regulations, the trade and population of the adjacent provinces was considerably increased. Azara gives the following annual average estimate of the trade and shipping of Buenos Ayres, taking the average of the years between 1792 and 1796.

Effects of the War with England on Commerce.

In the year 1797, hostilities commenced between Spain and Great Britain; and, in consequence of this event, the trade between the mother country and her South American colonies was necessarily exposed to the maritime hostility of Britain. So effectually was this hostility carried on by the British cruisers, that, in 1798, the trade of the Spanish settlements was at a stand; and it was calculated that above three millions of hides were lying at the warehouses of Buenos Ayres and Monte Video, for which no vent could be found. European goods were totally wanting, or had risen to excessive prices. Linen was not to be had, and the cotton stuffs of the country, or those which came from Peru, were substituted in lieu of it, and for brandy and Spanish wines, those of Cuyo were used. This stagnation of trade was at length relieved by the intervention of the neutral vessels of the Americans, which brought European goods to the colonies, and took away their surplus produce in return; and this contraband intercourse was found so indispensable to the trade of those countries, that it was either connived at or openly encouraged.

Interior Commerce.

A very extensive trade is carried on between the lower and upper provinces of this viceroyalty, and also with Peru and Chili. The herb of Paraguay, known by the name of Paraguay tea, and the cattle and mules of the provinces of Buenos Ayres and Tucuman, form the staples of this commerce. The herb of Paraguay is in such demand, that the crop on the ground is generally sold before it is gathered. The quantity exported to Peru is estimated at 2,500,000 libs., and about 1,000,000 of libs. are annually sent to Chili. The remainder is consumed in Paraguay, Tucuman, and the other provinces. There is a continual demand for mules in Peru and Potosi to carry on the work of the mines; and it is calculated that about 60,000 of these animals are annually purchased for Peru and Potosi at the price of between three and four piastres a-head. These are driven into the interior by easy journeys to Salta, where they are taken great care of during the winter, and when in good condition, they are conducted to Potosi, where they sell for eight, nine, or ten piastres a-head; and such as are carried to Peru sell for higher prices, some for 40 and even 50 piastres. Peru and Potosi, and the mountainous districts where the mines are situated, are also supplied with large droves of cattle from the provinces of Buenos Ayres and Tucuman. These are either caught wild, or they are purchased from the immense pasture lands which extend over a great part of the province of Buenos Ayres, and are conveyed by easy journeys into the interior. A great trade is also carried on, more especially when the usual intercourse with Europe is interrupted by war, between Peru and Potosi, and the other provinces which were annexed to Buenos Ayres in the year 1778. These provinces being the principal mining countries, are on this account populous, while, owing to their elevated situation, the climate is bleak, and the soil barren. Supplies therefore, both of subsistence and of manufactures, must be drawn from more fertile regions; and the trade in question consists accordingly in exchanging the produce of the adjoining provinces for the precious metals which form the great staple of the mining districts. Peru, Chili, and the provinces to the east, receive from the mining countries supplies of gold and silver, in exchange for which they send maize, wheat-flour, cotton, oil, pimento, sugar, hides, wax, soap, tallow, &c. baize, woollen manufactures, and articles for the use of the mines, &c.

Population.

Estalla, the compiler of a voluminous collection, which contains much valuable information on South America, called *Viagero Universal*, estimates the population of this viceroyalty at 1,000,000 of Spaniards and Creoles, besides Indians. He estimates the population of the city of Buenos Ayres at about 40,000, of whom one half are whites or Spaniards. Though reckoned the capital of the viceroyalty, it is not so populous as Potosi, which, according to Helms, contains a population of 100,000; an amount which so greatly exceeds all preceding accounts, as to render the accuracy of his information extremely doubtful. M. Humboldt, in his general table of the population of South America, which, however, he does not give as pretending to accuracy, estimates the Spanish and Creole population of this viceroyalty at 1,100,000; which exceeds Estalla's estimate by 100,000. Azara states the population of the province of Paraguay at 97,500, and that of the province of Buenos Ayres at 170,900.

British Expedition.

In 1806, a British squadron, commanded by Sir Home Popham, appeared in the Rio de la Plata, from which a force was landed under the command of Major-General Beresford, for the reduction of Buenos Ayres. Some trifling resistance was offered by the Spaniards; but, in the end, General Beresford entered the town with little opposition. He appears to have been partly indebted for his success to the surprise into which the Spaniards were thrown by this unexpected invasion, for when they had suffi-

ciently recovered from their panic, and had leisure to consider the inconsiderable numbers of their enemies, the British were assailed by such a superiority of force, that they were compelled to yield themselves prisoners of war on the 12th of August, having had possession of the place for about the space of six weeks. In the meantime, reinforcements arrived from the Cape, and Sir Home Popham, having made an unsuccessful attempt on Monte Video, took possession of the fort of Maldonado, at the mouth of the Plata. Additional reinforcements having arrived under the command of Sir Samuel Achmuty, the invaders succeeded at length in taking Monte Video by storm, and they only waited for farther succours to resume the attack of the capital.

The expected reinforcements at length arrived, in May 1807, under General Whitelock, to whom was committed the chief command of the expedition; and, on the 15th June, a farther reinforcement was received under General Crawford. With this force, amounting to 8000 men, it was resolved to attack Buenos Ayres by marching into the town. But no sooner had they entered the place, than they were assailed, from all quarters, with a commanding and superior fire of grape and musketry. The streets were intersected by deep ditches secured by cannon which poured upon the assailants an incessant and destructive fire; while, from the windows and tops of the houses, they were exposed to a galling fire of musketry, to hand-grenades, bricks, and stones. In this unequal contest, about a third of the British army was either killed, wounded, or captured, without any material advantage gained; and, next day, an armistice was concluded, which issued in a convention, by which it was agreed that the British should evacuate the Plata in two months; and that all prisoners taken on both sides should be restored.

Late Revolution. The project of the French Emperor to subdue Spain, for the purpose of establishing his brother Joseph on the throne, gave rise to a spirit of just indignation throughout the South American colonies; and when his successes seemed to pave the way for the subjection of the mother country, their first care was to take effectual measures for the security of their own independence. With this view, in the town of Buenos Ayres, the government of the viceroy was superseded by one of popular appointment; and though the leaders of the revolution still professed allegiance to Ferdinand, it was generally believed that they had secretly resolved to shake off the yoke of Spain. Different views, however, prevailed in other parts of the country. In Monte Video the Regency of Cadiz was recognised; and, in the interior, a counter-revolution was begun under the influence of Liniers and the adherents of the new government in Spain. To suppress this movement, a force was dispatched into the interior, at whose approach the chiefs of the counter-revolution fled, and being pursued and taken, they were barbarously murdered. The opposition to the revolution begun at Monte Video, was of a more formidable character. It was directed by Elio, an officer of marine, who arrived from Spain with the commission of viceroy, and who, not being able to prevail on the Junta of Buenos Ayres to recognise his authority, proceeded to bombard the city and to destroy its commerce. On the other hand, the Junta sent their army against Monte Video, and compelled Elio to take refuge within the walls of the fortress. An armistice was afterwards concluded between the parties; but the subsequent transactions are yet involved in considerable obscurity. We propose to reserve the account of the revolution which has been begun in these colonies, for the Article SOUTH AMERICA; trusting that, before we shall have advanced so far in the course of our work, the cause of independence will have finally triumphed, and that we shall then be able to exhibit a distinct and satisfactory view of its progress, and of its probable results both to America and to Europe.

(o.)

BUKHARA, or BOKHARA, an extensive country in central Asia, situated to the north of the Oxus, which separates it from Khoarism and the kingdom of Caubul. Its principal cities are Bukhara and Samarcand. This ancient seat of the conquerors of Asia is now almost entirely unknown to Europeans. A few particulars, however, respecting its present state, were collected by Mr Elphinstone, during his residence in Caubul.

About the beginning of the sixteenth century, the descendants of Timur were driven from this territory by the Uzbeks, who, crossing the Jaxartes, swept all before them, till they were stopt by the central barrier of mountains. They thus established themselves, and have ever since remained the ruling people in Bukhara, Bulkh, Fergannah, and Khoarism. The Uzbeks belong to the great race of Turk or Toork, which, with the Moguls and Mandshoors, comprises all the people known in Europe under the general appellation of Tartar. The beauty of this race is celebrated by the Persian poets; though, for this admiration, it seems chiefly indebted to the contrast with the hideous deformity of the Mogul aspect. The Uzbeks are generally short and stout. Broad foreheads, high cheek-bones, thin beards, and small eyes, form the national features. Their complexion is clear and ruddy, and their hair generally black. Part of the nation live in houses and part in tents. Of the latter description, Bukhara contains a large proportion, as a great part of the soil is fit only for pasturage. This people have not the remotest idea of travelling on foot; every man keeps a horse or a camel; even the beggar must have an ass to ride upon. Horse-flesh is the favourite food; but can be obtained only in small quantities unless by the rich. Their drink consists chiefly of tea, and koumiss or kimmiss, an intoxicating liquor drawn from mares' milk.

The Uzbeks, having embraced Mahometanism at a time when they probably had few other positive institutions, have adopted its precepts in their fullest

extent. All the details of civil government, and the minutest observances of common life, are regulated by the precepts of the Koran. The King of Bukhara assumes the title of Commander of the Faithful; he spends a great part of the day in teaching the Mahommedan religion, and of the night in prayers and vigils. He reads prayers in his own mosque; and will sometimes perform the funeral service, even for people of low rank.

In Bukhara, and in all the Uzbek countries, the form of government is almost entirely despotic. The country is formed into divisions and subdivisions, which are governed by officers appointed solely by the sovereign. The villages alone have some share in their own administration; but this cannot form any material check on the royal authority. The Uzbeks are brave; they charge with shouts, drawn up in three lines which advance successively to the attack; so that, till the third has given way, they cannot be considered as finally defeated. They make admirable light cavalry from the rapidity of their movements, and from being patient of thirst, hunger, and fatigue, in an extraordinary degree. Their laws of war are entirely barbarous; infidel captives are sold as slaves; and this treatment being unlawful in regard to Mahommedan enemies, these suffer a more cruel fate, and are butchered without mercy. Yet, in the intercourse of private life, they display many laudable qualities. They are honest and sincere; quarrels are rare, and a murder scarcely ever heard of. Their hospitality is such, that Mr Elphinstone considers Bukhara as the country of Asia through which a traveller may pass with the greatest security.

The capital city, called also Bukhara, appears to be very considerable. Its population is said to be equal to that of Peshawer, and, consequently, exceeds a hundred thousand souls. This city contains numerous colleges, supported either by the king, or by private foundations. The sciences exclusively taught, indeed, are those of Mahommedan Theology and Jurisprudence; and, even in these, the fame of this city is inferior to that of Peshawer. Besides these institutions for education, Bukhara contains caravanseries, on a great scale, for the accommodation of trade; and, notwithstanding the rigid attachment of the people to the Mahommedan faith, strangers of every religion experience the most liberal toleration. (B.)

BULKH, or BALK, a kingdom of central Asia, situated on the northern declivity of the immense chain of mountains, commonly called Hindoo Coosh, which separates it from Caubul. It forms thus the intermediate state between that kingdom and Bukhara. Some of its vallies, particularly along the Oxus, are lower, and suffer more from heat, than those of Caubul, on the southern side of the chain. This country was conquered, at the commencement of the sixteenth century, along with Bukhara, by the Uzbeks, who have ever since continued the ruling people. Bulkh was conquered by Nadir Shah; and, notwithstanding several revolutions, has since generally continued in a state of nominal subjection to Caubul. Killich Ally, however, an Uzbek prince, exercises at present an authority almost independent. The king of Caubul does not even draw any tribute from Bulkh; he is content if it serve as a barrier against the northern Uzbek tribes.

The country is chiefly divided into three large provinces,—Bulkh Proper, Khoolloora, and Koondooz. Its government and manners being those common to the Uzbek tribes, have been described under the head of BUKHARA. Killich Ally maintains an army of 12,000 horse; after paying the expence of which, he has a clear revenue of a lack and a half of rupees (about L. 19,000). He is much beloved by his subjects, and affords such effectual protection to trade, that his praises are celebrated by all the caravans which traverse this part of Asia. He seats himself daily in his public apartment, on a carpet, without pillows or cushions. Those of his visitors whom he wishes to honour, are seated by him on the same carpet; while others must be contented with the bare floor. He superintends in person every department of the administration, executes justice with strictness, and is particularly attentive to the regulation of the bazar, or public market.

Bulkh is the ancient Bactria, which, for wealth and power, held a high pre-eminence among the kingdoms of central Asia. The capital was known under the name of Bactra, and seems to have been the grand emporium for the commerce of this part of the world. The Asiatics are impressed with the deepest veneration for its antiquity, and call it commonly "the mother of cities." Immense ruins still attest its ancient grandeur; but the modern Bulkh merely occupies a corner of the circuit enclosed by the ancient walls. The country round, however, is level and fertile, contains a great number of villages, and is watered by artificial canals. Tausk Koorghaun, the capital of Khoolloom, contains 8000 houses, and the capital of Koondooz still exceeds it in magnitude. (B.)

Situation and Extent.

BUNDELCUND, or BANDELKHAND, an extensive district of the province of Allahabad, in Hindostan, between the rivers Cane and Betwah, occupying a superficies of about 11,000 square miles. The south-west frontier lies in about 24° north latitude, and 80° 45′ east longitude, and the territory extends about two degrees further north. In general, the face of this country is mountainous, high, and rocky; its vegetation is scanty, and the inhabitants do not bestow much care on the cultivation of it. The summits of many of the hills, however, are covered with low copses, amidst which there is but little grass interspersed. Other parts of the district exhibit a close jungle; and there are portions, consisting of fertile soil, which are brought under suitable culture.

Diamond Mines.

The most valuable of all fossils, diamonds, have been long found here, particularly near the town of Purna or Pannah. The mines producing them are situated in a range of hills called Bund-Ahill by the natives, extending above twenty miles in length by between two and three in breadth, and are said to be partitioned into twenty-one divisions; but we do not know that the whole belong to Bundelcund. Of these, the mines of Maharajepoor, Rajepoor, Kimmerah, and Guddaseah, contain the finest diamonds; and one dug from the last has been reputed the largest in the world. It was kept in the fort of Cal-

Bundelcund.

linger, among other treasures of Rajah Himmut Bahadur. Several different rajahs are proprietors of the mines, each having the charge of his own, without any interest in the produce of the rest. A superintendent is appointed to inspect the produce, and every diamond when found is registered, valued, and, if the rajah does not chuse to keep it, is offered for sale. When sold, he receives two-thirds of the value. In the reign of the Emperor Ackbar, the mines of Pannah produced to the amount of L.100,000 annually, and were then a considerable source of revenue; but for many years they have not been nearly so profitable, and it appears that about the year 1750, the government did not derive more from them than equivalent to L.50,000 *per annum*. Their present value is not exactly known. According to tradition, the mines were discovered by a fakir or religious mendicant.

Aspect of the country.

The country, at a distance from the mountains, is agreeably diversified with clusters of eminences or small hills, separate from each other, exhibiting a picturesque appearance; and the inhabitants invariably build their villages at the bottom of a hill. They are seldom seen in any other situation, and it is chiefly around the villages that the small quantity of grain raised in the district is cultivated. But Bundelcund not being a fertile country in itself, grain is brought from the banks of the Jumna and the Ganges. Many other commodities are supplied from the Deccan, or middle region of the peninsula, and large herds of bullocks are seen continually passing to the hilly part of the territory. The forests abound with tigers, and the nhil-gau or white-footed antelope, as also the wild boar, which are all hunted by the chief men of the country.

Inhabitants.

The inhabitants, who are called Bondelas, are a brave and warlike people, entertaining high notions of independence, and impatient of constraint or indignity. They act under the full impulse of those violent passions which sway the inhabitants of the east, and lead to catastrophes of a nature unknown to Europeans. An instance occurred not long ago, when the fortress of Adjyghur, besieged by the British troops, was evacuated by the garrison. The removal of the family of the refractory Zemindar who had occasioned hostilities having been directed, his father-in-law was desired to prepare the females of the family for it. Instead of doing so, however, he murdered the whole and their children eight in number, and then put an end to his own existence. But what was still more extraordinary, the perpetration of this horrible deed was apparently with the consent, and without any complaint of the sufferers. The Bondelas are either Bramins or Rajpoots. About Ditteah and Jhansi, they are a stout and handsome race of men, exhibiting an appearance of opulence and content. They commonly go armed with a bow and spear, both of which are of excellent quality; and they know very well how to use them. They testify no apprehension in engaging veteran troops. Owing to the intestine commotions which long pervaded this district, every man carried arms; and many, availing themselves of superior force, attacked and plundered travellers, or levied a contribution from them, on pretence of guarding the passes which they had necessarily to traverse among the hills. Very little of their manners and customs is known. Women occasionally burn themselves along with the bodies of their deceased husbands, according to a remarkable religious principle diffused in the east, which now seems universally on the decline. The inhabitants dwell in towns and villages, of which the latter are much better than most others in India; and they have numerous strong forts, which they are accustomed to take and defend with determined vigour.

Chief Towns.

There are several considerable towns in the district, such as Pannah, Pirna or Purna, where the Rajah resides on account of its proximity to the diamond mines, Chatterpoor, Ditteah, Callinger, Jyghtpoor, Jhansi. Chatterpoor, 30 miles distant from Pannah, and 698 from Calcutta, is extensive, well built, and the houses chiefly consist of stone. Formerly it was in a flourishing condition, a place of great and active commercial transactions, and a kind of depot for goods carried between the Deccan and Mirzapour, which is also in the province of Allahabad, and one of the principal trading towns of Hindostan. The goods were afterwards transported by numerous bullocks and camels to the places of their destination, and so much commerce was conducted here, that, when Chatterpoor preserved its greatest importance, the duties levied amounted to L. 50,000 yearly. It was founded by one of the rajahs of Bundelcund, and occasionally his residence. Ditteah, or Dutteah, is a large town surrounded with a stone wall, and is provided with gates. It extends a mile and a half in length, by nearly as much in breadth, and is populous and well built, the houses being of stone, and covered with tiles. A spacious edifice, with seven cupolas, stands at the north-west extremity, which was the former residence of the Rajahs; but a palace has recently been built for them on an eminence without the town, close to which is a considerable lake. The district of Ditteah was tributary to the Mahrattas, and the Rajah could raise 2000 horse, and as many infantry, esteemed excellent troops. Some years ago, they testified how much they were to be dreaded in an engagement between the veteran forces under M. de Boyne, a famous French General in the Mahratta service, where all the skill and ability of the commander could scarcely preserve the latter from destruction. But among the most important places of Bundelcund is Callinger, the chief town of a subdivision of this district, which seems to have once been an independent government, and now includes ten pergunnahs or circles of villages. It has a fortification built on a lofty rock of great extent, and is deemed impregnable by the natives. The walls are said to be six or seven miles in circuit; 170 pieces of cannon are mounted on them, and a garrison of 5000 men is necessary for their defence. Nevertheless, its natural strength has enabled a smaller number to sustain long sieges; and the earlier invaders of Bundelcund have been compelled to retire after unsuccessful blockades protracted during several years. So lately as the year 1810, the British army, having attempted to take it by storm, was repulsed with great slaughter. However, the garrison of this fortress, probably dreading a repetition of the assault, eva-

Bundelcund.

cuated the place during the night. No fortress can be more secure against the irregular approaches of an Indian army. Here the Rajah kept his military stores and treasure, and it was also the residence of the Europeans in his service. It is twenty or thirty miles from Pannah, and lies in 24° 58′ north latitude. Jhansi is a considerable town, but smaller than Ditteah, commanded by a stone fort on a high hill, in 25° 31′ north latitude, and thirty-two miles distant from Chatterpoor. There is a district dependent on the town, which, from having been seventy or eighty years in the uninterrupted possession of the Peshwa, or Chief of the Mahrattas, is in a more tranquil state, and better cultivated than most of the neighbouring territories which have undergone frequent changes. Hence it is frequented by caravans from various commercial towns of India; and its wealth is augmented by a trade in cloths, and the manufacture of carpets, bows, arrows, and spears, the principal arms of the Bondela tribes. In the year 1790, it afforded a revenue of about L. 50,000 annually. There is an ancient city called Ouncha, but now in decay, whose Rajah was formerly the head of all the tribes of Bundelcund, and from whom their chiefs received tokens of their investiture. A castle which stands here, or in the neighbourhood, resembles a gothic building, and is said to have been erected by a Rajah of old, who in one day gave orders for building fifty-two forts. This may account for the places of strength seen in Bundelcund, for which the particular character of its surface is extremely favourable.

Besides these, there are several towns, villages, and fortifications of consequence in this district, but recent events have rendered the preservation of the latter of less importance to their owners.

History.

Bundelcund from ancient times has been divided into many petty territories, whose chiefs have incessantly disturbed the peace of their subjects by predatory incursions on each other. The successful captures of strongholds in the mountains, was an encouragement to the subsistence of warfare; and in addition to the numerous ordinary sources of dispute, it is not unlikely that their joint interests in the diamond mines contributed to excite dissension. Though the predominance of power induced some one of the contending parties to claim the superiority, it was reluctantly acknowledged by the rest; whence, instead of a common bond of union to defend the country, it was weakened by the distractions of the whole. The Rajahs of Callinger are mentioned by Mahometan writers so early as the year 1008, but it does not appear to have been incorporated with Bundelcund for several centuries afterwards. Sometime in the sixteenth century, it is said that a Bondela, living in Benares, removed to a fort in the district of Ouncha, then governed by a Rajah whose confidence he speedily obtained. This Bondela had a daughter of exquisite beauty of whom the Rajah became enamoured, and demanded her in marriage. But her father, considering the proposal a grievous insult, from one whom certain circumstances now unknown prompted him to consider his inferior in rank, he, in concert with his daughter, plotted a diabolical revenge. Acquiescence was given on the part of both, and the Rajah was invited by his bride to the house of the Bondela, where the ceremony was to be performed. Here a magnificent entertainment was prepared, of which he partook plentifully along with his attendants; but it was soon succeeded by excruciating tortures,—poison had been treacherously administered, and when the victims became incapable of defence, they were treacherously massacred. The Bondela then placed himself on the musnud of the Rajah, which he enjoyed peaceably until his death. He was succeeded by his son Ber Sing Deo, whose descendant is the Rajah of Ouncha, and he gained an accession of power by his services to the Soubahdar of Allahabad. But he is accused of being a great plunderer, and his history is stained by the assassination of the celebrated Abul Fazel, Prime Minister of Ackbar, which is said to have been committed by a banditti under his command. Nay, it is affirmed, that he acted in compliance with the wishes of Jehangeer, the emperor's son, who was jealous of Abul Fazel's influence over his father, and who, on his accession to the throne of Delhi, entrusted Ber Sing Deo with the government of all Bundelcund, then called Dungush. On descending to a later period, we find that this territory was invaded during the government of the Rajah Chattersaul, about the middle of last century, by the chief of Furruckabad; and the Rajah, to aid him in repelling the enemy, applied for support to the Peshwa, Sewai Bajerow. Success having attended them, he adopted Sewai Bajerow as his son, and partitioned Bundelcund between him and his own sons. But allotting him a third of his dominions, the land revenue of which was estimated at about L. 1,300,000 Sterling, was under an express stipulation that his posterity should be protected by the Peshwa, in independent possession of the remainder. The rest of his male issue, said to exceed fifty, were in a state of dependence on their two brothers. In time this division opened the way to dissensions, a civil war ensued, and the consequent weakness of the chiefs afforded an opportunity for other invasions. Ali Bahauder, an illegitimate grandson of Bajerow, held a command in the army of Scindeah, the noted Mahratta chief, and in the same army was the Rajah Himmut Bahaudar, who not only commanded a great body of cavalry, but was the spiritual head and military leader of a numerous sect of devotees called Gosseins. Both seem to have fallen under the displeasure of the Peshwa, and the latter, after retiring to his estate in 1786, soon united with the other in attempting the conquest of Bundelcund. The Rajah Himmut seems to have had it in contemplation to establish a sovereignty elsewhere; and about the year 1787, he was actively engaged in assisting the prince Mirza Jurvaim Buklit, in raising an army, but whose death, which happened suddenly in 1788, probably allowed him more leisure to attend to the other object in view. He and his associates agreed that a large portion of the territory to be conquered should be assigned to himself, and its revenue applied to the support of certain troops which he engaged to maintain in the service of Ali Bahauder. The projected invasion took place in 1789; when Ali Bahauder conquered much of the district in

Bundelcund.

the name of the Peshwa, of whom he rendered himself nearly independent; and in a short time the whole was subdued except some fortresses, which the Mahrattas have never been able to reduce.

Some years elapsed before the complete establishment of their authority; but an arrangement was made with the Peshwa, whereby he was acknowledged lord paramount of all the conquests effected in Bundelcund by Ali Bahauder, who engaged to obey him as his sovereign, and to pay him tribute. The latter contrived to evade both conditions, however; and, after being occupied fourteen years in endeavouring to subjugate the country, died in 1802, during the blockade of Callinger, which, during ten years, he had fruitlessly endeavoured to capture. Ali was succeeded by his eldest son, Shumshere Bahauder, then absent at Poonah; and Himmut Bahauder, who, to retain his own influence, had for years been exciting disaffection among the different chiefs, now appointed a relation of Shumshere, the young rajah, regent of Bundelcund until his return.

A war next broke out between the British and the Mahrattas. Himmut Bahauder endeavoured to accomplish the transference of this district to the former, while Shumshere was determined to oppose them vigorously. In September 1803, Colonel Powell crossed the river Jumna for the purpose of entering Bundelcund, and was joined by Himmut with a body of 13,000 or 14,000 men. The united forces arriving on the banks of the river Cane, which, passing the fort of Callinger, falls into the Jumna, near the town of Oorah, found the army of Shumshere on the opposite side. It was numerous, occupied a great extent, and was strongly posted, but after a short cannonade on both sides it precipitately retreated.

At this time a proposal was made by the Mahrattas, and acceded to by the British, for the cession of a portion of the territory of Bundelcund in lieu of certain districts in the Deccan, which had been ceded to them by a former treaty. Forces were then stationed in Bundelcund for the protection of other parts, and successive engagements of a conciliatory nature were made with Shumshere, and all the rest of the chiefs, whereby the British authority was rendered paramount. Himmut Bahauder had previously secured an advantageous arrangement for himself; and his death ensuing in the year 1804, Government provided for his family, and assumed possession of his territory. The troops who had been retained in his service, a kind of irregular force, now dispersed. Still, however, the tranquillity of the country was liable to be disturbed, and indeed the cession of some parts of it by the Mahrattas was only nominal, as they had never been able to occupy the strong holds themselves. Thus it was judged expedient by the British to bestow a considerable tract, in 1807, to a descendant of the Regent Chuttersaul, who had been long dispossessed amidst contending factions, on condition of guarding the passes and preserving his territory in peace. Other arrangements were made, conceding to the chief of Calpee, on the confines of Bundelcund, a portion of the interior, in lieu of the city and district of Calpee, and several villages on the Jumna. Meantime it became necessary to besiege the fortress of Callinger; but notwithstanding the British forces had captured many strongholds of the Indians, previously deemed impregnable, they were unsuccessful in attempting to take it by assault, and, as already observed, gained possession by the garrison retiring in the night. Its reduction proved a great accession of power, and tended materially to tranquillize the district, which had previously been incorporated with the British empire in the East, and a civil establishment constituted for the regular management of its affairs.

Bundelcund || Bürger.

The possession of a country such as Bundelcund, occupying 11,000 square miles, is of considerable consequence in several respects; and it has been suggested that the revenue derived from it might be materially augmented, by assuming the direction of the diamond mines of Pannah. Nevertheless the occupation of the whole does not seem to have been judged an important object, more especially, as, by the arrangement above alluded to, with the chief of Calpee, he was left in the enjoyment of a third part of them, to which he was originally entitled. (s.)

BURGER (Godfrey Augustus), a celebrated German Poet, born the 1st of January 1748, at Wolmerswende, a village in the principality of Halberstadt, where his father was Lutheran minister. In his childhood he discovered little inclination to study; the Bible and the Canticles alone had any attraction for him: these he knew by heart, and his first attempts in versification were imitations of the Psalms, which, notwithstanding their defects, gave proofs of feeling and a correct ear. It is to this first direction of his studies that we are to attribute the *Biblical* phrases, the allusions to Christianity, and the theological style, if we may be allowed the expression, which we find even in his amatory poetry. He was fond of solitude, and indulged in all the romantic sentiments which deserts and the gloom of forests inspire. From the school of Aschersleben, where his maternal grandfather resided, and which he quitted in consequence of a severe chastisement, which had been inflicted on him for composing an epigram, he was sent to the Institution at Halle; but, at neither of these places did he make any very sensible progress. He discovered a taste only for the lessons in prosody and versification which were given to the scholars of the Institution, in which his friend Gökingk was a class-fellow with him, who afterwards distinguished himself by his Epistles and Songs; and who has lamented the premature death of Bürger in an elegy to his memory. In 1764, Bürger, who was intended for the clerical office, began to attend the course of lectures given by the professors of the university. Klotz, a learned classical scholar, admitted him of the number of young people whose talents he took a pleasure in cultivating; but this society appears not to have produced the same favourable effect on the moral character of Bürger as on his genuis. His conduct prejudiced his grandfather Bauer against him, and it was with difficulty that he obtained from him some farther assistance, with permission, in the year 1768, to repair to Göttingen, to prosecute the study of the law, instead of that of theology. This change did not make him more regular in his studies; his manners

became corrupted, and his grandfather withdrew his protection. Bürger contracted a number of debts, and his situation would have become altogether desperate, had it not been for the assistance of some friends. An association, memorable in the annals of German literature, had just been formed at Göttingen: it reckoned among its members Boje, Biester, Sprengel, Hölty, Miller, Voss, the two Counts Stolberg, C. F. Cramer, and Leisewitz. Bürger was admitted into it. All of these persons were versed in the Greek and Roman literature; and, at the same time, all of them idolised Shakespeare. The Germans are the only foreigners who seem to relish or understand the merits of this great genius in the same degree as his own countrymen profess to do; and they do not seem to like his genius the less on account of the irregularities objected to it by other nations. Bürger, in a great measure, owed his style to the enthusiasm which he showed in common with his literary friends for our celebrated tragic writer. The *Reliques of Ancient English Poetry*, published about this time by Dr Percy, gave an additional impulse to the direction which his mind had taken, and suggested to him some of the productions which his countrymen admire the most. Of all his friends, Boje was the one who exercised the greatest influence over him in the choice and management of his compositions. He taught him to make easy verses, by taking pains; and it is to his severe observations that the poetical stanza of Bürger owes a great part of that elegance and roundness which characterize it. To the same friend he was indebted, also, for some improvement in his circumstances, which, till the year 1772, had been very uncomfortable. On the recommendation of Boje, he was appointed to the Collectorship of Alvengleichen, in the principality of Calenberg. The winter following, some fragments of a ghost story, which he heard a peasant girl singing by moon-light, caught his imagination, and his *Leonora* appeared, which soon became popular in all parts of Germany. Soon after the publication of this ballad, a circumstance occurred to give him still greater confidence in his talents: Going a journey to his native place, he one evening heard the schoolmaster of the village, in the room next to that in which he lay, reading to the assembled audience collected at the inn, the ballad of *Leonora*, which had just come out, and which was received with the liveliest marks of admiration. This proof of success flattered him more than all the compliments of his friends. About this time, he married a Hanoverian lady, named Leonhart; but this union proved only a source of bitterness to him, an unhappy attachment to her younger sister having sprung up in his heart. The loss of a sum of money, of which his grandfather had made him a present, was the first commencement of the embarrassment of his circumstances. The taking a large farm, which he did not know how to manage, increased it, and the dismissal from his place, which he was obliged to submit to in 1784, in consequence of suspicions (probably ill-founded) raised against the fidelity of his accounts, gave the finishing stroke to his misfortunes. He had, a little before, lost his wife; and it is but too certain that her death was hastened by the culpable passion which Bürger cherished in his heart. Left with two children, and reduced to the inconsiderable emoluments of *The Almanack of the Muses*, published at Göttingen, which he had edited since 1779, he removed to this city, with a view to give private lessons there, and in the hope of obtaining from the Hanoverian government a Professor's chair in the Belles-lettres. Five years after, this title was conferred on him, but without a salary; yet this was the only public recompence obtained during his whole life by a man who was one of the favourite authors of his nation; and who, while yet young, had enjoyed the highest reputation. Scarcely were the ashes of his wife cold, when he espoused her sister Molly, whose name his poems have made but too famous, and who had embittered the existence of his first wife; but he did not long enjoy the happiness after which he had sighed. She died in child-bed, in the beginning of 1786. From that moment, his own life only lingered on; and the fire of his genius seemed extinguished with the passion which had so long nourished it. He had scarcely strength enough, in the intervals of his dejection, to finish his *Song of Songs*, a sort of dithyrambic or nuptial hymn, intended to celebrate his second marriage, and which is a strange mixture of frantic passion, religious devotion, and the most bombastic expression. It was the last production of Bürger. Having studied the philosophy of Kant, he had an idea of deriving some advantage from it at Göttingen, where it had not yet been taught. He undertook to explain it in a course of lectures, which were attended by a great number of young people. The satisfaction which the university expressed to him for two Cantatas which he composed in 1787, at the period of the fifty years' jubilee of this illustrious institution, and his nomination to the situation of Professor Extraordinary, reanimated his spirits. Fortune appearing to smile on him once more, he formed the design of marrying again, in order to provide a mother for his children. During one of the moments when he was most occupied with this idea, he received a letter from Stuttgard, in which a young woman, whose style indicated a cultivated mind, and her sentiments an elevated and feeling heart, after describing to him, with enthusiasm, the impression which his poetry had made upon her, offered him her hand and heart. Bürger spoke of the thing, at first, only in jest, but the information which he received respecting the character, the fortune, and personal accomplishments of his correspondent, having excited his curiosity, he took a journey to Stuttgard, and brought back with him a wife who embittered and dishonoured the rest of his days. In less than three years, he saw himself under the necessity of obtaining a divorce from her, and the ruin of his health aggravated the absolute disorder of his finances. Confined to a small chamber, the favourite poet of Germany wasted the remainder of his strength in translations ordered by foreign booksellers; but sickness and grief soon deprived him even of this resource, and he must have died in

Bürger.

the most frightful state of want, if the Government of Hanover had not extended some kindness to him. He died the 8th of June 1794, of a disorder of the bowels, of which he had never believed the danger.

Bürger is only remarkable as a lyric poet. He has tried all the different species of this class of the productions of genius; but he succeeded eminently only in the song and the ballad. We shall, perhaps, characterize his genius sufficiently by saying, that his imagination is more fresh than rich,—that he has more sensibility than elevation,—more naiveté and good nature than delicacy or taste. His style sparkles by its clearness, its energy, and from an elegance which is rather the result of labour than of natural grace; he possesses, in short, all the qualities which please the multitude. Allowing the title of poet only to those whose writings were calculated to become popular, he early habituated himself to reject whatever appeared to him not sufficiently intelligible and interesting to all classes of readers. Always clear and forcible, he is never either low or trivial; and if, at certain times, there appears a want of selection and care in the details, yet the sentiments are uniformly noble, and the moral intention of the majority of his pieces altogether irreproachable. Some breathe the loftiest piety and the purest love of virtue. Wieland said of him (see the German *Mercury*, 1778), that in composing his poem entitled *Mænnerkeuschheit* (on Chastity), Bürger had deserved better of the present and future generations, than if he had written the finest treatise of morality. This little piece has been inserted in most of the collections of hymns for the use of the Lutheran church.

There are three editions of Bürger's works. The two first appeared in his lifetime, in 1778 and 1789, in 8 vols. 8vo, and the third, after his death, was published by his friend Ch. Reinhard, in 4 vols., 1796. All three were printed at Göttingen. The last contains some posthumous pieces, and miscellanies in prose. We must confine ourselves to a short notice of those for which their merit or the singularity of the subject has procured the greatest degree of celebrity. I. A translation, or rather an imitation, of the *Vigil of Venus* (*Pervigilium Veneris*). It is a fine piece of poetic diction and rythmical harmony. II. *Leonora*, a romance, which belongs to the class which Bürger himself called the *epic lyric*. The story is borrowed from a popular tradition, of which the traces are to be found in the different countries of the north. *Leonora* was translated into Danish, in 1788,—six times into English, by Stanley, Pye, Spencer, Taylor, &c.—and from English into French, by De la Madelaine, in 1811. The translation by Mr Spencer is accompanied with engravings after designs by Lady Diana Beauclerc. Two German composers have set it to music. Bürger often appeared very ill-contented with the vast success of this production of his youth. He preferred a great number of his other poems, and was himself the first to blame the puerile trick of the play upon sounds which he has there indulged in. III. *The Minister's Daughter of Taubenhain.* It is the story of the seduction and tragical end of a young girl. There are in this, as in the other productions of the same author, some objectionable details, but the whole leaves a deep impression. IV. *The Inhuman Huntsman.* V. *The Song of the Brave;* in which the heroism of a peasant, who saves a family from the fury of the waves, is related with admirable feeling. VI. *The Song of Songs, conceived at the foot of the altar.* This is a hymn or ode in praise of his Molly. VII. *A Travestie of the Fable of Jupiter and Europa.* This is a piece of humour of the most clumsy kind, and in a taste the most wretched, yet it had a great run when it first appeared. VIII. *A translation, in iambic verse, of some books of the Iliad.* The choice of the measure is by no means happy. He was accordingly requested, ironically, to set about translating Anacreon into hexameters, when he had finished his version of Homer into German iambics. IX. An excellent *Translation of Shakespear's Macbeth.* X. *Pieces of Poetry and of Rhetorical Prose.* He had begun to write critical observations on his own works, with equal severity and sagacity. But he has only left some fragments of this work. XI. He was editor of the Göttingen *Almanack of the Muses*, from 1779 to 1794. Vetterlein, Pölitz, and Engel, have published a selection of the poetry of Bürger, with notes; and celebrated composers, such as Schulz and Reichardt, have set a great number of his songs to music. Bürger's third wife, whom German biography has thought worthy to have her name associated with his on account of her taste for literature, and particularly poetry, is author of several pieces in verse, inserted in the Collections. The one having for its title *The Raillery of a Mother*, is sufficient to prove her poetical talent.

See the account of Bürger in the sixth Volume of the *Biographie Universelle.* (z.)

Busching.

BUSCHING (Antony Frederick). This very eminent Geographer was born at Stadthagen, a village of Westphalia, on the 27th September 1724. In his youth he laboured under peculiar disadvantages, arising from the disorderly life led by his father, and from the narrow means of education which his native town afforded. Fortunately, a clergyman of the name of Hauber, pleased with the promising talents of the young man, undertook to give him gratuitous instruction. He laid a solid foundation of learning, and also of a piety which, though fervent, was always accompanied with moderation and mildness. At the age of eighteen, young Busching was driven from his father's house, on account of the zeal with which he espoused the cause of his patron, on occasion of a controversy in which he was involved. Hauber, however, procured for him the means of continuing his studies at Halle. There, by his application to learning, and his irreproachable conduct, he acquired numerous friends. They procured him the appointment of tutor in the family of the Count de Lynars, who was then going as ambassador to Petersburgh. The observations made by Busching on this journey decided the pursuits of his future life. In travelling through Poland and Russia, he compared the actual features of those

hing. regions with the descriptions given of them. He thus became sensible of the miserably defective state of geographical science, and resolved to devote his life to its improvement. He withdrew as soon as possible from the Count's family, and went to reside at Copenhagen, devoting himself entirely to this new pursuit. In 1752, he presented the first specimen of his powers in a *Description of the Counties of Sleswig and Holstein*, a work which produced a favourable idea of his accuracy and ability. He soon after removed to Gottingen, and married Christiana Dilthey, a young lady of great accomplishments, authoress of a volume of poems, and to whom he had been engaged from the time of his departure to Russia. Here, on account of a work which appeared to dissent from some of the Lutheran tenets, he was excluded from the theological chair, for which he had become a candidate. The chagrin occasioned by this disappointment, induced him to accept an invitation to the German congregation at Petersburgh. He was employed there, also, in organizing a school, which, under his auspices, soon became one of the most flourishing in the north. This school was superintended by Marshal Munich, who, at first, showed great favour to Busching; but being accustomed to entire obsequiousness from all connected with him, he did not accommodate himself to the hardy independence of the German sage. A collision arose, in consequence of which Busching announced to his congregation, that he was under the necessity of returning to Germany. The Empress expressed much dissatisfaction at the conduct of Munich, and made very high offers to Busching if he would consent to remain; but he deemed it unworthy of him, after having resisted the intreaties of his congregation, to yield to the favours of the Court. He returned to Germany without any fixed object or establishment in life, and went, at first, to reside at Altona. Next year, however, he was called to superintend an extensive establishment for education, which had been formed at Berlin, under the auspices of the great Frederick. His appointments here were liberal, and his exertions proved of signal benefit to the institution, of which he became the head. His writings and example gave a new impulse to education throughout Prussia. He spent a number of hours every day in the Institute,—superintended the progress of every pupil,—and inspected the minutest details connected with its prosperity. He gave also courses of Lectures on the History of the Arts and Sciences. This labour did not interrupt the composition of his numerous works. The Queen loved his society, and, at first, often invited him to dine with her; but, finding that such engagements occupied too much of his time, he intreated her Majesty to allow him to devote himself, as much as possible, to his numerous labours. Though seized with dropsy, which occasioned a series of the most cruel sufferings, he did not remit his academical labours, till the disease, coming to a crisis, terminated his life on the 28th May 1793, in the 69th year of his age. His wife had died in 1777, and he had contracted a second marriage with Mad^le^. Reinbeck, the daughter of a clergyman at Berlin. By the first marriage, he had two children, who survived him; by the second, he had six, who, except one, all died in infancy.

Busching || Buteshire.

Few authors, even in Germany, have produced a greater number of works than Busching. The entire number, as enumerated by Meusel, in his *Lexicon of German Authors*, amounts to more than a hundred. They may all be classed under the following heads: 1. Geography and History. 2. Education. 3. Religion. 4. Biography. The first class comprehends those upon which his fame chiefly rests. He possessed not, indeed, the geographical genius, if we may so speak, of D'Anville; his skill in the construction of maps, his quick eye, or his sagacity in eliciting the truth from hints and imperfect notices. He may be regarded, however, as the creator of modern *Statistics*,—that science which exhibits the present state of every kingdom, its civil and political constitution, its wealth, the productions of nature, the exchanges of commerce, and the establishments for public instruction: all these particulars are detailed in his works in the fullest manner, and from the most careful investigation of original materials. His works, devoid of the ornaments of style, and composed of minute details, are rather useful to consult, than profitable to read; but this is a fault to which most writers of his country are liable. His grand work is the *Neue Erdbeschreibung*, *New Geographical Description of the Globe*. The four first parts, which comprehend Europe, were published in four successive volumes, from 1754 to 1761, and have been translated into all the European languages. They appeared in English, with a preface by Murdoch, in six volumes 4to, London, 1762. He published also in 1768 the fifth part, being the first volume upon Asia, containing *Asiatic Turkey* and *Arabia*. It displays an immense extent of research, and is generally considered as his masterpiece; but has not been translated either into French or English.

Besides this great geographical work, Busching was the editor of a valuable collection, entitled *Magazine for the History and Geography of modern times*, 22 vols. 4to. 1767-88; also of a *Journal appropriated to the Notice of Maps*, Berlin, 1773-87.

The elementary works on education, published by Busching, are very numerous, and have long held a distinguished place, even in a country so eminent as Germany, in this branch of literature. If, in some departments, better works have now been produced, it is by labouring on the foundation of Busching. His theological writings are not very highly esteemed. In biography, he wrote a number of articles for the *Historical Magazine*; also *A Collection of Biography*, in six volumes, 1783-9, including a very elaborate life of the great Frederick. (B.)

BUTESHIRE, a county on the west coast of Scotland, in the Firth of Clyde, comprehends the Islands of Bute, Arran, the Cumbraes, Inchmarnoch, and a few smaller islets.

Situation and Extent.

Bute, which gives name to the county, is separated by a narrow channel from the district of Cow-

Buteshire. al in Argyleshire. It is about 15 miles long, and $3\frac{1}{2}$ miles broad, but so much indented by the sea that the heads of some of the bays on the opposite sides of the island are not more than a mile distant; and it contains nearly 30,000 acres, of which more than a half is susceptible of cultivation. The country is generally low, few of its hills rising more than 200 feet above the sea. The climate, though very moist, is so mild as to be compared with that of Devonshire; and the soil is for the most part dry, and naturally fertile.

Agriculture. A former Marquis of Bute, to whom seven-eighths of the island belonged, began, so early as 1758, to promote the improvement of the island and its inhabitants; but his plans, though apparently well calculated for this purpose, do not seem to have effected any favourable alteration, probably owing to his absence from the country, and to his time having been engrossed by public affairs. The present Marquis, however, has within these few years displayed a very laudable attention to the same object. An eminent agriculturalist has been employed to survey the island, and to point out the defects in its husbandry in a small treatise which is distributed gratis; and young men have been sent to the border counties, as apprentices to some of the best farmers in that district, to whom the noble proprietor means to give a preference as tenants. All the crops common in the lowlands of Scotland are cultivated in Bute; and, though modern husbandry be yet in its infancy, its progress in the southern parts of the island, where the land is enclosed with white-thorn hedges, is by no means inconsiderable.

Minerals. Slate and limestone are found in various quarters of the island, from which also there is ready access to the noted limestone quarries in the north of Ireland. Coal has not yet been discovered. Beds of sea-shells abound on the western side, and vast quantities of sea-weed are thrown upon its shores.

Fisheries. The herring-fishery was formerly prosecuted by the inhabitants of Bute with great success; but of late it has declined, and at present does not much interfere with agriculture, as it is chiefly confined to the town of Rothsay. White fish and shell fish, though abounding on the coast, have been hitherto much neglected. In the town of Rothsay, the principal town of Buteshire, from which the heir apparent to the British throne takes the title of a Scottish duke, there has been a cotton manufactory for several years. The vessels belonging to this port in 1812 carried 5195 tons; and it has a regular communication by packets with Greenock, and by a daily mail-boat with Largs in Ayrshire.

Ruins. In the ruins of the castle of Rothsay, the principal residence of the Stuarts, ancestors of the present family of Bute, till it was burned in 1685, are still pointed out the bedchambers and banqueting rooms of Robert II. and III. the last Scottish monarchs who inhabited this venerable pile. Mount Stuart, the seat of the Marquis of Bute, from which he takes his second title, is an elegant house, with fine woods and pleasure-grounds, situated about two hundred yards from the eastern shore, and commanding a delightful view of the navigation of the Firth of Clyde, and of the opposite shore.

Arran. ARRAN, lying about twelve miles south from Bute, is something more than twenty miles long and from eight to eleven miles broad; and contains, by the latest estimation, more than 100,000 acres, of which only a seventh part may be fit for cultivation. It is an extremely rugged and mountainous country, particularly the northern part, in which the valleys are deep and romantic. Surface. Goatfield, a mountain nearly in the centre of the island, is about 3000 feet high, and a few others approach to the same elevation. The climate, in winter, is exceedingly severe; and, like that of all the other western isles, moist during the other seasons. With the exception of a few farms, the whole island belongs to the Duke of Hamilton, who has very lately begun to take an interest in its improvement, and expended a considerable sum in making roads, bridges, and small harbours. Game is in great abundance, particularly grouse, which are surprisingly numerous on the mountains. Limestone, marl, and slate, are found in different parts, and there are indications of coal also. The herring fishery is prosecuted to great advantage. Harbours. Arran has two remarkably fine harbours, Lamlash on the east side, and Loch Ranza on the north. Agriculture. Its agriculture does not seem to have improved much since the time when Pennant visited it. The arable land of a farm is still occupied in intermixed ridges, or what in Scotland is called *run-rig*, by a society of tenants, who interchange their possessions every year, or every two years at the longest; and, adjoining to this portion, a common pasture is allotted for their cows, under the charge of a herd. The highest grounds are held in commonty by the tenantry at large; and, as soon as the crops are removed, the live-stock pasture indiscriminately over the whole island. See the Article ARRAN in the *Encyclopædia*.

Cumbraes. The CUMBRAES are two small islands on the coast of Ayrshire, but do not, as has been inadvertently stated in the article AYRSHIRE, make a part of that county. The largest, which belongs to the Marquis of Bute and the Earl of Glasgow, contains about four square miles, of which a half is cultivated; and the smallest, the property of the Earl of Eglinton, only one mile, on which there is a light-house, with four or five families, and a great number of rabbits.

Inchmarnoch. INCHMARNOCH, a beautiful islet, lies to the south-west of Bute, and takes its name from a chapel on it, dedicated to St Marnoch, of which the ruins are still visible. Its surface is less than a square mile, and about a third of it is cultivated.

Pladda. PLADDA, another islet belonging to Buteshire, is about a mile to the east of Bute. A light-house was erected on it a few years ago. The only other islet worthy of notice in this county is Lamlash, which covers the harbour of that name in Arran.

The county of Bute sends a Member to Parliament alternately with Caithness; and Rothsay, the only royal burgh it contains, unites with Ayr, Irvine, Campbelton, and Inverary, in electing a Member for the boroughs. Valued Real Rental. The valued rental, according to the books of the collector of the land-tax, is in Scots money L. 15,042, 13s. 10d., divided among only

eleven estates; and that of the lands held under entail is a third of the whole. The real rent in 1811 was, for the lands L. 18,591, 9s. 2d., and for the houses L. 2310, 1s. 7d. Sterling. The following tables exhibit an abstract of the returns made under the Population Acts of 1800 and 1811.

CAB

CABANIS (Peter John George), a distinguished Writer and Physician at Paris, was born at Conac in 1757. His father, John Baptiste Cabanis, was a lawyer of eminence, and chief Magistrate of a district in the lower Limousin; highly respected for his extensive knowledge and inflexible integrity, and entitled to the gratitude of his country for the many improvements he has introduced in agriculture and farming. He brought the culture of the vine to great perfection in his province, and introduced a mixed breed of sheep, by crossing the Spanish with those of Limousin and Berri. France is more particularly indebted to him, however, for the successful methods he discovered of grafting fruit trees, and also for contributing to render more general the use of the potatoe in the southern provinces. He was exceedingly anxious that his son, the subject of the present article, and who had given early indications of talent, should have the advantage of a learned education; and, accordingly, placed him, when only seven years old, under the tuition of a neighbouring priest. It was remarked, that, even at this early age, he had acquired habits of steadiness and perseverance, from which, under proper direction, the best results might be expected. At the age of ten, he entered the college of Brive, where the severity of discipline to which he was subjected, had an injurious effect upon his temper, and fostered that habitual impatience of restraint which formed part of his character, and which afterwards so frequently operated to interrupt his progress. When raised to the second class, he was fortunate in meeting with a master whose kind treatment soon softened a disposition, which harshness only had rendered stubborn and intractable. He was not only reconciled to study, but applied to it with the utmost diligence, and became passionately fond of the great models of poetry and eloquence that were put into his hands. At a later period, being again exposed to the rigorous control of one of the heads of the college, his spirit was again roused; he came to the determination of provoking the anger of his master, and even suffered himself to be accused of a fault of which he was innocent, in the hope that he might get expelled. Persisting in this extraordinary mode of conduct, he soon accomplished his object, and was sent back to his father. But far from enjoying any relaxation under the paternal roof, he now found himself under a subjection still more rigorous and insupportable than that from which he had managed to escape. Indignant at the yoke imposed upon him, he relapsed into his habits of obstinacy, and would do nothing. After a year had thus passed in sullenness, his father became sensible that other measures than those of severity must be tried, and adopted the bold expedient of taking him to Paris, and leaving him there, at the age of fourteen, without any restraint on his actions, or even commissioning

Cabanis.

any one to superintend his conduct. The experiment was hazardous in the extreme; but it was attended with complete success. Young Cabanis no sooner felt himself at full liberty to do as he pleased, than his love of literature revived, and he engaged with ardour in the pursuit. He had formerly paid no attention to the lectures of his professors; but he now, of his own accord, resumed those branches of his education in which he had remained deficient, and prosecuted them with the same perseverance which throughout marked his character. He devoted himself entirely to the cultivation of his mind, and associated only with a few chosen companions of his own age, who had a congenial taste for literature, and an equal desire of improvement.

Thus constantly occupied, two years passed away with a rapidity which astonished him, when he received a letter from his father, offering him the place of secretary to a Polish nobleman of high rank. He had now to choose between accepting a situation, which, although it would totally interrupt his present pursuits, might give him the power of resuming them at some future period, or returning to his family, where he felt that all his exertions must be paralysed, and his hopes blighted by neglect. He embraced, therefore, without hesitation, the offer made to him, and, though only sixteen, committed himself into the hands of strangers, in a distant country, which was represented to him as in a state of barbarism. This was in 1773, the year during which that Diet was sitting, which was to deliberate upon giving its sanction to the first partition of Poland. The corrupt intrigues and compulsory measures which were practised on that occasion, gave him an insight into the affairs of the world peculiarly revolting to a youthful and generous mind, and inspired him with a contempt for mankind, and a degree of misanthropic gloom, which are generally the fruits of a later experience of human depravity. He returned to Paris two years after, when Turgot, the friend of his father, was Minister of Finance. On being presented to him, he was received with kindness, and would soon have been placed in a situation perfectly conformable to his tastes and wishes, had not a court intrigue produced the sudden downfal of the minister.

Thus, the only fruits which he had gathered from his travels, were the knowledge of the German language, and a premature acquaintance with the world. He now felt the necessity of making up for the time he had lost, and again applied to his studies with his former ardour. His father feeling it incumbent upon him to second his efforts, secured to him the means of subsistence for two or three years longer, which was all that Cabanis desired. He had contracted a friendship with the poet Roucher, who possessed some celebrity. This connection rekindled his taste for poetry; and the French Academy, having proposed, as a prize subject, the translation of a passage in the *Iliad*, he not only ventured to appear as competitor, but set about translating the entire poem. The two specimens which he sent to the Academy, did not obtain any public notice; but they were judged of favourably by several persons of taste; and some other fragments that were published among the notes to the poem *Des Mois*, met with general approbation. He received the approbation of those critics who were the dispensers of literary fame in Paris, and was introduced at once into a large circle of acquaintance, where he was everywhere greeted with acclamation. He was soon, however, sensible of the emptiness of these applauses; and dissatisfied with successes that offered no prospect of solid advantage, he sunk into a state of melancholy, which, together with his excessive application to study, began visibly to prey upon his constitution. His father now urged him to choose a useful profession, and he at length decided for that of medicine, which, embracing such various objects of study, presented an ample field for the exertions of his active mind, while it necessitated that degree of bodily exercise, which had become so necessary for the preservation of his health. Dubreuil, whose counsels had had much influence with him in forming this determination, offered to be his guide in the new and arduous career which he was commencing. Cabanis continued for six years the pupil of this able master, following his steps both in his hospital and private practice, and conducting his studies conformably to his instructions. In 1789 he published *Observations sur les Hôpitaux;* a work which procured him the appointment of Administrator of Hospitals at Paris.

His state of health, in the midst of his laborious professional exertions, requiring occasional relaxation in the country, he fixed upon Auteuil, in the immediate vicinity of Paris, as his place of residence. It was there that he became acquainted with the widow of Helvetius, and ever after cherished for that excellent woman the affection of a son, as she, on her part, fulfilled towards him the duties of the kindest mother. He spent all his leisure hours in her society; and profited by the opportunity her house afforded him of cultivating the acquaintance of the most distinguished literary men of that period. He continued his intercourse with Turgot, was on terms of intimacy with Condillac, Thomas, and D'Alembert; and acquired the friendship of Holbach, Franklin, and Jefferson. During the last visit which Voltaire made to Paris, Cabanis was presented to him by Turgot, and read to him part of his translation of the *Iliad*, which that acute critic, though old, infirm, and fatigued with his journey, listened to with great interest, and bestowed much commendation on the talents of the author. Cabanis had now, however, long ceased to occupy himself with that work, and fully engaged with the studies and duties of his profession, had renounced the cultivation of letters. He even bade a formal adieu to poetry in his *Serment d'un Médecin*, which appeared in 1783, and is a free imitation of the Greek of Hippocrates, but is more remarkable as exhibiting the author in the light of a zealous friend to liberty. Political interests were now, indeed, beginning to engross the general attention, and the muses were deserted amidst the contentions of parties, the din of arms, and the various anxieties and passions, which were called into play during this eventful period. Cabanis espoused with enthusiasm the cause of the revolution, to which he was attached from principle,

and of which the opening prospects were so congenial to his active and ardent mind. But however he may have shared in the intoxication which seized its early partizans, it is certain that he had no participation in the criminal excesses which followed, and which have left so indelible a stain upon the history of those times.

During the two last years of Mirabeau's life, he was intimately connected with that extraordinary man, who had the singular art of pressing into his service the pens of all his literary friends, whom he engaged to furnish him with their ideas, in writing, on the political topics of the day, that he might afterwards combine them as he chose, and adopt them as his own. Cabanis united himself with this disinterested association of labourers, and contributed the *Travail sur l'éducation publique*,—a tract which was found among the papers of Mirabeau at his death, and was edited by the real author soon after, in 1791. During the illness which terminated his life, Mirabeau confided himself entirely to the professional skill of Cabanis; and though repeatedly and strongly urged, as his danger increased, to have farther medical assistance, constantly refused to have recourse to any other advice. Of the progress of the malady, and the circumstances attending the death of Mirabeau, Cabanis has drawn up a very detailed narrative, which, whatever proof it may afford of the warmth of his friendship for his patient, is not calculated to impress us with any high idea of his skill in the treatment of an acute inflammatory disease.

Condorcet was another distinguished character with whom Cabanis was on terms of intimacy. The calamitous events of the Revolution, and the relentless persecution which the former was suffering from the party which had gained the ascendancy, tended only to unite them still more closely in the ties of friendship; and Cabanis exerted every means in his power to avert his impending fate. But all his efforts were unavailing; and he had only the melancholy consolation of preserving the last writings of his unfortunate friend, and of collecting his dying wishes relative to his wife and children. Soon after this event he married Charlotte Grouchy, sister to Madame Condorcet, and to General Grouchy; a union which was a great source of happiness to him during the remainder of his life.

After the subversion of the government of the terrorists, on the establishment of central schools, Cabanis was named Professor of *Hygiène*, in the medical schools of the metropolis. He was chosen member of the National Institute the next year, and on the following, was appointed Clinical Professor. He was afterwards member of the Council of Five Hundred, and then of the Conservative Senate. The dissolution of the Directory was the result of a motion which he made to that effect. But his political career was not of long continuance. He was profoundly affected at the turn which the affairs of his country were taking, so unfavourable to the cause of liberty, and so dispiriting to the friends of humanity; and the latter years of his life were, in consequence, deeply tinctured with melancholy. A foe to tyranny under every shape, he was decidedly hostile to the policy of Buonaparte, and had constantly rejected all his solicitations to accept of a place under his government.

For some years before his death, his health became gradually more impaired, in consequence of the exertions and anxieties he had undergone; and, in the spring of 1807, he had a slight apoplectic attack, from which he soon recovered. He took, however, the warning that was thus given him, and retired from the laborious duties of his profession, spending the greatest part of his time at the chateau of his father-in-law, at Meulan, about thirty miles from Paris. Here he again solaced himself with reading his favourite poets, and even had it in contemplation to resume his translation of the Iliad, which had been the first effort of his youthful muse. The rest of his time was devoted to acts of kindness and beneficence, especially towards the poor, who flocked from all parts to consult him on their complaints. Increasing infirmity now made him sensible that his life was drawing near to a close, and he was fond of conversing on the subject of his approaching end,—an event which he always contemplated with perfect serenity of mind. A more complete attack of his disorder, at length, carried him off, on the 5th of May 1808, when he had attained his fifty-second year. He left a widow and one daughter to lament the loss of one, who united to the ornaments of a highly cultivated mind, the greatest sensibility and benevolence of heart.

Besides the tracts already mentioned, he was author of several other works. The only one among them which is purely of a literary nature, is the *Mélanges de Littérature Allemande, ou Choix de traductions de l'Allemand*, &c. Paris, 8vo, 1797. It is dedicated to Madame Helvetius, and consists of translations of different works of Meisner,—of a drama of Goëthe's entitled *Stella*,—of Gray's *Elegy on a Country Church-Yard*,—and of the Idyl of Bion on the Death of Adonis. His work, *Du degré de certitude de la Médecine*, appeared in the same year, and a second edition was published in 1803, containing a republication of his *Observations sur les Hôpitaux*, and his *Journal de la Maladie et de la Mort de Mirabeau l'ainé;* together with a short tract on the punishment of the guillotine, in which he combats the opinion of Soemmerring, Œlsuer, and Sue, that sensibility remains for some time after decapitation. This tract had already appeared in the *Magazin Encyclopédique*, and in the first volume of the *Mémoires de la Société Medicale d'Emulation*. This new edition also contains his *Rapport fait au Conseil des Cinq-cents sur l'Organisation des écoles de Médecine;* and a long dissertation entitled, *Quelques principes et quelques vues sur les secours publiques*. In 1799, he published *Quelques Considérations sur l'Organisation sociale en général, et particulièrement sur la nouvelle Constitution*, 12mo. His principal work, however, is that entitled, *Des Rapports du Physique et du Moral de l'Homme*, 1803, in two volumes 8vo; consisting of twelve essays, the first six of which had been presented to the National Institute, and were inserted in the two first volumes of their Memoirs, in the Class of Moral and Political Sciences. This work was reprinted in the following year, with the

Cabanis || Caermarthenshire.

addition of a copious analytical table of its contents by M. Destutt-Tracy, and alphabetical indexes by M. Sue. His *Coup d'œil sur les Revolutions et les reformes de la Médecine*, came out in 1803. Of this work we possess an excellent English translation, with notes, by Dr Henderson. His only practical work on medicine is the *Observations sur les Affections Catarrhales en général, et particulièrement sur celles connues sous le nom de rhumes de cerveau, et rhumes de poitrine*, 8vo, 1807. He wrote many interesting articles in the *Magazin Encyclopédique*. Several of his speeches to the Legislative Assembly are given at full length in the columns of the *Moniteur*. (w.)

CABINET-MAKING, see JOINERY.

Extent and Surface.

CAERMARTHENSHIRE, a county in South Wales, containing 926 square miles, or about 590,640 acres. The northern and eastern parts are mountainous. Near the sea the land is flat, but the general surface of the county is hilly. It is intersected in almost every direction by valleys, from the sides of which the hills rise abruptly. These valleys are, for the most part, very narrow. The most celebrated for fertility and picturesque beauty, as well as the most extensive, is the vale of Towy, which stretches thirty miles up the county, with a breadth of only two miles. From the celebrated Grongar Hill, and the ruins of the Castle of Dynevor, the picturesque beauty of this vale are seen to the greatest advantage.

Rivers.

The principal rivers in Caermarthenshire are the Towy, the Teivy or Tair, the Cothy, the Dulas, and the Gwilly. The Towy rises in Cardiganshire. It enters Caermarthenshire, at its north-eastern corner, crossing towards the south-west, and, passing Caermarthen, it empties itself into the large bay, between the counties of Glamorgan and Pembroke, called Caermarthen Bay. Many rivulets join the Towy in its course, among which is the Cothy. This stream rises on the north side of the county, and, running mostly in a southern direction, unites with the Towy about six miles above Caermarthen. The Teivy rises in Cardiganshire, between which county and Caermarthenshire it afterwards forms the boundary; soon after receiving the Keach, it enters the county of Pembroke.

Ports.

The principal ports in this county are Llanelly, Kidwelly, Caermarthen, and Llaugharne. Llanelly has a good port for vessels of ten feet draught, formed by an inlet of the sea called Burry River, which divides this county and Glamorganshire. Llanelly is the port of entry of Kidwelly and Caermarthen: its exports are coal and tinned iron plates. Kidwelly is situated on two small streams, called Givandraeth, which form a little haven, but mostly choked with sand. From this town a canal has been cut, at the expence of a private gentleman, between three and four miles long, to his coal-mines and lime-quarries; and, by means of this canal, Kidwelly has been enabled to export a considerable quantity of coals. Vessels of 250 tons burden ascend to the bridge of the town of Caermarthen on the Towy, but the entrance of the river is rather difficult, in consequence of a bar across it. The principal exports of Caermarthen are tin plates and cast-iron. Llaugharne, on a creek, is chiefly remarkable for a considerable flat tract in the vicinity, embanked from the sea, and of singular fertility.

Climate.

The climate of this county is soft and mild, but moist; the soil of the lower districts is fertile, being for the most part either a rich clay, or a sharp or deep loam.

Agriculture.

Little wheat is grown; and, except on the lighter soils, barley is not a common crop; but oats are extensively cultivated, and in respect both of produce and quality, are a very profitable crop. Great quantities are exported, chiefly to Bristol. The pasture land, especially where the soil is suitable, support a heavy stock; they are applied either to the dairy, or to the breeding of black-cattle and horses. The latter are reared in great numbers on the hills, and constitute the principal article of trade at the fairs of this and the adjacent counties. Much butter is exported. It is computed that 114,000 acres are in tillage; and about double that number in pasture; the rest is unfit for cultivation, though by no means unprofitable. According to the original agricultural report of this county, there are only about 170,000 acres of wastes and commons. This county was formerly extremely well wooded; but, of late years, great waste has been made of the timber. Its rivers and sea-coast abound in fish, especially salmon of excellent quality, and a species of trout, called Suen, in high request with epicures. (w.)

Minerals.

Caermarthenshire is rich in mineral productions. Coals and lead are the most abundant and profitable. The greatest lead-mines are not far from Llandowry. Limestone also abounds, and there are considerable quantities of iron ore. The sands in the vicinity of Llaugharne, according to Mr Donovan, abound in shells of great rarity and beauty. On the road from Caermarthen to Llandillo Vawr, a medicinal spring has lately been discovered, containing carbonic acid gas; carbonate of iron, and lime; muriate of soda and lime; and sulphate of lime. At Kastell-Karreg there is a fountain, which ebbs and flows twice in twenty-four hours. There are several remains of antiquity, chiefly Roman, to be seen in Caermarthenshire.

Manufactures.

The inhabitants, who are not engaged in agriculture, are principally employed in working the mines, in manufacturing the produce of these mines, or in making woollen stockings. The most extensive manufactures of tinned iron-plates are carried on at Kidwelly; here are also other manufactures of iron, for which there are large and excellent furnaces, forges, flatting-mills, &c. Tinned-plates and cast-iron are also manufactured at Caermarthen, and the works in both branches are extensive. In the neighbourhood of Llandowry, the woollen-stocking manufactory principally prevails.

Poor-rates.

The money raised for the maintenance of the poor in 1803 was L.17,046, at the rate of 12s. 9d. in the pound. In the year ending the 25th of March 1815, there was paid, in parochial rates, the sum of L.30,354, 6s. 9½d. from 83 parishes alone, the remaining 43 not having made any return.

Population.

By the population returns, in the year 1800, there were 13,449 inhabited houses, 67,317 inhabitants, 31,439 males, and 35,878 females; of this number 32,862 were returned as employed in agriculture, and 4343 as

Caernarvonshire || Caernarvonshire.

employed in trade. The following are the results of the last population-return, in 1811:

Inhabited houses, - -	14,856
Families inhabiting them, - -	16,083
Houses building, - -	113
——— uninhabited, - -	333
Families employed in agriculture, -	9878
——— in trade and manufactures,	5256
——— not included in these heads,	949
Males, - 36,080	
Females, - 41,137	
Total population in 1811, 77,217	
——— in 1800, 67,317	
Increase, 9,900

CAERNARVONSHIRE, a county in North Wales, is divided by the Conway from Denbighshire; from part of Merionethshire by a rivulet; from Anglesea by the straits of Menai: the residue is bounded by the sea. In figure it is very irregular, a great peninsulated point running out from it to the south-west. From the extremity of this point, the length is 45 miles; the breadth varies extremely; its circumference is about 150 miles. It contains, from a late survey, 300,000 acres of land, of which, by one account, about 200,000, and, by another account, only 160,000 are in a state of cultivation.

Boundaries. Extent.

This county is the most mountainous in Wales. Its central part is entirely occupied by Snowdon, and its subordinate mountains, extending from near Conway in the north-east to the shore that bounds the Perthorian road, including the Rhifel ridges. The Snowdon mountains are connected with another chain of hills, which approach the sea at Aberdaron. Among these are very deep passes, forming narrow valleys, through which numerous streams, issuing from various lakes, rush in some places with great violence. The highest region of the mountainous district is covered with snow, during the greatest part of the year; the middle region affords fuel and pasturage, though the woods which once clothed it are nearly exhausted. The bases of the mountains and the valleys are in general temperate and fertile. The vale of Conway is the most extensive in the county; it is a long and narrow tract, equally romantic and beautiful, through which the river of the same name runs. At first it is very narrow, but it gradually widens to the breadth of a mile. Its extent is about twenty miles, terminating at the town of Conway. It affords rich pasturage, especially near Llanwost, where it is formed into the finest meadows, corn-fields, and groves,—and exhibits a striking and pleasing contrast to the bleak regions of Snowdon frowning above it.

Surface.

The general escarpment of the mountains, which rise from the sea towards the centre of this county, fronts the sea. But the particular escarpment of the detached groups, depends upon the course of the streams. The mountain of Snowdon is composed of various cliffs of different heights; the altitude of the highest point of the mountain is about 3600 feet from the high-water mark on Caernarvon quay. Snow lies all the year in the hollows near the top of Snowdon, the temperature here being very low, even in the middle of summer. On the morning of the 5th of July 1795, just after sunrise, Mr Aikin observed the thermometer at 34, whereas in the vale of Beddgelest, at seven in the morning, it was at 62; at one in the afternoon it had reached only 48 on the top of Snowdon.

Snowdon.

The principal rivers in Caernarvonshire are the Conway and the Seiont. The first rises from a lake on the confines of Denbigh, Merioneth, and Caernarvon. Its course is nearly in a northerly direction, along the east side of the county, for about twenty-four miles, when it empties itself into the sea, at the town of the same name; it is half a mile wide at the Tash at high-water; and not above fifty yards at low, the remaining space being sand-banks, which, at high-water, are covered twelve feet. These sands still abound in the pearl muscle, as they did in the time of the Romans, but they have been long neglected. The Conway is navigable for about twelve miles. The Seiont rises from a lake near Snowdon; its course is westward, and it discharges itself into the Menai Straits at Caernarvon. The bar admits vessels of about 300 tons into the haven.

Rivers.

The sea coast of this county presents many objects worthy of notice. Traeth Bach, and Traeth Mawr, are two inlets of the sea having one entrance, and each receiving a little river; the greatest part of them are dry at low-water, and become quicksands. They lie between Caernarvonshire and Merionethshire, but as they seem more properly to belong to the latter county, the attempts of Mr Maddocks to embank the sands of Traeth Mawr, will more properly be noticed under Merionethshire. Passing from this county into Caernarvonshire, the first seaport is Pwllheli, on an inlet which receives three or four rivulets. It has a considerable coasting trade in small vessels. St Tudwell's bay is sheltered by two small islands. To it succeeds the bay named Hell's Mouth, from the height and form of the shores, which cause the wind to blow continually into it, while there is also a constant in-draught of the current. The promontory of Lyn extends to the west of the mass of mountains, that occupy the space between the west entrance of the Menai, and Traeth Mawr. At the extremity of this promontory lies the Isle of Bardsey, two miles long, and one mile broad; the tides run with great rapidity between this island and the promontory. The gulf between the peninsulated hundred of Lyn and Anglesea is called the bay of Caernarvon. It is lined by the high ridge of Snowdon. The only port on this coast is Porthyn Lyn, formed by a long point of land jutting into the sea, and sheltering a cone on the west. Port Penryhn, on a small rivulet, has been recently enlarged into a haven for vessels of 300 or 400 tons; from it are exported immense quantities of slate, from Lord Penryhn's estate in this county, to the amount of 500 tons a-week when the demand is great. About seven miles to the

Sea Coast.

Caernarvonshire.

west-south-west of Conway, on the road from that town to Bangor, is the stupendous precipice of Penmæn Mawr, the last of the long Caernarvon chain. It is 1400 feet perpendicular from its base, and, according to Mr Caswell, who was employed by Mr Flamstead the astronomer to measure it, 1545 feet above the beach at low-water. In 1772, application was made to Parliament to improve and secure the road across this precipice, which was accordingly done; and there is now a good road, on a ledge of the rock, defended by a wall five feet high. The county of Caernarvon is terminated by the lofty round promontory, called Llandudno, or the Great Orme's Head, on the east of the Conway river. It is a fine sheepwalk, ending in a steep precipice over the sea, which is hollowed into various inaccessible caverns.

Agriculture.

In consequence of the elevated surface of the greatest part of the county, and its cold, piercing, and damp atmosphere, there is little corn grown in it. Near the sea, however, and in some of the vales, barley of fine quality is grown; and in some of the higher districts, oats are cultivated. The vales yield a little meadow grass for hay, which is got in without the aid of wheel-carriages, the uneven surface of the ground not admitting their use. Sheep and black cattle, however, constitute the principal agricultural stock of the Caernarvonshire farmers. The former are pastured on the mountains, which, in general, are commons; and the latter on the lower grounds. A considerable quantity of cheese, made from the mixed milk of ewes and cows, is made. From the peninsulated hundred of Lyn, which is in general flat, oats, barley, cheese, and black-cattle, are exported; of the last, about 3000 annually. The numerous herds of goats, which used to frequent the rocky districts of this county, are now nearly extinct. There are some profitable orchards in the vales, but in general the climate is very unfavourable to fruit-trees.

Mineralogy.

Caernarvonshire is an interesting county to the Mineralogist; but we can only very briefly notice the principal features of its mineralogy. The highest and interior regions of the Snowdon mountains are composed of granite, porphyry, whin, and other primitive aggregate rocks, inclosing considerable blocks of quartz. The western side of Snowdon itself consists of ironstone, on which are placed basaltic columns, of different lengths, and about four feet in diameter. On each side of the primitive rocks, there are mountainous banks of slate, the coarsest on the eastern, and the finest invariably on the western side of the central ridge. At Nantfrancon are the slate quarries of Lord Penryhn, who has constructed admirable railways from them to Port Penryhn. The banks of slate, growing finer as they descend, occupy the country between Snowdon and the Menai, usually terminating within a few hundred yards of its banks. The channel of the Shast, as well as its banks, consists of limestone; breccia, or the fragments of the Snowdon mountains, in a calcareous cement, and hard marl, inclosing shells. The general dip of the strata, in the promontory of Lyn, is to the south-west; on the north coast is chlorite slate and coarse serpentine. On the former rest beds of primitive argillaceous schistus. The argillaceous schistus in some places is largely mixed with carbon, forming a kind of hard drawing slate; and in others it is penetrated by carbon and pyrites, forming alum slate. No mines have been opened in this district. A hard stone, used instead of brass, for supporting the pivots of light machinery, and another stone, something resembling the French burr, have been found in this county. There are some lead mines near Gwydir; but the most important and valuable metal found in this county is copper. The richest mines of it are in the vicinity of Llanberis; it is also found in various parts of the Snowdon mountains; and the green carbonate of copper lies between the limestone strata, in the promontory of Orme's Head. There are mines of calamine on the Caernarvon side of the river Conway.

Caernarvonshire ‖ Cæsalpinus.

Many rare vegetables, met with only on the most elevated spots, grow in this county. Some of the steepest crags of the Great Orme's Head are inhabited by the peregrine falcon. Considerable quantities of fish, particularly herrings, are caught on the shores of this county; and lobsters and oysters are found in great abundance. In some of the lakes are found the char, and the gwyniad, another alpine fish. Foxes are the chief wild animals.

Poor Rates.

The money raised for the poor in 1803 was L. 9137, being at the rate of 4s. 0¾d. in the pound. In the year ending the 25th of March 1815, there was paid in parochial rates the sum of L. 15,776, 17s. 6d. In 1800, there were 8304 inhabited houses, and 41,521 inhabitants; 19,586 males, and 21,935 females, of whom 12,808 were employed in agriculture, and 4234 in manufactures, trade, and handicrafts. The inhabitants live in a state of the utmost simplicity, manufacturing their clothes from the wool of their own flocks, and dyeing them with lichens: a little oatmeal added to the produce of their dairies constitutes their food. In 1811, the results of the population returns were as follows:

Population.

CÆSALPINUS (Andrew), one of those great and daring geniuses, who, contending with the mists of a dark age, elicit the most brilliant truths on the one hand, while they sometimes wander into great absurdities on the other, was born at Arezzo

Cæsalpinus. in Tuscany in 1519. Of his family nothing is recorded, nor does he appear to have left any progeny, nor to have been ever married. Devoted to the studies of physic and natural philosophy, he attained at length the honour of being physician to Pope Clement VIII., during the chief part of whose pontificate, from 1592 till his own death in 1603, at the age of eighty-four, Cæsalpinus lived at Rome, in the highest credit and celebrity; for which, as we trace the circumstances of his history, and inquire into his opinions, it seems, at first sight, difficult to account. Eminent talents have seldom proved a shield against persecution. On the contrary, by adding fear to its malice, they have generally tended to envenom its darts. How then could Cæsalpinus, a professed Aristotelian, an open unbeliever of revealed religion, whose opinions nearly approached those of Spinosa, exist in the holy court of Rome, which was then beginning to persecute the immortal Galileo! This mystery will but too readily unravel itself.

Cæsalpinus seems to have been furnished with two distinct philosophical intellects, which, like a good and evil genius, directed him by turns. Under the influence of the one he discovered the circulation of the blood, the sexes of plants, and the only true principles of botanical classification; under the guidance of the other, he became entangled in the metaphysics of the schools, the dreams of Aristotle, and a philosophic contempt for everything, good or bad, connected with the nonsense he was obliged publicly to respect. It is scarcely necessary to remind the reader, that however brilliant the reign of literature and taste in the golden age of Leo X. and the times which immediately succeeded, true science and experimental philosophy were as yet in the cradle. In this respect the time of Cæsalpinus was "dark as Erebus," and the light he struck out was altogether his own.

We have no account of this great man, till we find him seated in the botanical chair of the University of Pisa, where also he studied, if he did not teach, anatomy and medicine. His first publication was entitled *Speculum Artis Medicæ Hypocraticum*, in which it were too much to expect he should release himself from the shackles of his venerable guide; but he has left evident proofs, in a passage often quoted, of his having a clear idea of the circulation of the blood, at least through the lungs. In botany his inquiries were conducted on a more original plan, and their result was one of the most philosophical works in that science, which came from the press at Florence in 1583, in one volume 4to. The title page runs thus: *De Plantis libri XVI. Andreæ Cæsalpini Aretim, Medici clarissimi, doctissimique, atque Philosophi celeberrimi ac subtilissimi*; yet he appears to have been himself the editor of the work, to which is prefixed, in his own name, an elegant and learned epistle dedicatory to Francis de' Medici, Grand Duke of Tuscany. This book, now rarely to be met with, is not only the unacknowledged source from whence various subsequent writers, and especially Morison, derived their ideas of botanical arrangement; but it was a mine of science to which Linnæus himself gratefully avowed his obligations. His own copy evinces the assiduity with which he studied the book. He has laboured throughout to remedy the defect of which Haller complains, of the want of synonyms, and has subjoined his own generic names, nearly to every species. He has particularly indicated those remarkable passages, in p. 13 and 15, where the germination of plants and their sexual distinctions are explained. In the former we trace the first rudiments of a natural classification of plants by the differences in their cotyledons; or, in other words, we find the origin of the natural systems of Linnæus and Jussieu; in the latter passage we detect the fundamental principle of the Linnæan artificial system. On these subjects the reader may consult our article on BOTANY. Nor were these merely incidental suggestions of the illustrious author. He has pursued his enquiries to a conclusion on which the existence of Botany as a science depends, and which the no less eminent Conrad Gesner detected about the same time, though his ideas respecting it were not then made public. The principle to which we allude is the classification of plants by their parts of fructification alone. This was afterwards extended, by the greatest writers on the subject, as Ray and Tournefort, and more completely by Linnæus, to the discrimination of their genera by the same parts, more particularly considered and contrasted. To this more extensive conclusion, indeed, the principle of Cæsalpinus directly and inevitably leads. He pursued it himself to such a length, as to develop some of the most important characters for generic distinctions, such as the flower being superior or inferior with respect to the fruit; the heart of the seed situated at its summit or base; the seeds, or the cells of the seed-vessels, solitary or otherwise; the partitions of certain pericarps parallel or contrary to their valves. Linnæus remarks that this author, though the first systematical botanist, found out as many natural classes, or orders, as any of his followers. He did not indeed well define the philosophical limits of genera in the vegetable kingdom, and therefore his work cannot regularly be quoted throughout for generic synonyms. The want of plates of his own, and of references to other authors, render, as we have already hinted, some of his names and descriptions unintelligible. Yet Linnæus has in manuscript filled up many blanks which he had been obliged to leave in his own *Classes Plantarum*, where the system of Cæsalpinus first assumed a synoptical form. This author might probably have adopted a more clear and methodical mode of arranging and explaining the botanical part of his subject, had he not had in view the vague and desultory manner of Pliny, whom he closely imitates in the materials of his numerous chapters, as well as in his style of description. A small and unimportant *Appendix* to this work, of 19 pages, appeared at Rome in 1603, which is of very rare occurrence, but may be found reprinted in Boccone's *Museo di Piante rare*, p. 125.

Cæsalpinus printed at Rome, in 1596, a 4to volume of 222 pages, entitled *De Metallicis*, dedicated to Pope Clement VIII. which, like his botanical publications, is now extremely rare. In the philosophy

Cæsalpinus.

of this work, Aristotle is his guide; in its method and composition, Pliny. A prefatory address to the Pope declares it to have been undertaken in opposition to a certain treatise on the same subject, which, though written with diligence and elegance, contained many things inconsistent with the principles of philosophy, and subversive of the peripatetic doctrines; and with the author of which, as being excommunicated by the holy church of Rome, no measures were to be kept.

In our author's *Quæstionum Peripateticarum libri quinque*, published at Rome in 1603, it appears that he scrupled not to stand forth, as an open defender of the Aristotelian philosophy, without any concealment of his own peculiar opinions and hypotheses, derived from thence. By these he incurred the charge of atheism, from a physician named Taurel, who, punning on the name of his antagonist, entitled his book *Alpes cæsæ, hoc est, Andreæ Cæsalpini monstrosa dogmata discussa et excussa*. This attack however met with little or no countenance, and the learned Aristotelian died in the course of the year, receiving, no doubt, in the very focus of sanctity itself, the funeral honours due to an orthodox physician of his holiness.

Of the medical publications of Cæsalpinus, entitled *Praxis universæ medicinæ*, and *De medicamentorum facultatibus*, we have had no opportunity of forming an opinion for ourselves. By what is to be gathered from his other writings, his ideas of the medical qualities of plants and fossils seem adopted from ancient writers, rather than from any considerable portion of actual experiment. Like other physicians of his time, he was too much occupied in ascertaining the articles of the *materia medica*, to find leisure for doubt, or for practical enquiry, respecting the truth of their reputed virtues. He did however promulgate some original ideas, relative to the investigation of the properties of plants by their taste and smell. With Botany he was not only theoretically but practically conversant. He left behind him a collection of above 760 dried specimens, one of the earliest upon record, which is said to have come into the hands of Micheli, and therefore is doubtless still preserved in the museum of Dr Targioni Tozzetti at Florence. A catalogue of this venerable *Herbarium* is reported to have been prepared for the press; but we do not find that it ever appeared.

Cæsalpinus having been settled at Pisa, when the great Galileo first presumed to doubt the infallibility of the Aristotelian philosophy; and, most likely, when that rising character became, at the age of twenty-six, Professor of Mathematics in the same university; we cannot presume him to have been free from the party spirit which so disgracefully manifested itself there. He must have concurred in the measures which his own associates, leagued with the ruling powers, thought proper to adopt. The ancient school philosophy, derived from the Peripatetics, whether it was considered as a mere abstract speculation, or whether, as being equally absurd and unintelligible with the orthodox establishment, it did not excite alarm, was, as every body knows, allowed to go on very lovingly with that establishment; nor did it, in general, raise any more suspicion than the heathen mythology, studied and exemplified in the same and other schools. But when a spirit of truth and enquiry arose; when principles and opinions were to be submitted to the tests of reason and experiment; the same fatal results, which the preceding age had witnessed in what was called religion, were justly apprehended for what was now, with scarcely more propriety, denominated philosophy. Hence the papal authority, which had suffered shipwreck in the one case, wanting the wisdom to avoid a similar disgrace in the other, gladly clung for support to any ally. These two celebrated occasions, the divorce of Henry VIII., and the base persecution of Galileo, are almost the only ones in which the authority of the Pope has been exerted about any matter that human reason could determine, or that much signified, except to his own immediate dependants, how it might be determined. It is a memorable fact, that his decision was no less just in one case, than unjust in the other; yet both were equally ruinous, the former to his power, the latter to his credit. So hazardous is the exercise of usurped or over-strained authority, and so infallibly, thanks to the Author of all Good! do truth and justice rise, with renovated vigour, from such contests!

Cæsalpinus || Caithness-shire.

By this view of our subject, the mystery above alluded to becomes clearly unravelled. Cæsalpinus, though a known heretic and infidel, professing to be an obedient son, and even a champion, of the church, tried to rise by the ruin of equally learned, and more honest, men than himself. On the side on which he was absurd and censurable, and on that side only, he was unjust and unprincipled; nor is such a character uncommon. Where he exercised his unbiassed judgment, and honestly sought for truth, he, like Galileo, enlarged the bounds of human knowledge, and made discoveries which will for ever claim the gratitude and admiration of mankind. (J. J.)

CAITHNESS, a Scottish county, the most northern of the mainland of Great Britain, is situated between 58° 20′ and 59° of north latitude, and between 2° 50′ and 3° 27′ west longitude; and, including the island of Stroma, in the Pentland Frith, extends over 618¼ square miles, or 395,680 English acres, of which 8414 acres are covered by lakes and other waters. About a fourth of the surface is mountainous, more than a half consists of deep mosses, and only about an eighth part is cultivated. The boundaries, promontories, bays, climate, wild animals, &c. having been particularly described in the corresponding article in the *Encyclopædia*, we shall confine our notices at present to what is omitted there, and to the alterations which the progress of time has introduced. Situation and Extent.

This county is divided into thirty-four estates, eight of which comprise two-thirds of the valued rent, which is L.37,256, 2s. 10d. Scots; and more than a third of the whole is held under entail. Nine proprietors of the names of Sinclair, one of whom is a Peer, hold more than the half of this valuation. The real rent, for the year ending April 1811, was for the lands L.30,926, 1s. 9d. Sterling; and for the houses L.1,698, 7s. 6d. The Earl of Caithness is the only nobleman who resides in, or is connected Division of Property. Rental.

with the county; most of the other proprietors have modern mansions, and reside, at least a part of the year, upon their estates. Rents in this, as in almost every part of Scotland, have experienced a very great advance within the last fifty years; in one instance, noticed in Captain Henderson's survey of the county, published in 1812, nearly eight-fold, from 1762 to 1809. In 1792, Sir John Sinclair established a flock of Cheviot-sheep on his farm of Langwell, which have been found to prosper in that climate; and several other spirited improvements were about the same time promoted by this gentleman, though unfortunately they have not been attended with all the success that their indefatigable, but perhaps too sanguine, projector had contemplated. Several other proprietors have shown a very laudable zeal for the interests of this remote, and, till of late, much neglected quarter of the island. About twenty-four years ago, an act of Parliament was procured for commuting the statute-labour, under which L.550 has been annually expended on the repair of roads; and, within these few years, the proprietors have availed themselves of the aid granted by Parliament to the northern counties, of half the estimated expence necessary to make the great lines of road; more especially from the Ord to Wick, and from Wick to Thurso. No attempts to raise plantations in this county have yet been successful, though it appears, from the trees found in mosses, that woods had formerly grown, even on the sea-coast. As a great part of the county is nearly level, the want of plantations is much felt in this rigorous climate.

It has been the practice in this county, from time immemorial, for a few of the superior class of farmers, under the name of tacksmen, to take a lease for 19 or 21 years of a town land, occupied by from 10 to 40 small farmers, at a rent commonly paid in money, and not partly in kind, as was the case with smaller tenants. These men occupied only a part of the lands themselves, and subset the remainder to small tenants, for a certain money rent, payments in grain, customs, and services (the latter in many cases unlimited), so as to have, upon the whole, a surplus rent for the trouble and risk of recovering their rack-rent from these subtenants. Though this arrangement has been much, and perhaps justly complained of, both in the Highlands of Scotland and in Ireland, as oppressive to the lower classes, yet it seems to be the natural consequence of that minute division of farm-lands which has been so injudiciously recommended for improving the condition of the poor. The surplus rent drawn by the tacksman is merely a charge against the proprietor for factorage and insurance; and, notwithstanding the oppression of the small tenants, which may be the consequence of thus placing them at the mercy of one who must have a much slighter interest in their welfare than the proprietor himself ought to feel, yet there appears to be no remedy but such a one as would dislodge these small tenants altogether,—the enlargement of farms to such a size as would make them an object to professional farmers. A few young men, from the south of Scotland, have taken farms here, but it is said they have not been successful in establishing a mode of management superior to that of the natives. A great part of the county, accordingly, is still divided into small holdings, of which the rent is paid in money, in the Highland district of it; and, in the Lowlands, partly in money and partly in grain; and in some instances, with customs, casualties, and services, as formerly. When the small tenants possess upon leases, the term is commonly too short to encourage any expensive improvements, or even to permit any favourable change in their modes of cultivation.

Caithness-shire.

Small Farms.

Agriculture.

The implements of that numerous class are, in general, extremely rude and inefficient: ploughs and harrows, entirely of wood, excepting some thin plates of iron nailed to the sole of the former, to prevent its wearing by the friction of the soil, with four ponies or oxen yoked abreast, attended by a driver who walks backwards according to the ancient custom; seldom even a winnowing machine to separate their grain from the chaff,—and fences formed by a ditch and sod-wall. Their crops are bear and oats, alternately on the infield or old tillage lands, and grey oats successively, for four or five years, on the outfield or inferior land. Wheat has been tried by a few proprietors, but it does not succeed so well in that climate as to encourage its extensive culture. Turnips are beginning to attract notice among the small tenants, and to come into the regular course of cropping on large farms; and potatoes are now cultivated with the plough, as well as with the spade, in every part of the county. The cattle in Caithness have been long the worst breed in Scotland; but a considerable improvement has been lately effected on some estates, by the introduction of bulls from Argyleshire and the Western Isles. Oxen continue to be worked at the plough and harrow. With the exception of a few flocks of the Cheviot breed, the sheep are of the ancient race of the island, mostly horned, bearing a white fleece, but coarser than the wool of Shetland, and weighing from seven to ten lbs. *per* quarter. Since two-horse ploughs have been partially established, some attention seems to be paid to the breed of horses, though the *garrons* from 11 to 14 hands high, are still by far the most numerous description. The native breed of swine is small, short bodied, and generally of a redish or grey colour; there are a few black, but the grey are reckoned the best.

Manufactures.

In a county where the want of coal is added to the many disadvantages under which it labours from its soil, climate, and other circumstances, it is not to be expected that manufactures or commerce should have acquired any footing. A tannery, bleachfield, and woollen factory, were long ago undertaken under the direction, and chiefly at the expence, of Sir John Sinclair, of which only the first has been found profitable. A brewery is still carried on at Thurso; and a small ropework in the village of Castletown. In winter 1810, about 250 women and girls were employed in Thurso plaiting straw for ladies' bonnets; the straw-plait being returned to London, from whence the straw itself is imported. Caithness exports a few cattle and sheep, but of the former not a tenth part of what has been stated by Pennant. About twenty years ago from

Commerce.

Caithness-shire.

20,000 to 30,000 bolls of grain were annually sold out of it, but the quantity has diminished; and there used to be about 140 tons of kelp prepared from the sea-weed on its shores. But their fish form the most important article of export. Herrings, cod, lobsters, and salmon, bring in L. 43,400, of which the herring-fishery alone yields L. 40,000. Besides a great number of boats employed in the several creeks and harbours in fishing for haddock, ling, &c. which are consumed in the county; about twenty smacks from Gravesend fish for cod and ling, on the north coast of Caithness, and are said to have, in a great degree, destroyed the cod-fishery on its shores.

Fisheries.

John-o-Groat's House.

Among the antiquities of this county, the far famed *John-o-Groat's* house deserves to be noticed. The tradition regarding this celebrated personage is, that his ancestor came from Holland, and settled in this county in the reign of James IV.; and that he built this house of an octagon form, inclosing a large table of the same shape, to obviate disputes about precedency, at their anniversary meetings, among the Groats in his time, consisting of eight families. Each family, by this contrivance, entered separately at its own door, and was seated at the corresponding side of the table. A variety of these singular structures called Picts Houses, are still to be seen in Caithness. Many of the stones are of an enormous size, and must have been brought from a distance; fragments of earthen-ware, and a few small copper coins, have been found in them; and some singular articles made of bone fixed with nails of the same material. They are almost always of a conical form, and their exterior being now covered with a thick sward of fine grass, they have the appearance of large tumuli or barrows. The internal structure, as well as the size of these *Duns*, as they are called by the Highlanders, is various. The smallest, and apparently the oldest, have only one circular wall which contracts as it rises, till, at the top, only a small hole must have remained open, or been covered with flat stones. The largest ones have two concentric walls, two feet distant, which in some instances meet at a certain height, and in others ascend parallel to the summit; the space between them being entered by a door only two feet high, and occupied by a winding stair from the bottom to the top of the building; and these are surrounded by a broad deep ditch, and a sort of rampart. The walls are usually nine or ten feet thick, without cement of any kind; and from their situation on high land near the sea, or on the banks of precipitous rocks, stretching in a chain from one headland to another; they are supposed to have been used either as storehouses, or as retreats for women and children when the men were at a distance engaged in war.

Picts Houses.

Representation in Parliament.

The county of Caithness sends a Member to Parliament alternately with Buteshire, on the west of Scotland, an arrangement which of late has been much objected to, not only because one of these counties must always be without a representative, to which each, it is thought, is entitled, but also because there can be hardly any common interest between districts so distant from one another, and placed in circumstances so different. Five of the northern boroughs, of which Wick, the only royal borough in this county, is one, join together in the election of a Member for that department.

Language.

On the low grounds, the people differ little in their dialect from the inhabitants of the south of Scotland; but on the mountainous tract, where Caithness borders with Sutherland, the Gaelic prevails; though many of the natives can speak both languages with nearly equal facility.

Population.

By comparing the population lists taken under the acts 1800 and 1811, it will be seen that, even in this remote and comparatively unproductive portion of the British Empire, there has been an increase of numbers in the intermediate period, though not so considerable as in most other counties. The inhabitants of the towns bear a very small proportion to those of the country.

Calcutta.

CALCUTTA. The *Encyclopædia* contains some account of the settlement and subsequent improvement of Calcutta; and in the present article, which is compiled from the works of recent writers, we have endeavoured to comprehend whatever is most useful and interesting in the description of this celebrated city.

Situation and Aspect.

Calcutta is situated upon the river Hooghly, which forms the western channel of the Ganges, and though not the principal, is the only one of its numerous branches which is navigable for large vessels. The town is 100 miles from the mouth of the river, the navigation of which is difficult and often dangerous, on account of its numerous sand-banks, many of which are continually shifting their situation. Vessels drawing more than seventeen feet water cannot, except at spring-tides, ascend with safety above Diamond Harbour, where the vessels of the East India Company usually load and unload. This is about sixty miles below Calcutta, and passengers are conveyed to the city in smaller vessels or in boats. The country, from the mouth of the Hooghly to Diamond Harbour, is dreary in the extreme; the banks of the river are high, and the adjacent land, on each side, which is perfectly flat, forms a complete wilderness of timber and brushwood, the haunt of tigers, and of other beasts of prey. Advancing up the river, the scene gradually improves; the country becomes more and more cultivated, the shipping and the bustle on the river increase, and the beautiful country-seats on its banks announce the approach to the capital. The city, with its numerous spires and other public edifices, presents, at a distance, a striking appearance, and, on landing, the magnificence of the buildings command the admiration of all strangers. The town and suburbs extend along the left or eastern bank of the river above six miles, but varying much in breadth at different places. In the middle of it, and very near the landing-place, is an immense square, each side of which extends above a quarter of a mile, and the centre is occupied by a large tank or open reservoir of water, for the supply of the town. This square, together with the adjacent buildings and those towards the south, forms, what is properly termed, the town of Calcutta, the residence of the European inhabitants and of the natives of distinction. To the south, along the bank of the river, lies the Black Town, which is occupied entirely by the lower classes of inhabitants, and is rather considered as part of the suburbs; and about a quarter of a mile to the north stand Fort-William, and the barracks, which form, on this side, a great ornament to the city. The intermediate space, which is an extensive open plain, is termed the Esplanade. The citadel of Fort-William, which was begun by Lord Clive in 1757, after the battle of Plassey, is the strongest and most regular fortress in India, but the works are so extensive, that they would require at least 9000 or 10,000 men, with 600 pieces of cannon, to defend them. On the west of the Esplanade stands the government-house, built by the Marquis Wellesley, which is the largest and most splendid building in Calcutta. It is the residence of the Governor-General, where he holds levees, and transacts all the government business; it also contains magnificent apartments for public entertainments. The other principal buildings are a town-house, with public rooms, which, though handsome, are too confined for the climate, and for the number of inhabitants; the hospital and jail, which are situated on the Esplanade; two English churches, the one of which is a plain building, but the other has an elegant appearance; also a Scottish church, which is newly finished; and, besides these, there are various churches belonging to the professors of almost every religion in the world. Portuguese, Greeks, Armenians, Hindoos, and Mahomedans, all enjoy here the most perfect toleration.

The customhouse faces the river, and forms part of the west side of the great square. It is built upon the site of the old fort, which was taken in 1757 by Surajah Dowla. Near to it is the famous Black Hole, which is now converted into a warehouse; and before the gate stands the monument which has been erected to commemorate the unfortunate persons who perished there. It is surrounded by an iron-railing, but it has been struck with lightning, and has since been allowed to go to decay. In front of the customhouse is the quay, which has been of essential service to the numerous shipping which there load and unload. On the west side of the river, and in a beautiful situation, stands the botanic garden, at a bend to which it gives the name of Garden Reach. It contains a splendid collection of plants from every quarter of the globe, and is laid out with great taste, but more with a view to practical utility than scientific arrangement. Above the garden there is an extensive plantation of teak. Horse-racing having been discouraged by government, the course, which was to the south of the town, is now converted into a ride; but the practice still continues at Barrackpore, sixteen miles up the river, where the fashionable society of Calcutta assemble to partake of the amusement. The south side of the great square is occupied by the writers' buildings, which make but an indifferent appearance. They form the residence of this class of the Company's servants who are newly arrived from Europe, and who are students at the college of Fort-William. The private houses in Calcutta, in the central or genteel part of the town, are built, mostly, after the European fashion, but modified to the nature of the climate, and to the magnificence of eastern manners. In a line with the government-house, is a range of elegant buildings, ornamented with large verandahs, and another, at right angles with it, called Chouringee, formerly occupied by native huts. These houses are built of brick, covered with a species of stucco called Chunam. They are all separated from each other, every one having attached to it a considerable piece of enclosed ground, in the middle of which it is situated. The approach is by a flight of steps, under a large portico. The architecture is Grecian, and the profusion of columns, porticos, and verandahs, gives them more the air of palaces than of private houses. To this part of Calcutta the Black Town forms a striking contrast. It has been already described in the *Encyclopædia*, but has been considerably improved

Calcutta. by the widening of the streets, the filling up of ponds, and by tiling instead of thatching the houses, by which means the danger from fire has been much diminished.

Though building materials are abundant in the neighbourhood of Calcutta, house-rent is not moderate. This is owing partly to the high interest of money, and partly to the constant repairs which are required, from the casting of the wood in this hot climate, and from the ravages of insects, particularly the white ants. Though the wood-work of a house appear externally quite sound, it often turns out upon examination to be completely excavated or honey-combed by these insects, which assemble in incredible numbers, wherever they can find an entrance.

Precautions to be observed by Strangers.

The houses here, which are known under the name of taverns, are greatly inferior in respectability to those in Europe. They are, with the exception of two or three particular houses, resorted to only by the lowest company, and strangers who are enticed into them are exposed to every species of imposition, and frequently to total ruin. A European, on his first landing, is surrounded by numerous dangers and inconveniencies, which he finds it extremely difficult to escape. These are so well described in the *East India Vade-Mecum*, by Captain Thomas Williamson, that we shall extract the following passages, for the instruction of such of our countrymen as propose to visit those distant regions.

"The tavern-keeper, under the plausible pretext of aiding towards the completion of the youth's wishes, never fails to inquire whether the gentleman has any friends in town? or even in the country? If affirmatively answered, 'mine host' feels himself tolerably secure of his money: but will probably assert, that the friend in town is out of the way, and will not be back for some days. Should the gentleman be totally destitute of friends, then comes the rich harvest. Imposition following imposition, swell the bill; which, if appearances warrant forbearance, is kept back as long as possible, under the pleasing assurance of perfect confidence: but, in the end, a catalogue of items is produced, which never fails to alarm, if not to ruin, the unsuspecting victim!"

"If, unhappily, the guest should so far lower himself as to associate with the ordinary company of the common drinking-room, he is irretrievably gone. Quarrels, riots, and inebriety, must follow; in all probability rendering him subject to the notice of the police. *Should his face ever be seen at that office, it would be next to impossible that he should be admitted into any respectable circle.* What with lodging, dinners, wines, &c. of the worst description, but all rated at the highest prices, he must be a fortunate wight who escapes under a gold mohur (*i. e.* two guineas) *per* day: in general, double that sum is charged; so that a person starts at the rate of L. 1000 *per annum*, at least; while, in all probability, no established, or even apparent, provision exists, whereby he may be maintained."

"To state the evil, without pointing out the remedy, would be next to useless; but, when I suggest the means of avoiding those difficulties, or any portion of them, attendant on arrival in a foreign land, it must be understood, that I consider the stranger to be possessed of pecuniary means: that is, that he can pay his way. Without this, he can do nothing; and must undergo all the afflictions and miseries attendant upon despised poverty, in every part of the globe. It may be proper to point out in this place, that what might here appear to be liberal calculations, would not suit the East; where every article of European manufacture bears so enormous a price, where house-rent is so expensive, and where it is indispensably necessary to retain so many servants. The first thing to be done (setting a letter of recommendation out of the question) should be to report arrival at the Secretary's Office, depositing the certificate of the Court of Directors' licence to proceed to India; without which, the party is considered as an alien, and scarcely considered as entitled to British protection. This does not arise from ill-will on the part of government, or of the inhabitants; but from that strict attention the politics of the country imperiously demand to be paid to the several characters, and descriptions, of persons residing within our territory.

"The above relates equally to all persons in the civil or military branches; the certificate granted at the India House must be produced, in order to identify the party; but if it should have been lost, he himself, together with the commander who received the order for taking him on board, must attend, to make affidavit to that effect, before the appointment can be admitted upon the registers in India.

"Such as appertain to the civil service, being always strongly recommended, and often finding many old acquaintances of their families on the spot, require but little advice; nor does the cadet stand much in need of instruction, as to the manner in which he should provide himself with a home. All he has to do, is to wait upon the town-major, at his office in Fort-William, when he will receive the necessary order for his admission into the Cadet Corps, at Baraset, about sixteen miles from Calcutta.

"He who has not these advantages, must do the best his circumstances may afford; he will find temperance to be not only cheap, but indispensable; for, if he should act so indiscreetly at the outset as to injure his health, a thousand privations, and a certain increase of difficulties, must follow. The first point must necessarily be to get under cover. This will not be found so easy, as those who have never quitted England may suppose. It will be after much research, that a small house will be had, and then only the bare walls; for no such thing is known in India as a furnished house to be let; and lodgings are, if possible, still more out of the question. Fortunately, there are, among the European shopkeepers in Calcutta, some most respectable characters; men distinguished for their urbanity, philanthropy, and generosity. Application should be instantly made to one of these firms, for aid and advice. The case should be candidly stated; aad, in order to insure confidence, a deposit of money should be made, either with them, or at one of the banks. The consequences will be, that, in a few hours, some small tenement will be obtained, either on hire, or granted as a temporary accommodation, and the whole of the articles really necessary will be provided, at

Calcutta. some one or other of the auctions which daily take place within the central parts of the town."

Commerce. Calcutta is the great emporium of the east. By means of the Ganges, and its tributary streams, it has an uninterrupted water communication with the whole of the north of Hindostan, on the one hand, and with the whole of Europe, Africa, America, and great part of Asia, on the other. Thus advantageously situated for commerce, it trades extensively with almost every country in the world, and numbers of vessels of every form and description are constantly arriving or departing from the river, which, in the vicinity of the town, presents the busiest scene imaginable. Numerous dock-yards have also been established, in which are built vessels of great burden and of admirable construction. Piece-goods, shawls, indigo, silk, sugar, opium, and rum, are the staple commodities of export. Treasure is imported from all quarters. From London, the imports consist principally of articles of consumption for the European inhabitants, consisting of porter, ale, confectionaries; and, generally, of all the finer manufactures.

Public Establishments. In 1808 a bank was established at Calcutta, under the name of the Calcutta Bank. Its capital amounts to 50 lacks of rupees, of which ten were subscribed by Government, and the remainder by individuals. There are twelve Insurance Companies. Several newspapers are published weekly. The charitable institutions are numerous. Of these the principal are two schools for the education and maintenance of the children of Europeans in the military service of the Company, one for the children of officers, and another for those of privates; a free school at which about 100 children are educated, and a native hospital or infirmary. The Asiatic Society still continues its sittings, and publishes its Transactions, which contain much interesting matter concerning the history, literature, languages, and antiquities of Asia. An Auxiliary Bible Society has also been established at Calcutta.

Supreme Court. The Supreme Court consists of a Chief-Justice and two puisne judges, all nominated by the Crown. Its jurisdiction extends to all British subjects in India, and to all civil actions between natives, or between natives and Europeans. Criminal cases are tried in this Court by a jury, consisting exclusively of British subjects; as also all criminal charges against the Company's servants, and all civil actions in which the Company, or any of its servants, are concerned; but it takes no cognizance of the land revenues. The law practitioners attached to this Court are fourteen attornies, and six barristers.

College of Fort William. The College of Fort William, for the education of the junior servants of the East India Company, which promised at one time to be so great an establishment, is now reduced to a few lecture rooms in the Writers' buildings. It was begun in 1801 by the Marquis Wellesley, then Governor-General, and its object was to remedy the evils which had arisen from the ignorance of the Company's servants; to fill, if possible, the important situations of the Empire with men of learning, talents, integrity, and moderate habits; and along with a just administration of government, to spread the influence of literature, science, and the Christian religion, over the eastern world. The arrangements of the institution seemed well adapted in many respects for this purpose. But the extensive nature of the plan did not meet the views of the Court of Directors, and in June 1802, their instructions were received for its abolition; the period of which, however, the Governor-General delayed for various reasons till December 1803, having, in the meantime, addressed to the Directors a strong defence of the institution. In January 1804, instructions were received to continue it on its original footing. The institution accordingly proceeded with new vigour. All promotion to the service was made through the college, and was regulated entirely by the merit of the students, among whom an unexampled emulation in literary pursuits had arisen. In four years from the time of its establishment, one hundred original volumes in the oriental languages and literature had been published, and the plan of translating and printing the Scriptures in all the languages of the east had made great advances. In 1805, the students of the establishments of Madras and Bombay were separated from those of Calcutta; in consequence of this reduction of the extent of the college, the duties of the Provost and Vice-Provost were united by a minute of the Governor and Council in one person, under the title of Provost; and in January 1807, the offices of Provost and Vice-Provost were abolished; the Professorships were restricted to three,—those of the Hindostanee, Bengalee, and Perso-Arabic; the period of attendance was reduced to one year, and all control over the private expences or conduct of the students was given up. On this reduced and limited footing the establishment still continues.

Population. The population of Calcutta, which is stated by some to amount to 500,000, by others to 700,000, is composed of persons from every quarter of the world. British, and other Europeans, Armenians, Persians, Chinese, Hindoos, and Mahomedans, are all seen mixing in the streets of this metropolis. The occupations of these various classes are nearly what might be expected in the luxurious capital of a great Empire, and in so great an emporium of maritime commerce. Public officers, lawyers, physicians, merchants, and their families, make up the bulk of the British inhabitants. The natives and foreigners of respectability are mostly engaged in trade, or living upon their property, and the lower classes are principally composed of retail-dealers, mechanics, and servants.

Different Classes of Merchants. The British merchants form a most respectable class of men, and contribute essentially to the prosperity of the settlement; many of them are possessed of large fortunes, and live in a style of suitable splendour. The Armenians are the most numerous body of foreign merchants in Calcutta. They trade extensively to all parts of India and China, are uncommonly diligent and attentive to business, and are considered to have the most minute intelligence from foreign ports of any other body of merchants. The native bankers, agents, and money-dealers, are numerous. Though formerly timorous, the Hindoo now adventures in almost every species of mercantile speculation; and cloths belonging to the native merchants, to the amount of

L. 1,000,000 Sterling, are generally lying for sale in the warehouses of Calcutta. The native merchants of an inferior class, engross nearly the whole of the retail trade of Calcutta, under the titles of Banians, Sircars, and Writers; and they are generally described as fond of money to excess, and most unprincipled in all their dealings.

Cold and Hot Season.

The cold season, which lasts from September to April, is generally allotted to amusement and festivity in Calcutta. It is only during part of this season that it is possible to venture abroad in the heat of the day, which, in the rest of the year, is devoted to repose. The hot season begins in April. Every day the heat increases until the middle of June, when the periodical rains begin, and last till August. The weather then being extremely close, is more oppressive, and more unhealthy than before. The thermometer, throughout the year, generally ranges between 75° and 95°, but frequently rises to 100° and 110°.

Markets.

The markets at Calcutta are open at day-break, and they afford, at very moderate prices, meat of every kind, and poultry, with various kinds of choice fish, fruits, and vegetables; also game, such as wild ducks, partridges, snipes, &c. with various kinds of ortolans. The wild venison is not nearly so good as that of Britain, but the park or stall-fed is equally good. The hare is very different from that of England, being defective in size, strength, and swiftness.

Rise of the Ganges called the *Bore.*

That sudden rise of the waters, termed the *Bore,* is quite common on the Hooghly, as well as on the other branches of the Ganges. The general cause of this appearance is sufficiently understood, but it is not easy to explain the details. It is common on several of the rivers in England; it is also known on the waters of the Dordogne and Garonne in France, under the name of *Mascaret,* and in the Amazons in South America, where it is termed the *Prororoco.* It is an immense wave, which, in the Hooghly, heads the spring flood-tide, travelling before it, at the rate of 80 miles an hour; and, what is most singular, not occupying the whole breadth of the stream, but ranging along one of the banks, and crossing over to the opposite shore at every considerable bend of the river. It begins about 40 miles below Calcutta, and is felt, but with continually decreasing effect, nearly as far above it. At Calcutta it ranges on the opposite bank. The swell is prodigious; and, on its approach, all the small craft fly for safety to the middle of the river, where, though the swell is still considerable, they are not exposed to the same imminent danger. At Calcutta it often causes an instantaneous rise of the water of five feet.

(O.)

CALEDONIAN CANAL. The importance of this great national undertaking, whether considered as a work of magnitude and expence, as tending to open up and improve some of the most barren and rugged districts in Scotland, or to facilitate the intercourse between the eastern and western sides of Great Britain, by rendering unnecessary the navigation of a circuitous and dangerous coast, induces us to treat of it separately, and to furnish our readers with a correct map or plan of its line, reduced from the maps laid before Parliament.

First idea of this great Work.

So early as the year 1773, Mr James Watt of Soho, to whom mankind and the arts are so much indebted for his improvements in the steam-engine, was appointed by the Trustees or Commissioners for certain Forfeited Estates in Scotland, to make a survey of the central Highlands. Mr Watt, in his Report to that public body, recommended, amongst other improvements for the Highlands, the formation of the Crinan Canal, which has long since been executed, and also of the Caledonian Canal, from Inverness to Fort-William, now in progress, and which we are immediately to describe.

Circumstances which led to its adoption.

The late rapid introduction of the sheep-farming system having necessarily deprived multitudes of the inhabitants of their former means of subsistence, the formation of roads and canals, and the multiplication of fishing stations, came to be looked to, as affording the most likely means of mitigating the evils consequent upon this great and sudden change of system; and in pursuance of this view of things, the Lords of the Treasury, in 1802, directed Mr Telford, Civil Engineer, to make a survey of the coasts and central Highlands of Scotland. The Report which he in consequence drew up, involves a variety of considerations connected with the improvement of the Highlands, and the employment of the population of these districts; but the part of it which we are more particularly to consider, is that which refers to the proposition of an inland navigation from Loch Beauly and the German Ocean on the eastern coast, to Loch Eil and the Atlantic Ocean, on the western coast. Mr Watt proposed that the depth of this canal should be ten feet, or two feet more than the Forth and Clyde Canal; but Mr Telford, considering the great command of water from the chain of lochs or lakes in its line, and aware no doubt of the advancing state of maritime adventure, and of the inconveniences which are felt from the small scale on which that navigation has been executed, though originally termed the *great canal,* was induced to propose a depth of twenty feet for the Caledonian Canal; that it might thus be capable of floating twenty-eight gun Frigates, and the largest class of Baltic traders.

The Parliamentary Committee, which had been appointed in reference to the situation of the Highlands, had corresponded with the Highland Society of Scotland as to the means of improvement; and, before finally reporting upon this great and bold plan, they called before them the most eminent Engineers, nautical Surveyors, Mariners, and Merchants in the kingdom. In particular, Mr Jessop and Mr Rennie, Civil Engineers, were severally examined with regard to the practicability and expence of the plan proposed by Mr Telford; and Captain George Duff, of the Royal Navy, Captain Huddart of the Trinity House, London, Lieutenant Gwynn, Commander of the Fort-Augustus galley on Loch Ness, and several others, were examined upon points touching the navigation and anchorage for large vessels.

Caledonian Canal.

Returns were also procured from the ports of Dublin, Liverpool, Greenock, Leith, and Aberdeen, regarding the probable advantages of the proposed inland navigation, and to what extent it would be useful. This Committee, after much investigation, reported as follows:

"Your Committee, from a full consideration of all the evidence laid before them, and annexed to this Report, by way of Appendix, submit to the House their opinion: That the execution of the inland navigation, proposed in Mr Telford's plan, under all due regulations, for the economical expenditure of such monies as may be employed in this great work, will be a measure highly conducive to the prosperity and happiness of that part of Scotland in which it is situated, and of great importance to the general interests of the whole United Kingdom."

First Act of Parliament.

A Bill was, accordingly, brought into Parliament, on the Report of this Committee, in the Session of 1803, entitled, "An Act for granting to his Majesty the sum of L. 20,000, towards defraying the expence of making an inland navigation from the Eastern to the Western Sea, by Inverness and Fort-William; and for taking the necessary steps towards executing the same;" which Act received the Royal Assent on the 27th day of July 1803.

The Board of Commissioners for the Caledonian Canal, appointed by this act, accordingly met, and made certain arrangements for the immediate commencement of the work; having, in the first place, appointed Mr Thomas Telford to be their Engineer. He had formerly been employed by the Lords of the Treasury in making various surveys of the Highlands. But in so important an undertaking, the Commissioners judged it necessary to call to his assistance Mr William Jessop, another eminent and experienced Engineer. Mr Telford, instructed by the Commissioners, proceeded immediately for Scotland, and again made an entire survey of the whole line of the canal from Inverness to Fort-William. To ascertain the soil, trial-pits and borings were made from shore to shore, at distances not exceeding half a mile. Mr Murdoch Downie, an experienced Marine and Nautical Surveyor, was employed to make a survey of the chain of lochs upon the line, in order to sound and determine their respective depths and anchorages. The line of the canal, where *cutting* was necessary, was now carefully laid out. Stone and lime quarries, timber and other necessary materials were looked after, and some idea was formed as to the probable value of the land to be passed through. Places were also fixed upon for the entrance-basins or sea-locks, at both extremities, and every possible information prepared for Mr Jessop's survey, which took place in the month of October. He was met by Mr Telford at Edinburgh, and these gentlemen proceeded together to a full examination of the whole; and, upon this survey, Mr Jessop reported his opinion to the Commissioners, and furnished an estimate of the expence. The chief difficulties alluded to in his Report, as incident to this great work, refer to the cutting new channels or courses for the rivers Ness, Oich, and Lochy,—the deepening Lochs Doughfour and Oich by excavation,—the damming up and raising the surface of Loch Lochy, which is about ten miles and a half in length, to an additional depth of twelve feet,—the *spilling* or running off its flood-waters by a new cut into the River Spean; and some extra cutting at the summit level between Lochs Oich and Lochy. But one of the most difficult parts of the navigation, is stated to consist in the deepening and management of Loch Doughfour. Mr Jessop seems to have been prepared to meet with rather an unfavourable soil for canal operations; he was of opinion, that the whole valley between Loch Ness and Fort-William, has been one entire sheet of water; and that the portions of land intervening between the lochs are the *debris* of the adjoining mountains. The first *trial-pits* dug in the neighbourhood of Inverness, did not fail to give some alarm upon this subject, as the ground consisted of sand and gravel so open and porous, that the tidal waters of Loch Beauly flowed and ebbed through it. But on other parts of the line of the canal, the gravel was found to have such a mixture of earthy particles as would be sufficient to render it impervious to water.

First Dimensions and Estimates.

The extent of canal to be formed and cut, is stated to be about $21\frac{1}{2}$ miles, and the loch or lake navigation at $37\frac{1}{2}$, making a total distance of inland navigation from sea to sea of about 59 miles; the bottom width of the cutting 50 feet, with slopes of 18 inches to a foot, with *benchings* at the water-line, making the width at the surface to be about 110 feet. The general dimensions of the canal, though afterwards enlarged, were now estimated at 20 feet for the depth; the width of the locks is taken at 38 feet, and their length at 162 feet. The number of locks is estimated to be 23. They are to be built of masonry, with gates and platforms of American pitch-pine. After critically examining the whole intended line of the Caledonian Canal, its proposed dimensions, soil, materials and workmanship, Mr Jessop estimated the expence at the sum of L. 474,531, including 8 *per cent.* for contingencies; but exclusively of the price of land, and the necessary moorings for the anchorages at the respective lochs. Upon a joint Report afterwards by Messrs Jessop and Telford, this sum is proposed to be expended, and the works completed, in the course of seven years from the period of their commencement.

Dimensions finally adopted.

In this stage of the affairs of a work so extensive in its operation, and so important in its consequences, it became of the last importance, in finally resolving upon the dimensions of the first lock, to fix upon such as would answer, in the fullest manner, all the purposes of the intended navigation. To this point, therefore, the attention of the Engineers was again directed; especially as the dimensions of the first lock would not only regulate all the rest, but also the works of excavation along the whole line of the canal. After maturely deliberating upon all the information which had been obtained, regarding the description and tonnage of the shipping which navigate the northern seas, and advising at large, as before noticed, with Engineers, Mariners, and Merchants, upon the important subject of the dimensions of the canal;—it having been specified in the act authorizing this work, that such an inland navigation should be formed, as, when completed,

might "enable ships and vessels of considerable burden, trading between the eastern and western coasts of Great Britain and Ireland, and the German Ocean, to avoid a long and dangerous navigation round the northern coasts of Scotland;" the Commissioners, considering also that the proposed dimensions of the works of excavation, viz. 20 feet of depth, 50 feet of width at bottom, and 110 feet at the surface water-line of the canal, would admit and be sufficient to float a 32 gun frigate; and as only a very small addition to the original and annual expence would be incurred by enlarging the locks for that purpose;—it was finally ordered, that the length of the locks should be increased from 162 to 172 feet, and that the breadth should be from 38 to 40 feet, the depth to remain at 20 feet as before intended. The Commissioners thought it their duty to prefer this large scale of construction, as, although it would increase the expence, the canal would thereby be capable of affording an occasional passage to that class of His Majesty's ships, of which there was, at that period, upwards of forty in the service, which must otherwise have been excluded from it. In this resolution, the Board of Commissioners had also in view the increasing tonnage of merchant ships, as some of the vessels trading between Liverpool and the Baltic, approach to the dimensions even of these enlarged locks.

Side Locks.

With a view to give greater facility to the passage of small vessels, and to avoid the consequent wear of the large locks, the Engineers had been directed to consider the propriety of constructing small *side-locks* for vessels of about 200 tons, which draw about twelve feet water, or of such dimensions as to correspond with the depth of the Crinan Canal. This appendage of small locks, it appeared, would have added to the original expence about L. 75,200; and considering that two, or even three small vessels might pass together through the large locks, the advantages attending the side-locks appeared to be very uncertain, and the idea was therefore laid aside for the present.

New Act of Parliament.

It appears from the first Report of the Commissioners for making the Caledonian Canal, that the sum of L. 6052, 10s. 10¾d. had been expended in the preparatory measures for this great undertaking. In the Session of Parliament 1804, another act was passed, entitled, "An Act for making further Provision for making and maintaining an Inland Navigation, commonly called The Caledonian Canal, from the eastern to the western Sea, by Inverness and Fort-William in Scotland." By this additional act, a further provision of L. 50,000 was made for this undertaking.

Commencement of the Work.

In the month of June 1804, the Commissioners resolved that Mr Jessop should again visit the line of the intended navigation in concert with Mr Telford, that they might jointly inspect the progress of the works already commenced, and re-examine all the particulars of the former survey; that they might determine the position of each lock on the whole line of the canal, and, as far as possible, fix the situation, dimensions, and construction of the bridges, culverts, and other necessary works; and that they might take into consideration the manner in which it would be most convenient to connect the line of the canal with the several lochs or lakes forming part of the intended navigation; and also fix and arrange the price of labour, and the mode in which the several works would be most advantageously let or contracted for.

During the first year (1803), the operations were merely of a preparatory nature, and the number of workmen did not exceed 150. But in the year following they were increased to upwards of 900, when it became necessary to appoint resident Engineers, particularly at the extremities of the line, to which the first works were entirely confined. For this highly important charge, Mr Matthew Davidson, who had acquired much experience at the works upon the Elsemere Canal, particularly at the great aqueduct of Pontycycelte in Denbighshire, was appointed to the eastern division, and Mr John Telford took charge at the western end.

Prices of Labour and Materials fixed.

In the commencement of operations of this public nature, it became an important consideration to interfere as little as possible with the rates of the stated labour of the country; and therefore, as well as from motives of economy, only about one-sixth part of the work was done by *day-labour*, the other parts being done by *contract* and *measurement*. The rates for day-labour and workmanship, as fixed by Messrs Jessop and Telford in 1804, we shall state, more as a matter of future, than of present interest. Labourers by the day, were paid from 1s. 6d. to 1s. 8d. and 2s., according to the description of work. The works of excavation and embankment varied according to the distance of removal. That for the earthen work of coffer-dams of the eastern division was 9d. *per* cubic yard, exclusively of pumping water, working the puddle in the banks, or expence of railways. The rate or price of iron-work to be 5½d. *per* lib., when the price of Swedish iron is at L. 30 *per* ton at Inverness. Timber work in coffer-dams, and sheeting to locks, 6d. *per* cubic foot for labour only. Ruble masonry, laid in lime mortar, at 11s. *per* cubic yard, cut stone or squared masonry at 1s. 7d. *per* cubic foot, exclusively of pozzolano or tarras, where necessary. In common earth cutting, including puddling and forming the banks, the price throughout the whole works was not to exceed the average rate of 6d. *per* cubic yard; excepting in cases where the removal of the puddle should exceed 100 yards, when an extra allowance was to be made by the award of Mr Thomas Telford. Also, wherever the removal of earth by barrow exceeds 60 lineal yards, or 120 yards by barrow-carts, an allowance to be made over and above these prices, at the rate of ¾d. *per* cubic yard for every *run* of 20 yards by barrow, or 40 yards by barrow-carts. The same rate of prices is applicable to the works of the western division of the canal, only in such instances as the circumstances differ materially. Part of the excavation at the western end is in rock, which is to be paid for at the rate of 2s. *per* cubic yard, and the excavation and embankment at 8d. *per* cubic yard. The most considerable difference here was in the price of cut stone, or squared masonry. At the eastern division, the quarry of Redcastle is only about five or six miles from the work; while

at the western division, the cut stones for hollow quoins, coping stones, &c. were brought from the Cumbrae Island in the Clyde, distant, even by the Crinan Canal, upwards of 100 miles; the price of cut stone work was consequently fixed at 2s. 5d. *per* cubic foot, instead of 1s. 7d.; or if granite from Ballahulish, distant about twenty miles, should be used, the price to be at the rate of 2s. *per* cubic foot. But even these prices were, upon due investigation, found to be insufficient, and the contractors were afterwards allowed at the rate of 3d. *per* cubic foot in addition for cut stone, and 1s. *per* cubic yard for ruble work.

These highly important arrangements being made, the masonry, and much of the work of excavation and embankment, were undertaken by contract, and proceeded with great alacrity. Men skilled in the various branches of canal work resorted to the Caledonian Canal, from all parts of the united kingdom; and no less than about one thousand men have been employed on an average for the year; so that this tract of country, lately a forlorn waste, became all at once a place of active industry. The Highlander, hitherto accustomed to loiter away his days in indolence, looked on for a time with astonishment at the exertions of his southern brethren, and ere long mixed with this busy scene. In this respect, the Caledonian Canal has been of immense advantage to the Highlanders, a fact which the writer of this article has had many opportunities to observe.

Description of the Line of the Canal.

Having thus stated the commencement of the Canal, we shall next give a general description or outline of the country through which it passes, proceeding from the east to the west sea. Mr Watt, in his Report of 1773, observes, that the regularity of this extensive tract is quite astonishing, in so mountainous and rugged a country. Mr Jessop, in his first Report, says, that at some early age of the world, it seems probable this immense chasm (the line of the Canal) has been nearly open from sea to sea. Though the investigations of the Geologist have, as yet, we may observe, made small progress in elucidating the probable revolutions which the earth has undergone; and although, upon every hand, he is met by difficulties, and contradictory appearances, yet it is scarcely possible that any one who has examined and considered the appearances of this interesting chain of salt and fresh water lochs or lakes, can doubt that, at some period of the world, the sea has occupied a higher level; that the country in the vicinity of the towns of Inverness and Fort-William have been, at one time, covered by it to a much greater extent; and that at some period the whole of this chain of lakes, thus forming one great sheet of water, had only one *barrier*, at the eastern, and another at the western extremity. These barriers or fences, in the course of time, being worn down, the increased issue of the waters from the original loch, would have a tendency to lower the surface of the water, and thereby expose the highest parts of the bed, and thus ultimately form the divisions or necks of land which we now find separating and dividing these lochs. So much of probability does this theory carry with it, that, along the whole length of the line of canal, the excavated matters, with little exception, are found to consist chiefly of gravel and water-worn stones: these subdivisions, once formed and exposed to the atmosphere, would acquire vegetable and adventitious matters; and in time, by the wearing of the beds of the original outlets, these patches of land would rapidly increase.

Compared with other parts of the country.

But whatever may have been the actual state of matters here, at an early period, the great vale, or perhaps more properly, the chasm, of the Ness and Lochy, is, without exception, the most remarkable in the kingdom; for, in a distance of about sixty miles, from sea to sea, the summit level of this navigation is only about 94 feet above the level of the ocean. There are, indeed, some approximations to this state of things; as, for example, between Crinan and Lochgilphead,—(the line of the Crinan Canal.) This may also be noticed of various other parts of the kingdom,—as between the great Wash of Lincoln on the east, and the vale of Gloucester and Severn on the west; between the river Tyne and the Solway Firth; the Firth of Forth, by Blair Drummond Moss, and the Clyde. Perhaps the nearest to the vale of the Ness and Lochy of those mentioned, is that between the Forth and the Clyde, which passes between two ranges of hills; but all of these come far short, in sublimity of effect, to the line of the Caledonian Canal, where the hills rise to a stupendous height, while the bottom of the *dell*, or vale, is interspersed with extensive sheets of water.

1. Eastern District.

We shall now proceed to notice the position of the first, or sea lock, of the canal at Loch Beauly on the east, and so advancing westward, describe the works of this great Inland Navigation. The precise spot originally intended for the Eastern Sea or tide-lock, was rather to the north-eastward of the present site; but the ground, upon trial, was found not to answer the purposes of a foundation, for such a weight of masonry.

Sea-Lock.

The sea lock of Clachnaharry is about three quarters of a mile to the westward of the much frequented Ferry of Kessock. It extends upwards of 400 yards into the sea, or beyond the high water mark, where it is expected a depth of water, equal to about 30 feet, will be obtained at high water of spring-tides. The writer of this article, attracted by the magnitude and novelty of this particular operation, visited it in the autumn of 1811, when the masonry was then in a half finished state; and cannot pass this extensive and interesting part of the works, without noticing more particularly its progress and completion. The unexampled price of foreign timber, especially of large dimensions, about the year 1807, had induced the Engineers to delay commencing the sea lock as long as possible, in hopes of a change of circumstances. In 1808, however, it was thought advisable to lay down an immense quantity of rubbish, in the form of two parallel mounds, extending from the second canal lock into Beauly Firth. This was done by means of two sets of railways; one from the ruble stone quarry of Clachnaharry; and the other, consisting of a kind of indurated clay, was carried across the line of the canal from an adjacent hill, along the site of the intended sea lock; that it might answer the purposes of a

coffer-dam, and consolidate the subsoil or strata of matters deposited from the joint operation of the River and Firth of Beauly. These strata, when bored to the depth of about 54 feet, were found to consist of soft bluish clay or mud, overlying a whitish clay, similar to the base of the neighbouring hill of Clachnaharry. These mounds of rubbish extending into the sea, were found to settle and subside so much, as to require an additional stratum of 11 feet in thickness to restore them to their former level; an effect which was, no doubt, expected; but this, however, was the means of suggesting the propriety of laying also a quantity of rubbish between these mounds or parallel banks upon the site of the sea lock, which, in the same manner, had the effect of compressing the subsoil, and preparing it for the immense weight of masonry it had to support, which could not have been the case, had it been built with a coffer-dam in the usual way: the finished work might, in that case, have subsided in the same manner as the mounds had done, which would have been productive of the most serious consequences to the work. This consideration, in conjunction with the high price of timber, induced Messrs Jessop and Telford to adopt the simple but more secure method just described; and when the mass of rubbish had sufficiently subsided, they commenced their operations by excavating the lock-pit in the mound of rubbish lying upon the site of the lock to the depth of about 30 feet, when the subsoil was found in such a state of consolidation, that the excavation had proceeded to a considerable depth before it was found necessary to have recourse to the power of steam, for pumping the water out of the lock-pit. It has indeed been remarked of the adhesive nature of this ground, that although piles were driven with great ease into it, yet, after they had remained for a time in the silt, it was neither found practicable to draw them out, nor to drive them farther into the ground. When the area of the lock-pit had been dug to a sufficient depth, a course of large stones, two feet in thickness, was laid in the middle for supporting the key-stone of the inverted arch of the lock. This foundation course increased in thickness to five feet towards the springing in front of the side walls, which were built upon it with all possible dispatch, in lengths or compartments of six yards at a time, till the whole was brought to the height of the silt, or to about eight feet, that it might not be unduly exposed to *wet and dry*. In this manner the work proceeded, till the chamber of the lock was formed by the side walls, when the inverted arch and sides of squared masonry was built upon this layer of ruble work, which finished the work. The construction of this lock is particularly noticed in the Parliamentary Reports with marks of approbation to all concerned; and, with much propriety, the Commissioners have there been pleased to notice the successful exertions of Mr Davidson, the Resident Engineer.

Clachnaharry Lock and Basin.

Having thus given a general description of this tide-lock, which has a lift or rise eight feet six inches, and is, perhaps, the most extraordinary work upon the whole line of this navigation, or, indeed, in any part of the kingdom; proceeding eastwards, we come to the second, or Clachnaharry lock, which is contiguous to the sea-lock, being itself barely within the high water mark. It is close to the small fishing village of Clachnaharry, which, prior to the commencement of these works, consisted of six or eight fishermen's huts. It has still but a few additional houses, yet when this navigation is fully opened, it may rapidly increase, and in time become the port of Inverness, and a place of considerable trade. Clachnaharry lock has a perpendicular rise of six feet, and forms a division between the sea-lock-basin, and the great basin of Muirton, containing an area of about twenty acres. This great basin is of an oblong, and rather irregular form, but is well suited to the figure of the ground; it is formed by works of excavation and embankment, and has a wharf wall of considerable extent, which will be convenient for the town of Inverness, from which it is distant only about one mile. To defend the projecting mounds upon each side of the sea-lock, ruble stones are laid upon the external slopes with such a gentle declivity to the sea, as to be sufficiently secure against the impression of the waves of the Beauly Firth, while the exterior bank of the Muirton basin is defended from its encroachment, by a dike of considerable extent.

Swivel Bridges.

At the southern extremity of this basin, the road from Inverness to Beauly crosses the line of the canal; and here a handsome Turn or Swivel Bridge of cast-iron, on a very light construction, has been erected upon piers of masonry. Canal bridges were formerly constructed of timber, and lifted in two leaves or halves by chains and a large timber framing; but they are now chiefly framed of cast-iron, the roadway only being covered with timber; and by the latest improvements they are raised by a wheel and pinion, as originally projected by Mr Perronnet for the Neva, at St Petersburgh, and now introduced on the Forth and Clyde Canal; or as here managed, they are made to turn in two pieces, each placed upon an opposite abutment of masonry, and move upon a centre, similar to those of the West India and London Docks. The compartments which project over the water way of the canal, meet and joggle into each other, while the opposite ends, towards the land, are loaded so as to balance and become a counterpoise to the projecting parts. When a vessel is to pass, the two parts of the bridge are disengaged, and turned off the line of the canal in a horizontal position, by a person stationed on each side of the canal, who works it with a kind of key-bar with a cross head. This key is made to fit the pinion, which works in the segment of a wheel several feet in radius, and is thus easily turned out of the way of the rigging of passing vessels.

Muirton Locks.

The Muirton locks are four in number, and have each a rise of eight feet. The foundations of these locks were upon the whole easy, being upon a bottom of hard whitish clay, mixed with gravel; by building them in one connected range, it was necessary to lengthen each a few feet, to give accommodation to the largest vessels; but still a considerable saving is introduced by this method, as the head and tail walls, and also one pair of gates, are saved. These locks, when viewed from the bridge below, and especially when the gates are open, present a very noble

appearance, and seem to be upon the whole an excellent piece of masonry. The gates or valves consist of British oak for the lower and upper gates, being more liable to accident of ships coming against them than any of the intermediate ones, which are framed of cast-iron in great bars, covered over with strong oak planks, attached to the cast-iron work by numerous screw bolts with nuts. Lock-gates of cast-iron have been for a considerable time in use. Perhaps the first of these were constructed on Carron River, upon a small dock for the repair of the Carron Company's ships; but they are very trifling compared with the great dimensions of the Caledonian Canal-gates, which measure 30 feet in height, and each leaf is 22 feet in breadth. Cast-iron gates, however, seem to have been brought into use here, rather as a matter of necessity than of choice, from the difficulty and expence of procuring oak of sufficient scantling or size. The lock-gates have a very stupendous appearance, yet are moved with comparative ease, by means of chains with a wheel and pinion upon the most approved principles. The *heel* of the gate, or that part which works in the hollow quoins, is placed upon a pivot, and the *toe*, or outward extremity, is fitted with a roller connected with a screw-bar, in such a manner that the roller may be raised or lowered to suit the ground-sill of the lock, where a segment of cast-iron is inlaid, on which the roller and gate traverse, in opening and shutting; so that these stupendous gates, weighing about 40 tons, are opened and shut with great facility, by one man on each side of the lock.

onry of
Locks.

The masonry of the sea lock is executed wholly of freestone or sandstone, from Redcastle quarry; but the second, or Clachnaharry lock, and also the four locks at Muirton, and the abutments of the Muirton and Bught Bridges, are only faced with Redcastle stone, the inward walls or backing being ruble stone, from the more contiguous quarry of Clachnaharry.

It deserves to be noticed, in this place, that the whole of the face-walls of the masonry here were only specified and paid for as common ruble work, instead of which, with few exceptions, the work is executed of a superior quality, in regular courses, technically called *coursed ruble*. This certainly does much credit to the spirit in which the contractors for this great undertaking seem to have conducted their operations; and it is but justice here to notice the name of a person who, for many years, was eminent as a contractor for masonry, especially for canal works, harbours, and bridges, throughout the kingdom—we mean the late Mr Simpson of Shrewsbury, principal contractor upon the Caledonian Canal,—a native of Scotland; and who, it is believed, has superintended and executed more work of this kind than perhaps any other individual in the line of his profession.

pence
Locks.

It is not always possible to apportion the expence of the several compartments of a large work, so as to show the neat cost of each, but it seems probable that these locks, upon an average, exclusively of the sea lock, will have cost, when entirely finished, not less than L.8000. This sum, compared with other works also of considerable magnitude, appears to be very moderately stated, although it is somewhat higher than the estimates of 1804, and considerably more than had been originally calculated upon in 1802. Besides the difference of time between the estimates and the execution of the work, the unexampled rise in the price of labour, and indeed of every commodity. The estimate of 1802 applied to locks of a very different construction from those actually executed. The locks originally proposed by Mr Telford would, no doubt, have been considerably less expensive, probably not exceeding L. 5000, as they were only meant to have had masonry at the gates, while the space between was to be embanked, like the other parts of the canal. But as this would have made the navigation much more tedious, it was determined to line the lock-chambers with masonry, in the usual way, when the locks were then estimated, each, at L. 7500; so that this part of the work may fairly be considered as not greatly exceeding the estimate.

Reach from
Muirton
to Loch
Doughfour.

On the Reach of the canal between Muirton locks and Loch Ness, the distance is about five miles. The works of excavation here are chiefly in gravel, some parts of a loose and others of a more compact nature; and containing various proportions of earthy matters. But, upon the whole, the soil is exceedingly bad for canal work; which renders it necessary to trust a great deal to the puddle-walls of the banks and bottom, against the pressure of the great depth of water in this canal. On this reach there is some deep cutting, in passing the singular hillock of Tomnahurich; and the road on the eastern side of Torvaine hill, has been carried by a new line on the western side. A considerable embankment also became necessary to the westward of the lands of Bught, where the eastern bank of the canal is actually formed on the bed of the river Ness, under the hill of Torvaine. Here the course of the river has to be altered and widened by cutting away part of its eastern bank, for the space of about half a mile. A similar operation, but of smaller extent, became necessary under the hill of Toremore, where the canal banks again trench upon the river Ness; after which, the only work of expence on this reach, is the construction of a regulating-lock and weir for the waters of Loch Ness.

It was, no doubt, a bold attempt, to place the bank of a canal upon the verge of a considerable river, but after a trial of several years, it has sustained no material injury. This arises entirely from the waters being, in a good measure, regulated and apportioned by the great receptacle of Loch Ness, which so regulates the stream of that river, and checks its velocity, as to prevent the injurious effects that would, under other circumstances, attend the exposed state of the canal banks at this place, however well armed and secured by a facing of boulder or ruble stones, upon the slope of the outward bank.

Regulating-
Lock.

The Regulating-lock for Lochs Doughfour and Ness has a rise of six feet six inches, and is situated about half a mile northward from the former, which connects with Loch Ness by the narrow channel of Bona Ferry. This lock was intended to have been placed somewhat nearer the loch, and was proposed to be carried across the stream of the river Ness; but a proper foundation could not be found for it there. The close connection of its site with the river, has necessarily increased the difficulties of this part of

the canal, while the operations were unavoidably retarded by the land-carriage of the Redcastle stone, for the outward walls, brought over land from Clachnaharry, a distance of about six miles. Great labour and perseverance were exerted here, in clearing the lock-pit of water, to the depth of about 20 feet under the level of the bed of the river. This work commenced in July 1812, and the masonry was completed in about two years, without the occurrence of any material accident. The name of Regulating-Lock sufficiently implies its use. Connected as the canal is at this end with Lochs Doughfour and Ness, which extend about twenty-four miles to the south-westward, through a range of mountains, and, consequently, forming the drainage of a great extent of country, it is obvious that these extensive lochs must receive vast quantities of water during wet and rainy seasons, but especially in time of thaw, when there is much snow upon the ground. The effect must be, to raise the surface of the water of Loch Ness, which has been known, on such occasions, to rise from six to eight feet above its ordinary summer level. Indeed, the remarkable regularity of the gravel beach round its margin,—the present position of many aged alder trees, even within the summer water-mark along the shores, sufficiently indicate this, and lead us to suppose, that the surface waters of the loch are, upon the whole, in a state of increase. At all events, we are certain, that the water of these lochs must have a tendency to rise, from the great quantity of debris which is constantly falling in and silting up the bottom, while the surface to be drained, and the quantity of water flowing into it, remains nearly a constant quantity. This process is, therefore, likely to keep pace with the wearing away of the bed or channel of the river, by which the flood or speat waters are let off; considerations which, of course, form the limits of the regulating lock and weir across the River Ness, connected with this chain of lochs.

Operation of deepening Loch Doughfour.

One of the most difficult operations in forming this navigation, is the deepening of Loch Doughfour. This Loch, as will be observed from the map, is connected with the eastern end of Loch Ness by the narrow pass of Bona Ferry. It is about one mile in length, and varies from 100 to 150 fathoms in breadth. From the rapid current at Bona Ferry, it appears that the fall of the water, towards the river and the sea, commences here, and with Loch Doughfour forms a receptacle for much of the gravel and debris, which is brought down from the extensive shores of Loch Ness. This part of the navigation it was therefore found necessary to deepen, by artificial means, in some places, to nearly the full depth of the canal. This was done partly by a powerful dredging-machine, which is floated upon a barge. The apparatus is somewhat complicated, but the chief part is a succession of iron buckets, connected by an endless chain made to revolve round a frame, which is let down into the water to any convenient depth, and lifts silt, gravel, and other matters from the bottom. This machine has been long in use in clearing mud from the bottom of harbours and rivers. Till of late years it was worked by the power of men and horses, but where much is to be done, as on the Caledonian Canal, the steam-engine is substituted as the moving power; which requires a barge or vessel of great strength to carry it. The dredging-machine has been used with much success at Loch Doughfour, where it is calculated to have lifted about 90,000 tons of gravel in a twelvemonth. The stuff lifted is received from the dredging-machine, as it comes out of the water, in punts or lighters, and is carried to a proper place for deposition. By such means, the navigation from the eastern end of Loch Doughfour to Loch Ness is brought to a depth no where less than ten feet. In the course of this arduous operation, the roots of large trees have been lifted, weighing several tons. Even rock has been excavated at this depth under water, by means of placing picks instead of buckets upon the revolving apparatus.

Weir across the Ness.

To obtain the additional depth of water, beyond the reach of the dredging-machine, a weir or dam is to be placed across the eastern end of Loch Doughfour, where the river Ness properly commences. This dam or weir will not only deepen the loch, but will check the current at Bona Ferry, and prevent the tendency of the *debris* from being carried from Loch Ness into Loch Doughfour. The waters of the Ness will then be drawn off from the surface of the loch, and will cease to carry with it quantities of stones and gravel, as at present, and Loch Doughfour will become an excellent place of anchorage for wind-bound ships. The operation of building this dam or weir across the Ness, has not yet been commenced. It will be attended with considerable difficulty from the current of the river, and from the requisite strength and important purposes to be served by it.

Loch Ness.

Loch Ness, forming so considerable a part of this navigation, is about twenty-two miles in length, of a pretty uniform breadth, varying from about one mile to three quarters of a mile. Its depth of water is from 106 to 130 fathoms in the middle or deepest parts. The sides of the loch appear to be steep and precipitous, as it suddenly deepens to 70 and 80 fathoms; except in the creeks or bays of Dores, Urquhart, Inver Morrison, Cherry Island, and the western extremity of the loch. The depth of water in these varies from 12 to 20 fathoms; but even these soundings are so close to the shore, that it has been suggested to lay Mooring-Buoys to enable ships to stop for a time; as it would be quite unsafe, especially for ships of great tonnage, *to let go an anchor*, chiefly from the difficulty of *purchasing* or lifting it. Indeed the necessity of this in these lochs is in a great measure superseded, by the proposed use of the steam-boat for tracking ships; and the anchorage or mooring buoys for large vessels may now be confined almost entirely to the east and west ends of the loch; as the distance to return to either end, in the event of such weather as may prevent the steam tracker from proceeding, cannot be a matter of much moment. The application of steam as a power for impelling ships, is a discovery of the greatest importance to the speedy navigation of the Caledonian Canal. Upon the formed banks a tracking-path is readily obtained, but along the precipitous shores and cliffs of the lochs, this would not be so easy a matter; and, even if formed, would not be conveniently brought into use for tracking ships of burden. For although vessels of about 200 or even 300 tons, might *tack* or work in Loch

Steam-Boats.

[Cale]donian [C]anal.

Ness and Loch Lochy, yet even for these it would be an extremely troublesome operation; and altogether impracticable in the case of ships of war, or the largest class of merchant vessels.

[Effe]ct of [the] Winds [o]n this [nav]igation.

There has been much discussion respecting the sailing of ships on the loch part of this navigation. It had been asserted, that the winds blow almost constantly in a current from the south-west so as to render it difficult, if not impossible, to pass by this navigation from the eastern to the western sea. But, upon a more minute attention to the subject, from the returns or register of the winds, and state of the weather, by the barometer and thermometer, kept at Clachnaharry, Fort-Augustus, and Fort-William, by order of the Commissioners, since the year 1804 up to the last return of 1816, it appears, that the winds are nearly as subject to change in the great vale between Inverness and Fort-William, as in other parts of the country.

[2.] Middle [Dis]trict.

In the Parliamentary Reports, the Caledonian Canal is generally laid out in three districts, viz. the Clachnaharry or eastern district, comprehending the works from Loch Beauly to Fort-Augustus; the middle district, extending to the west end of Loch Lochy; and the Corpach or western district, from Loch Lochy to Loch Eil, or the western sea. With regard to the middle district, we observe that hitherto the sum annually allowed for this work does not admit of every part being carried on with equal vigour. The works of this compartment have, therefore, been almost wholly confined to excavating the ground; it being of importance to have the eastern end opened to Loch Ness, and the western division to Loch Lochy, before much was done to the masonry of the central parts; in order to facilitate the transport of materials from the respective seas. This may now be confidently expected to be accomplished, at least for vessels drawing eight or ten feet water, in the course of the current year, 1817.

[L]ocks.

The extent of the navigation comprehended in the middle district is about twelve miles. The whole height, from the Beauly Firth or the east sea to Loch Oich, the summit level of the canal, is stated at about 94 feet; and as 53 feet of this has been overcome in rising to Loch Ness, it appears that about 41 feet will form the rise of the lockage of the middle district; while the fall on the western side to Loch Eil is only 90 feet. This is to be overcome by a chain of four locks at Fort-Augustus, and one at Callachie, near three miles westward, independently of the Regulating-lock within half a mile of Loch Oich. The foundation of the chain of locks at Fort-Augustus has been long a matter of uncertainty; and when the writer of this article visited the works, in the month of August 1816, though preparations had been made by changing a part of the course of the river Oich, and a steam-engine of 36 horses' power was then erected for clearing the lock-pits of water; yet the foundation of the lowest lock was nevertheless looked forward to with anxiety, from the loose nature of the gravel, and the quantity of water which continued to flow into the excavated part. But the official gentlemen of this establishment are so much accustomed to encounter difficulties, that they had other expedients in reserve, in case of any failure attending the plan then in hand. The lock at Callachie is curiously situate, being founded and built upon a *dike* or stratum of rock called *Grey Wacke* by Mineralogists, which runs across the moor, and is indeed the only piece of rock on this part of the line of the canal. It is just large enough for the site of the lock, and was preferred to gravel as a foundation. This rock being found very compact, it rendered an inverted arch for the lock unnecessary.

Works of Excavation.

Considerable progress has been made upon the middle district in excavation, which, with little exception, is in gravel. The greater part of the canal is now formed, and cut to the requisite depth. For the purpose of deepening Loch Oich (on which is situated the famous castle of Glengary, the seat of the Macdonnels), a dredging machine of great power is to be employed, which is to have four punts or lighters attached to it. This will form a difficult part of the works of the middle district; but the experience and practice acquired upon Loch Doughfour will prove of much advantage to the operations upon Loch Oich.

Loch and River Oich.

The track of the canal is here so close upon the river Oich, that the course of that river requires to be altered in two or three instances. Nor is this river quite so manageable as the Ness; owing to the smaller capacity of Loch Oich, and its connection with Loch Gary, it forms the drainage of a great extent of mountainous country, without having any very considerable space for containing its flood waters, like that of Loch Ness; for the waters of the river Ness cannot be swelled till the whole surface of Loch Ness is raised. We are therefore to look upon the river Oich, in so far as it interferes with the track of the canal, as much more troublesome, and requiring a different management.

3. Western District.

The western or Corpach district of the Caledonian Canal, may, in a great measure, be supposed to resemble the eastern or Clachnaharry district in its general outline and operations, making a due allowance for the difference of situation and local circumstances.

On the Clachnaharry or eastern division of the canal, we have endeavoured to give some account of the principal works as they occur. To go again into detail, would only be to repeat, in some measure, what is already sufficiently noticed for the general reader. Those who wish to be more critically informed, would do well to look into the Parliamentary Reports; and we think a visit to this great national work, quite as necessary to the traveller, as the Languedock Canal is considered by many who visit France; while the mountainous tract through which this navigation passes, is likely to be far more interesting to the Mineralogist, and to those who seek after and admire the bold scenery of a country, almost completely in a state of nature.

Loch and River of Lochy.

The first great work upon the western district is the raising the surface of Loch Lochy about twelve feet perpendicular; which is effected by shutting up the present course, and excavating a new channel for the river Lochy, the only stream that flows from the loch, raising the level of its new alveus or bed, and thereby rendering the works of the summit level more easy than by works of excavation. By this means, the new course of the river Lochy, about

half a mile in length, cut through a piece of flat ground, called Mucomer, forms its confluence with the river Spean, nearly half a mile further up that river. The joint waters of the Lochy and the Spean soon afterwards skirt the eastern bank of the canal, where it becomes necessary to make a strong defence against their joint effects, by arming and fortifying it with ruble stone.

From Loch Lochy to Loch Eil, the distance is about eight miles, on which the canal works may now be considered as very nearly finished, having kept pace with those of the eastern district; so that there is little doubt that this end will also be opened for the purposes of the work in the course of the year 1817. The works of this compartment, both in regard to masonry, excavation, and embankment, have been more expensive than those of the eastern division; in particular, the deep cutting at Moy, Strone, and Muirshearlich, and excavating the sites of the locks and basin for shipping at Corpach in rock. But, perhaps, if all the expence of the foundations and earth work on the Beauly Firth are taken into account, they may be found to have been as expensive, if not more so, than the blasting of rocks on the Corpach district.

Aqueducts. The aqueducts and masonry in general of this district are executed in ruble work, excepting the principal stones of the lock-work, which are of sandstone from the Clyde. In the regulating lock of Loch Lochy, the hollow quoins, from the difficulties attending the land-carriage, are actually constructed of cast-iron, being a new application of that British manufacture in massive building. Over the Mucomer channel of the river Lochy, a very handsome stone-bridge of two arches of fifty feet each has been erected. From the irregularity of the ground on this part of the track of the canal, which is much cut up with mountain brooks, a number of aqueducts have been found necessary; one, in particular, over the Loy, consists of a centre arch of 20 feet span, and two side arches of 10 feet each, and, owing to the width of embankment here, the arch is no less than 250 feet in length. But in this and other cases the side arches answer the purpose of passages under the canal, and thus save the expence of bridges. Another very difficult and troublesome part of the navigation, occurs at East Moy, where like that of Doughfour Burn, on the eastern division, the water is allowed to flow into the canal, but the gravel and stones are intercepted, by a kind of cess-pool, formed in the adjoining valley.

Great Chain of Locks. In our progress towards the western sea-lock of Loch Eil, after passing the aqueduct of the Lower Banavie burn, we reach the famous chain or suite consisting of EIGHT LOCKS, not unaptly termed "NEPTUNE'S STAIRCASE" by the artificers and workmen. This majestic chain of locks was finished, excepting the gates, in 1811. The probable cost of these locks may be stated at about L. 50,000. They occupy a range of 500 yards, and rise altogether about 60 feet perpendicular. The common void or cavity of the lock-chambers is 40 feet in width, and the depth 20 feet; the bottom, forming an inverted arch, gives the whole a very grand appearance, presenting the greatest mass of masonry any where to be found as applicable to the purposes of a canal. After passing this interesting part of the work, the canal gets easily along Corpach Moss (to the House of Corpach, the former seat of the Camerons of Locheil). Here a double lock is situate, connected with a basin for shipping, measuring 250 yards in length by 100 yards in breadth, which joins the sea-lock, and so communicates with the Western Ocean by two mounds projecting about 350 yards into Loch Eil, and completing the inland navigation of the Caledonian Canal from sea to sea.

Probable Termination of the Works. As before noticed, the operations of the canal have been hitherto chiefly confined to the eastern and western divisions, so as to render these subservient to the operations of the middle or central division. The artificers have now been employed to a greater or less extent upon the middle part for two seasons, and the probability is, that the canal may be opened from sea to sea in about three years, or in 1820. But, in works of this kind, it is almost impossible to foresee every contingency, and much depends upon the annual extent of funds to be laid out, and the effect which may thereby be given to the works. Time must also be allowed for proving the banks, and puddle-walls, which, in all similar works, are found to leak in the first instance, and require the banks to be partially opened.

Probable Expence. The expence of this great work, up to the month of April 1816, by the Parliamentary Reports, appears to amount to about L. 600,000; and, in all probability, before it is opened from sea to sea, it will require the expenditure of L. 200,000 more, or L. 800,000 in whole; independently of the expence of the various improvements to be made for the navigation, which experience alone can point out and determine, after the canal is opened.

Access to the Canal. To render the access from *seaward* to the canal more safe, and give every facility to the navigation, there will require to be beacons fixed, and buoys moored in various parts, and even a light-house erected at Tarbetness, in the Murray Firth, and another, as a direction for the Sound, between the Islands of Mull and Kerrara. Nor will the full advantages of this navigation be felt, until *west* Loch Eil is connected with Loch Shiel, and a passage found to the Western Ocean, in the direction of the districts of Ardnamurachan and Moidart.

Its Utility. The question of the ultimate advantage of this work, has been matter of much discussion. But, we believe, this may, at once, be restricted to the consideration of the propriety of the excess of dimensions above the depth of fifteen or sixteen feet, so as to admit almost the largest class of merchant ships, using the Baltic and North Sea trade. Now, we think it was proper that it should be constructed upon a scale calculated to meet the increasing dimensions of merchant vessels. For when the Forth and Clyde Canal was determined, in the year 1768, to be of the depth of eight feet, and the locks in proportion to measure seventy-four feet in length, and nineteen feet in breadth, it was termed the "GREAT CANAL," and it is worthy of remark that its uncommon size, for that day, was considered unnecessary and useless for the trade of the country. The reverse of all this, however, has been found by

experience; and if its dimensions could now be enlarged and its depth increased to the rise of the tides of the Firth of Forth, or to the depth of sixteen feet, the benefit of that navigation to the country would be incalculably greater. The Commissioners for the Caledonian Canal certainly acted wisely, in keeping its dimensions large; as this will be of great service in navigating vessels even of a middling size; the force applicable to the trackage of ships being found to be in proportion to the quantity of the fluid compared to the bulk of the vessel. Although the inducement for frigates and the smaller classes of his Majesty's ships of war passing through this navigation, does not appear very obvious, yet cases may occur when this may be found advisable; and as there is an abundant supply of water from the lochs upon this line of canal for the wants of any supposable lockage, it was certainly proper, in a national work, that such an event should be provided for.

The writer of this article has made frequent voyages from the Firth of Forth to the Firth of Clyde by the Orkneys, and is well acquainted with all the tracks of that navigation; and can easily imagine its dangers, in long winter nights, even with all the advantages of light-houses and accurate surveys of the coast. He has also repeatedly visited the works of the Caledonian Canal. With regard to the quality of the workmanship, he shall only mention, as a pretty conclusive circumstance with regard to the masonry, that, from end to end of this great work, he has not seen a single *set* or *shake* in the whole of the locks and walls. Upon the subject of the navigation of a ship in the lochs or lakes, he cannot speak professionally; but, upon one of these visits, he went over the whole line in company with a captain of the Royal Navy; and although this officer did not much relish the idea of his ship putting about or tacking with *eddy winds* in these *narrows*, nor of being *dragged* along by the power of horses or of steam, yet he had no doubt as to the fitness of the navigation for smaller vessels. Indeed, since the discovery of the application of the *Dalswinton steam dragger*, the practicability of this navigation, from Fort George on the east coast, to the Ferry of Curran, at the junction of Loch Eil and Loch Linnhe on the west coast, is reduced to a certainty, for all vessels which can pass the canal locks. And thus, we have the firmest conviction, that the Caledonian Canal will, in the end, be universally viewed, as a truly great and noble undertaking, issuing in the most solid benefits to the country. (H.H.)

Use of the Calender.

CALENDER, a mechanical engine employed by cloth-lappers, for dressing and finishing cloths and stuffs of various descriptions and fabrics, before exposure to sale, or delivery to purchasers. It is also used by calico-printers, in order to extend and smooth the surface of their cloths, after they have been bleached, and before they are subjected to the operations of the printing table or copperplate press.

In all cases two, and in many three, requisites must be attained, in order to give to cloth that appearance which it is deemed necessary that it should possess, to attract the eye and gratify the fancy of the purchaser and consumer,

The first of these requisites consists in as perfect extension and smoothness of surface as can be attained; so that no wrinkle or doubled folding may remain in it, excepting such as shall afterwards be intentionally made, in order to the reducing of it to the proper form and shape.

The second requisite acquired by the calendering of cloth, is the compression of the yarn or threads of which the texture is composed, which in some degree divests them of their cylindrical shape, and reduces them to a degree of flatness, which, by bringing them more closely into contact with each other, gives to the fabric a greater appearance of closeness and strength, than it would otherwise possess. The operation of the calender also improves the superficial appearance, by flattening down all knots, lumps, and other imperfections, from which no material, from which cloth is fabricated, can ever be entirely freed during the previous processes of spinning and weaving.

And thirdly, in many fabrics it is desirable, and esteemed a great addition to the effect and beauty of the superficial appearance, that cloth should receive, by means of friction and an application of bleached wax, an additional lustre or polish, which is generally distinguished by the appellation of glazing, and is chiefly required in those stuffs which are employed in the ornamental descriptions of female attire.

Such, in a strictly limited sense, are the sole and exclusive effects resulting from the mechanical operation of the calender; but, as other operations besides smoothing or glazing are necessary for the proper preparation of cloths for the market, these also are carried on by the same persons and in the same premises. Hence by a natural, although not strictly correct, extension of its acceptation, the term calender, which really means only the chief mechanical engine employed, gives the general name to the whole establishment where all the varied operations of cloth-lapping are carried on; and it is as usual to say that goods are *packed*, as that goods are *dressed*, at a calender. In the illustration, therefore, of those operations, which the limits of this article will admit, the first object will be to convey a distinct idea of the principles, construction, and operation of the principal machinery employed; and then to add such general and miscellaneous observations as may serve to elucidate how the business of cloth-lapping is carried on in its present extended form.

For the purpose of smoothing both surfaces of a piece of cloth, it is necessary that they should be exposed to universal contact and pressure in every point, with some body of sufficient density to acquire the requisite degree of superficial polish. Such equality of surface, however, as will produce this effect, is not very easily attainable in large plane surfaces. Hence the contact of cylinders, in this operation, has been found to be in all respects infinitely preferable to that of planes, both in the speed and the effect of the operation. The common domestic smoothing iron is the most simple of all calendering utensils; but, even in the application of its small and limited surface, it would be difficult to procure any table or board sufficiently level to bring the whole cloth into equal contact with the iron, without the intervention of a few folds of blanket, or some other thick and soft woollen cloth.

The old, and now almost entirely superseded, ma-

Different kinds of Calenders.

chine, termed a *mangle*, gives the most simple and rude approximation towards cylindrical calendering, and the substitution of circular for plane surfaces. Its operation is that of a cylinder applied to a plane, upon which it is rolled backward and forward, until some degree of smoothness is produced by this reciprocating motion. It is, therefore, very analogous in principle to the common gardener's roller, with which land is resmoothed after having been dug up for sowing or other agricultural purposes.

The smoothing calender completes the substitution of cylindrical for plane surfaces, all the parts which operate upon the cloth being of that form. This ingenious engine, which was introduced into Britain from Flanders and Holland, during the persecution of the Hugonots, has, since its introduction and adoption here, undergone no very material or important alteration or improvement in point of theoretical principle; nor, until the extension of the cotton manufacture had introduced a general spirit of mechanical improvement, had it received any great amelioration in practical execution. Two very important improvements have, however, since that period, been introduced and adopted. The first of these, which originated in Lancashire, is now almost universally employed. The second, which was invented at Glasgow, is still limited to the original proprietors or their assignees by the operation of a patent, the period of which, however, has now nearly determined.

The scope of the former of these improvements consists in the substitution of pasteboard, in the place of wood, in constructing three out of the five cylinders of which the engine is composed. These cylinders, when previously composed of wood, were found to be liable to two serious and important objections. Calenders employed in general business are necessarily subjected to frequent alternations and vicissitudes of heat and cold. These are entirely unavoidable, because, in smoothing or dressing cloths of the denser fabrics, the effect, as in the common operation of ironing linens, is found to be greatly heightened by the application of as great a degree of heat as can safely be communicated without danger to the fabrics which are to be smoothed.

The expansion of every thread which composes a given extent of cloth, although individually indistinguishable, even with microscopic aid, produces very considerable general effect, when exerted upon eight or ten thousand of these minute cylindrical substances, all combined together, in the space of one single square yard. In this expanded state, the pressure of the calender divests them more easily of their cylindrical form, and flattens them down until they come more closely into contact than before. This effect, which is in exact unison with the general theories of expansion and contraction, will at once produce an apparent increase of closeness and density to the texture, as well as of gloss to the surfaces; although the former is in fact deceptive, as no *real* acquisition of strength to the fabric can thus be obtained. The apparent density of fabric, as well as a higher accession of gloss, are also frequently obtained by impregnating and stiffening the cloth, after it has been bleached, with a mucilage of starch; and this is too frequently carried to a very unfair height for the purposes of deception, which is not very easily detected, until the cloth be again exposed to moisture, when the delusive appearance instantly vanishes. Hence, in all dense fabrics, the calender is generally used in a heated state, whilst in flimsy fabrics, in which transparency of appearance is more the requisite than strength, the operation is conducted with the calender perfectly cold.

The effect of these frequent and sudden transitions upon wooden cylinders was necessarily productive both of *fissure* and *warping* or *twisting*; and no care in drying or seasoning the wood before turning could entirely remove these defects. The substitution of pasteboard, however, afforded a radical cure for both, as well as a collateral advantage arising from its being susceptible of a much higher degree of superficial polish, which is always transferred to the cloth.

The paper or pasteboard cylinder, besides total exemption from all defects incidental to ligneous substances, from the immense density of which it is susceptible, by compression, presents a superficies capable of receiving and retaining an almost unparalleled smoothness and polish.

In order to construct cylinders of this description, an axis of malleable iron, and two circular plates of cast-iron, are, in the first place, provided. In these plates, which must be at least from one to two inches thick, there are six equidistant perforations near to the circumference, each capable of admitting a rod of malleable iron at least three-fourths of an inch in diameter. The entire space between the two iron-plates is then to be filled with circular pieces of the strongest pasteboard, exceeding, by about one inch in diameter, the iron-plates, and having each a correspondent perforation, through which the six iron rods may pass parallel to the axis. A cylinder is thus formed, the substance of which is of pasteboard locked together by plates of iron at the extremities, and susceptible, by means of screws on the extremities of the six connecting rods, of *immense* compression.—After undergoing this preparation, the cylinder is exposed to strong heat in a confined apartment; and, as the pasteboard daily contracts, the screws are every day tightened for the space of some weeks. The density of the cylinder is thus increased, whilst it is contracted in length upon the axis, for which contraction adequate allowance must be made in its original measure, and the operation is continued until it has gradually acquired the requisite compression. It is then re-exposed to the ordinary temperature of the atmosphere, and by its re-expansion presents a body almost inconceivably compact, its specific gravity in this state being greater than even that of silver.—The only operation now required is that of turning its superficies until correctly cylindrical; and this is a work of immense labour and patience.

The rotatory motion in turning does not exceed 40 or 50 revolutions *per* minute; and the turner requires two or three assistants constantly employed in sharpening his tools. When properly finished and smoothed, a pasteboard cylinder, however, amply compensates, by its strength, its gloss, and its dura-

Calender. bility, for the great labour and expence which its construction has created.

A second practical improvement in calenders of the common description consists in the substitution of cast iron for wood, in the construction of the connecting frames. This improvement is now common to almost every description of machinery; and when applied to the calender, it is of more than usual advantage, because, independently of the accession of strength and diminution of space occupied, the total exemption of iron from warping is of peculiar advantage in an engine so rapidly exposed to alteration of temperature as the calender must be. The entire exemption of iron framing from combustion forms also another advantage of some importance in an engine frequently heated by the application of red-hot cylinders of iron. With this cursory outline of general improvement, the next object of the present article is to afford a description of calenders in their present state of improvement, referring for illustration to the figures which are delineated in the Plate.

Smoothing calender. A representation of a common smoothing calender, combining in its construction all the improvements which have been detailed, will be found represented by fig. 1. Plate XLV.

The framing of this calender, as well as of the glazing calender (fig. 2.), and which will afterwards be noticed, is represented as composed partly of iron and partly of wood; the upright posts which form the lateral connections, and which contain the *bouches* or sockets in which the axes or *journals* of the cylinders revolve being of the former substance, whilst the horizontal parts at top and bottom are represented as of the latter. The latter, however, may also be very advantageously cast in iron.

The constituent parts of this calender are as follow: MA is the chief or main cylinder, which is represented as 24 inches in diameter, and five feet in length, betwixt the connecting and compressing plates at the extremities. It must, however, be premised, in order to avoid misconception, that different Engineers adopt different dimensions for their cylinders; and that those adopted and specified in the representations given, are merely selected as specimens of such diameters as are in general use, and found to answer their end sufficiently; but they may unquestionably be either extended or contracted, according to particular circumstances, without any perceptible alteration of effect, provided care be taken that the ratio of velocity be always correspondent with that of dimension.

BB are two cylinders of cast iron externally turned until perfectly smooth. Their diameter is fixed at six inches each, allowing the substance of iron to be one and a-half inches, and leaving a central cavity or perforation of three inches diameter, for the reception of red-hot cylinders of cast iron, when the calender is required to operate at a heated temperature. Both extremities are perfectly open, in order that the heated cylinders, which, for the sake of convenient exposure in the furnace, should not exceed 12 or 16 inches in length, may be easily introduced at one end, and, after cooling, may be expelled at the other by fresh cylinders from the furnace. Their diameter should so far correspond with that of the cavity into which they are to be introduced, that, in their utmost state of expansion from the heat, they may slide freely along, with as little vacant space as can safely be allowed, but without exposing them to the danger of occasional obstruction from excess of diameter.

Calender.

The cylinders CC, like the main cylinder A, ought to be constructed of compressed pasteboard, and their diameter is assumed to be 12 inches. These five cylinders, with the wheels which put them in motion, constitute the whole dynamical or moving apparatus of the calender; and, at the diameters which have been assigned to them, will occupy, when in contact fit for working, a space of five feet perpendicular in whole. To this must be added the thickness of the top and bottom parts, and an allowance of two or three inches vacancy to clear these from the upper and lower cylinders. A space in whole of about two feet will be sufficient for these purposes, and the total altitude of the calender from the floor to the vertex will be about seven feet.

The cylinders revolve in *bouches* or sockets, generally of smooth hard brass or bell-metal; and all these, excepting those of the main cylinder, are so connected with the lateral framing by which they are supported, as to render them capable of being shifted upwards or downwards occasionally. This admits of altering the degree of pressure given by the cylinders, so as to suit the great variety of fabrics which are necessarily subjected to the operation of the same calender, if employed in general business. The *quantum* of pressure exerted upon the cloth is sometimes regulated by projecting levers, operating as steelyards. The short end of these being connected with the centres of the cylinders, the pressure is proportional to the weight applied to the longer extremity, and its distance from the fulcrum.

This is perhaps the best and surest mode of tempering and adjusting the quantum of pressure. The steelyards, however, require more space than the proprietors are generally willing to allot for their calenders; and, consequently, the pressure is most commonly regulated by screws. This, however, subjects everything to the discretion of the operator, and an unskilful person often injures the machinery, and even stops its motion by overscrewing the calender. At other times, he is apt to set it so open, as to permit the cloth to pass through it without receiving nearly the effect which will be derived when the calender is skilfully adjusted.

In order that the operating effect of the calender may be merely by pressure, it will be obvious that the relative velocity of rotation, communicated to each cylinder respectively, should be reciprocally as its diameter; for thus each will expose equal superfices in equal times. And to effect this, it will be equally obvious, that the diameter of the wheels (reckoned to the *pitch lines* or working parts of the teeth) should be commensurate with those of the cylinders, upon whose *axes* they are respectively placed. These diameters being respectively 6, 12, and 24 inches, and that of the wheels the same, the perimeters of this latter (avoiding minute fractions) will be nearly 18.8, 37.6, and 75.2 inches; and to deduce from these the requisite number of teeth, it is only necessary to ascertain what strength it will

Calender.

be necessary to allow for each. An epicycloidal tooth, measuring .75 inch thick at the pitch line, will be abundantly strong to undergo any opposition which it may encounter in a well constructed calender; and should this be adopted, the numbers of the wheels will be

	Inches.	
Main cylinders A,	24 diameter,	48 teeth *nearly.*
Iron cylinders BB,	6	12
Extreme cylinders CC,	12	24

liable to such modification as the engineer may deem it proper to adopt, under the special circumstances of each case.

When these connections betwixt the cylinders are formed, and a sufficient moving power is applied to the main cylinder A, the whole will revolve with velocities proportional to their diameters; and as equal surfaces will be exposed by all in equal times, pressure alone will be applied at the lines of junction, and the calender will smooth, *by compression exclusively*, whatever pieces of cloth may be exposed to its operation. This pressure, it is also apparent, will take place at the four lines of contact between the cylinders, and, of course, will be four times applied during the transit of the cloth. Those who attend the calender must be careful that the pieces are fairly extended before insertion, to prevent *cressing;* and that they are regularly although loosely collected into regular folds after being calendered; and in this state delivered to those whose business it is to refold and press them into the proper folds, which they are permanently to retain, until they shall come into the possession of the consumer.

The above description of the common calender supersedes, in a great measure, what it might otherwise be necessary to detail respecting that employed for glazing. Both engines are, in fact, nearly the same; and the same calender may, by a few minutes labour, be altered so as to answer either purpose.

Glazing Calender.

Previously to the introduction of this improvement, the operation of glazing, although performed sufficiently well, was somewhat tedious, being effected almost exclusively by the mere application of manual labour. It was performed upon a table, the cover of which was oblique to the horizon, forming with it an angle of 15° or 20°. The cloth being stretched on this, and a quantity of wax being thinly spread on its surface, the glazing was effected by the reciprocation of a smoothed flint, vibrating at the end of a rod, somewhat similar to the oscillations of a pendulum. The centre of oscillation was also moveable on a spring, in order to reduce the arc of vibration to a plane, and keep the flint in uniform contact with the cloth. But a man's power was competent to glaze only a few inches in breadth at once, and it was only by successive shiftings, that the whole breadth was successively brought under the friction of the flint. The glazing calender produces the same effect, with increased uniformity, simply by changing the relative velocities of the cylinders to each other, and generating friction, as well as pressure, at the points of contact.

Indeed, the whole changes necessary to convert a smoothing into a glazing calender, consists merely in accelerating the rotatory velocity of the main cylinder A, whilst those of the other cylinders remain unchanged. The shifting of one wheel upon the main cylinder, and the addition of four smaller wheels or pinions to the engine, is entirely adequate to produce this effect; and, in point of fact, this is the whole extent of the improvement. The extent of alteration in the relative velocities, of course regulates the quantum of friction, and the extent of gloss which is given to the cloth; and this must be varied in proportion to the strength and density of the fabric to be glazed. As an illustration of the principle, let it be supposed, that a friction of one inch is to be communicated in every three inches of cloth, and the effect will be attained in the manner represented by the glazing calender, fig. 2. Plate XLV.

Let the wheel on the main cylinder A be reduced to thirty-two teeth, and let the power be so applied, that its own velocity of rotation shall be increased until it makes three revolutions where it formerly made only two. Then the diminished wheel, which has been substituted, in place of direct operation, will communicate rotation to the iron cylinders BB, by the intervention of two intermediate pinions DD, the diameters and teeth of which are entirely discretionary, as they affect only their own respective velocities, and not those of the cylinders in general.

Notwithstanding the extreme simplicity of this improvement, it has given very universal satisfaction, and, as the time of the patent will very shortly expire, there is little doubt of its universal adoption, to the entire supersession of the common and tedious operation of glazing.

Small Calender for Light Fabrics.

For dressing muslins, gauzes, lawns, and other goods of the light and transparent fabrics, a smaller species of calender, represented by fig. 3. is employed. It consists of only three cylinders of equal diameters (generally about six inches), and is easily moved by a common winch or handle at F. The mid cylinder is iron, and the others wood or pasteboard. They are of equal diameters, and are moved with equal velocities by the small wheels at E. This machine is always used in a cold state.

The folding of cloth is so entirely regulated by fashion, that no precise rules can be laid down for its regulation. In general, as all the different manufactures of cloth have been imported from other countries, the original foldings have been copied to complete the resemblance. In the infant state of imitation there was probably some policy in this, but the continuance may be ascribed almost exclusively to the power of habit. Preservation and portability are the main requisites to be attained by folding; and these are attained by subjecting the cloth, when folded, to a very powerful compression.

To communicate this, very strong presses are employed, of which various kinds are in use.

Process of Folding.

The capstan press, which is the most usual, is represented by fig. 4. at G. They are now generally constructed of cast iron, the screw and handle excepted, which are malleable. They are tightened to a certain pressure, by merely using a lever of 10, 12, 16, or more feet in length, to turn the screw. When greater compression is required, the end of the lever is connected by a strong rope or chain with the capstan at I, which is heaved round by handspikes until the desired compression be obtained. The pieces of cloth are separated in the press

Calender. by smooth wooden boards and folds of that species of glazed pasteboard, which, from its application to this very use, has acquired the appellation, among stationers, of pressing-paper.

Water-presses, upon the forcing principle of Mr Bramah, or acted upon by the pressure of a column of water, are also employed; but the latter depend much on local situation, and cannot easily be applied in large towns like Manchester or Glasgow, where the chief command for calendering exists.

Operations connected with Calendering. To the mechanical art of calendering, it is found expedient, in the extended states of commerce, to add many of the operations of packing, sheeting, and preparing goods for shipment, and these generally form a branch of the establishment. In order to suit the great extent and variety of manufacture practised in Britain, and to adapt these to the prevalent tastes and views of the extensive range of consumers to be supplied, a multiplicity of foldings or lappings have been necessarily adopted, few of which, probably, possess much claim to entire originality. The high, and perhaps preeminent, station which the productions of the British looms have gradually attained, seem to be rather the effect of assiduous and enterprising industry, than of great originality of invention, or precedence in mechanical improvement. Certainly, she can, at the utmost, boast of only one *raw material*, from which cloth is manufactured, as peculiarly indigenous.

At an early period, no doubt, the British wool had attracted the peculiar attention of economists and statesmen, as of paramount value; and the prohibition of its exportation became an object of legislative enactment. That manufacture, therefore, has long been the staple of England, as the linen trade, at a later period, has become that of Ireland.

The attempts to introduce both of these branches of industry into Scotland, although, during the latter part of the last century, they engrossed much of the attention, both of public bodies and of patriotic individuals, cannot be regarded as having proved eminently successful; and the progress actually made, has been almost entirely superseded and extinguished, by the more recent introduction of the cotton manufacture.

The latter branch of industry, since the splendid invention of spinning by the aid of machinery, has, indeed, made most rapid advances in every part of the United Kingdom; and has attained to a height, which has, perhaps, absorbed a greater portion of national industry, than consumers can easily be found to employ. The extension of external commerce has constantly supplied the raw material at easy, and, generally, moderate rates; and even the India Company have long ceased to oppose to it any very formidable competition in the market.

The silk manufactures of Britain have never been carried to a very great extent; and whatever may have, directly or indirectly, tended to regulate the finishing, folding, and preparing of British goods for the various markets of consumption, will chiefly refer to the three former branches of manufacture.

Extensively as the woollen trade is carried on, it is, in a great measure, absorbed either by internal or colonial consumption, and does not, therefore, enter so generally into actual competition with the cloths of other nations, as to render it either peculiarly desirable that its marketable aspect should be either servilely copied from those of other countries, or very peculiarly distinguished from them. The chief object appears to have generally been, to prevent the intrusion of foreign cloths and stuffs into our own markets; and hence adopting their usual folds into such rolls, as most effectually preserve the dressed surface from acute cresses, is found to be most expedient and convenient, the goods being distinguished by letters denoting them to be "British manufacture," on the ends of the pieces.

In the Irish manufactures of cambrics and linens, the case is almost entirely reversed. From the superiority of climate, the French flax is admitted to be of finer appearance; and although the importation of manufactured cambrics be strictly prohibited, the restraint, during periods of peace, has always been considerably evaded, in consequence of the demand experienced, and the reputation in which they are held. Indeed, it was found generally most expedient, by many retailers, to sell Irish cambrics under the title of French, and hence the fold was correctly imitated. The pieces, after being folded into lengths of about 12 inches, and twice laterally doubled, until the whole breadth of 34 inches was reduced to about $8\frac{1}{2}$ inches, were subjected to a powerful compression in the press until fully flattened. They were then packed in purple coloured wrappers or papers, and a small engraved card or ticket was attached to each piece, specifying the length, generally about 8 or $8\frac{1}{2}$ yards. The cards were attached by a silken string, so as to be easily cut away with a penknife or pair of scissors, in order to avoid seizure; and French or Irish goods were sold indiscriminately as "foreign cambrics." Custom has even carried this practice farther; and cotton cambrics, which are avowedly *British manufacture*, and subjected to no risk whatever, because easily distinguishable from any cambric manufactured from flax, are put up into the same folds, papered, and ticketed, in exactly the same manner.

In linens, hollands, and sheetings, whether of foreign or Irish manufacture, the same fold is also employed; and in cotton shirtings and sheetings, is closely imitated. The form is that of a cylindric roll, somewhat flattened by subsequent compression; and, in general, all dense fabrics, whether of linen or of cotton, are rolled up and compressed in a similar manner; the object of which is, evidently, safety, and diminution of space, in land carriage or exportation.

In others of the extensive varieties of cotton cloths of British manufacture, some are avowed imitations of the manufactures of Hindostan, whilst others profess no such imitation. Very few among the manufactures of Lancashire are either distinguished by Indian names, or copied from Indian cloths, although some of great extent are directly so. Calicoes, cossacs, and jaconets, for printing, as well as Ballusore, Bandana, and Pullicate handkerchiefs, are amongst the leading articles of the latter description; whilst amongst the latter may be classed the very extensive manufactures of corduroys, thicksetts, velveretts,

Calender.

velveteens, &c. although their origin is also probably Asiatic, but because well known and manufactured by the Genoese, French, and other European nations, even before the discoveries of De Gama, and other mariners, had first laid open the maritime intercourse with India by the Cape of Good Hope.

When, at a period infinitely more recent, the splendid invention of spinning cotton by the agency of machinery, to any degree of fineness, afforded new scope to the British weaver, the imitation of the lighter Indian fabrics fell chiefly into the hands of the Scottish weavers; for executing which, they had been, in a considerable degree, previously prepared, by their habits of weaving lawns in imitation of the French, as well as their lighter fabrics of silk and thread gauzes. To their share, in consequence, fell the bouks, mulls, and japuns, almost exclusively; as well as the lighter jaconets, designed for ornament, from the needle and tambour frame. And whilst they have made no successful attempt to compete with their Lancashire brethren in the dense fabrics of corduroys, quiltings, and other ponderous articles, they have shared with them the manufacture of the middling textures of cambrics, Pullicates, and ginghams.

Indeed, whatever prepossession may, at an early period, have existed in favour of the real Indian fabrics, it has now so entirely subsided, as to possess no influence whatever in swaying general opinion. The British workmanship has proved itself long ago so decisively superior to the Indian, both in spinning and weaving, as to eradicate every doubt in the minds of all who are really competent to decide the question of comparative superiority. Still, however, candour will compel us to allow, that the Indian possesses advantages in the rich qualities of his cotton, and the brilliancy of some of his dyes, which, in some degree, compensate for the immense superiority of the British skill and machinery, and which, to those who examine superficially, may appear to entitle him to the preference.

Nothing, therefore, exists in the cotton manufacture which could, in general cases, prompt to a servile imitation of external appearance for the purposes of deception; and the Indian mode of lapping their cloth is too rude and laborious to admit of its being copied as a matter of conveniency. Their method consists merely in doubling a piece of twenty yards, to reduce its length to ten yards; which is again doubled, in order to reduce it to five; and thus they continue to redouble, until the piece be reduced to a moderate length, capable of being contained in a chest or bale. Thus often redoubled, an Indian piece cannot be examined throughout, unless the whole piece be again unfolded; and this, in large transactions, would be utterly impracticable.

British muslins are folded generally to a yard in length, with a small allowance for extra measure; and as the folding is alternately from right to left, every part can be instantly examined upon a table or counter, every fold opening as easily as the leaves of a book, in its uncut state. The piece, when folded, is reduced by doubling it longitudinally to about 19 inches, and it is then folded across to the breadth of about 18 inches. An ordinary sized trunk, 39 × 19 inches, thus contains three layers of pieces; in which package, goods for exportation to the colonies are generally packed; the trunk there forming an article of merchandise as much in general demand as the muslins which it contains.

Even the Indian ornaments of gilt silver threads, which were at first woven into one end of each piece, although they did not exceed the value of twopence each, have been either greatly curtailed, or totally given up upon principles of economy. Even the cost of this trivial ornament has been computed to have amounted annually in Glasgow and Paisley to about L. 30,000.

Pullicate, and other handkerchiefs, are most commonly folded up in dozens. For the African, and some other foreign trades, pieces containing only eight handkerchiefs are preferred. These are still imitations of Indian precedents, confined to markets where competition continues to exist, not only with the British Company, but with Americans, and others trading to India. A species of pale orange-coloured India handkerchief, distinguished by the name of *Mudrus*, being in extensive reputation in the Caraccas, and other Spanish settlements in South America, at the period of the capture of Trinidad in 1795, patterns were procured by some British traders, who ordered very large quantities to be manufactured in Scotland, of the same quality and appearance. With such effect were these imitated in texture, in dye, in finishing, and even in the packages, that some hundreds of pieces sent to London for exportation, were actually seized at the Custom House, as India goods, either illegally imported, or stolen from some of the Company's ships in the river. A scrutiny, however, clearly ascertained that these goods were not Indian, but British; and that no trespass against either the privileges or the property of the Company had been even attempted. The goods were of course released, and permitted to proceed to their destination, where, after examination and trial, it was found totally unnecessary longer to conceal their real origin, and a very extensive trade, through direct channels, has been since carried on for similar goods.

General Observations.

From the above general and cursory sketch, it will be obvious that the management of an extensive calendering establishment will require, on the part of its conductor, not only a competent knowledge and experience of the mechanical operations, and duties of his particular profession, but that a more extensive mercantile acquaintance with the demands, habits, and tastes of particular markets, will conduce equally to his own interests, and those of his employers. From the variations of markets, and fluctuations of mercantile transactions, there can be no precise or definite limit to the extent of such knowledge. It is only by constant attention and sedulous inquiry, that he can preserve accuracy, in what is liable to almost daily change. His immediate employers will, no doubt, be often both able and desirous to supply him with this. But, as even they must sometimes be liable to error or deception, he ought to omit no opportunity of extending his inquiries, and arriving, as nearly as he can, at the most comprehensive and unambiguous information. Calico-Printing

CALICO-PRINTING. This important art is treated of under the article DYEING in the *Encyclopædia*, in the third chapter of that article; but as the nature of this species of Printing, and the processes employed in it, require to be more fully examined and described, we shall resume the subject under the same head, or under that of PRINTING, as circumstances may best permit.

Cambridgeshire.

Situation and Extent.

CAMBRIDGESHIRE is divided into two parts by the river Ouse. Its most northerly division, which is principally composed of the Isle of Ely, is bounded by rivers, and their communicating branches. The limits thus formed are so intermixed, as with difficulty to be traced. The southern half has an indented and undistinguished boundary-line on the adjacent counties. The form of Cambridgeshire bears some resemblance to that of the human ear, the county of Huntingdon cutting deeply into its western side by a circular projection. The number of acres assigned to it in the *Encyclopædia* is taken from Dr Halley, but Dr Beeke reduces them to 530,000; and they are still farther reduced in the agricultural report, and in the returns in 1803 of the poor-rates, to 443,300, and 439,040 respectively. When the original agricultural report was made in 1794 by Mr Vancouver, he calculated that, of the 443,000 acres, there were 132,000 open field, and 150,000 waste and unimproved fen; but since that time, both these descriptions of land have been very considerably reduced by enclosure and cultivation.

Surface.

The surface of this county presents considerable variety. The northern part, including the Isle of Ely, is chiefly fen land, and perfectly level, intersected with numerous canals and ditches, and abounding with windmills, for the purpose of carrying the water from the lands. This district is naturally a bog, formed by the stagnation of the water from the overflowing rivers. It comprises nearly half of that extensive tract, called the Bedford Level, the whole extent of which is 400,000 acres, and not 300,000, as stated in the *Encyclopædia*. This great level has been, from an early period, divided into three parts, the north level, the middle level, and the south level. The largest portion of the middle level, and a considerable part of the south level, are in Cambridgeshire, comprehending the Isle of Ely, and a few parishes to the south-east of the Isle. The principal of the drains, by means of which this immense fenny district has been, in a great measure, rendered either rich meadow or arable land, are the Bedford old and new rivers, which run navigable in a straight line upwards of 20 miles across the county, from the Great to the Little Ouse. There are some rising grounds in this part of the county, on the most considerable of which the city of Ely stands. Those parts of Cambridgeshire, which lie adjacent to Suffolk, Essex, and Hertfordshire, have their surface varied by gently rising hills and downs. The Gogmagog hills, which begin about four miles to the south-east of Cambridge, and which are one of the terminations of the range of chalk hills that commence in the south-west of England, are the highest in the county; but their height is very inconsiderable. The district which extends from these hills to Newmarket, is bleak and thinly inhabited. This district is connected with that vast tract of land, which, extending southwards into Essex, and northwards through Suffolk into Norfolk, forms one of the largest plains in the kingdom.

Soil.

The substrata of this county are chalk, *clunch*, gravel, *gault*, sand, *silt*, and peat-earth. The chalk extends through the hilly part of the county from Royston to Newmarket. The *clunch*, an impure limestone, chiefly abounds in the parishes of Burwell and Iselham. On the east and west sides of the upland division of the county, *gault*, a stiff blue clay, chiefly prevails. The sand enters Cambridgeshire from Bedfordshire, in the parish of Gamlingay. In the northern extremity of the county, near Wisbeach, *silt*, a fine sea-sand, is found. The peat-earth extends through the whole of the fen-land.

Rivers.

The principal rivers are the Ouse, and Granta or Cam. The Ouse enters the county between Fen Drayton and Erith; thence it runs eastward through the fens, till, at some distance above Denny Abbey, it takes a northerly course, and, passing Streatham, Ely, and Littleport, flows into Norfolk. From this river are many cuts, called *loads*. The Cam enters the county to the west of Gilden Morden; thence flowing to the east, it receives several rivulets. Near Grantchester, its stream is enlarged by the united waters of several rivulets from Essex. After their junction, it takes a northerly direction, and, having passed Cambridge and several villages, it falls into the Ouse in the parish of Streatham.

Canals.

Besides the numerous canals in the fenny district, principally for the purposes of draining the land, there are the Cambridgeshire Canal, which commences in the Ouse at Harrimere, and terminates at Cambridge. A cut of 3 miles extends to Reche, and another of $3\frac{1}{2}$ miles to Burwell; and the Wisbeach canal, which joins the Wisbeach river at the old sluice in the town, opening a communication with Norfolk, Suffolk, and other places.

Climate.

The climate of Cambridgeshire differs considerably in different parts. In the south-east it is cold and bleak; in the fenny district damp and unhealthy, though much less so than formerly; in the south and south-western districts, the climate is the mildest, most agreeable, and healthy.

Landed Property.

Estates vary much in size. There are many large ones, especially those of the Earl of Hardwicke and the Dukes of Bedford and Rutland. College tenures are numerous. There are some large farms of 1000 acres or more, but the general size is from 100 to 500 acres.

Agriculture.

Cambridgeshire is not celebrated as an agricultural county. It may be considered as chiefly arable. Wheat is grown principally in some parts of the fenny district, and in the south and south-western parts of the county. Barley is cultivated in these parts, and in some of the more fertile portions of the south-east district. Immense crops of oats, of good quality, are grown in the fenny district, and also in most other parts of the county. It is supposed, that about one-fourth of the fen-lands are cropped with cole, which is principally sown to be eaten green with sheep, very little being now cultivated for the seed. The cultivation of hemp and flax is carried on to a considerable extent, in that part of the county which

Cambridge-shire.

borders on Norfolk, particularly in the parishes of Upwell and Wolney. Saffron has been very little, if at all cultivated, for upwards of 40 years. In some parts mustard is a favourite and valuable crop. Sedge is cultivated near Chippenham; but the cultivation of the reed is rapidly decreasing, in consequence of the improvement of the fens. White seed, or fen-hay, is grown abundantly in several places. It increases the milk of cows. Oziers are grown in the Wash, as well as in many parts of the fen: they are a profitable crop in these districts. So great is the value of turf, that the land producing it has been sold at from L. 50 to L. 80 *per* acre. At Ely, Soham, Wisbeach, &c. are many large gardens, producing so abundantly of vegetables and common kinds of fruit, as to supply not only the neighbouring towns, and counties, but even London. Great quantities of strawberries are grown in the vicinity of Ely, which are chiefly conveyed in barges to Lynn, and carried thence to Newcastle and other places in the north of England. There are numerous and large orchards in the same districts as the gardens; their chief produce is apples and cherries. Soham is remarkable for the latter.

Pasture.

That district of the county which, by old authors, is termed the *Dairies*, comprehends the parishes of Shengay, Wengy, Whaddon, &c.; but the dairy farms in this district are, at present, much less considerable than those in the parishes of Chattris, Mepal, Sutton, Cottenham, Soham, Ely, and Streatham. The whole number of cows kept in this district is supposed to be between 9000 and 10,000; in the parish of Cottenham alone, about 1500 are usually kept; in Willingham, about 1200. These two parishes make the cheese, so much esteemed, which goes by the name of Cottenham cheese; the parish of Soham is also esteemed for good cheese. Little cheese is made in other parts of the county; rearing of calves and making of butter being the chief dairy management. The butter is sold, rolled up in pieces of a yard long, and about two inches in circumference: this is done for the convenience of the colleges, where it is cut into pieces called *parts*, and so sent to table; its quality is excellent. The cows kept on the dairy farms are mostly the breed of the county: most of the calves that are suckled, are sent to the London market. Immense numbers of sheep are pastured on the heaths and commons, with which the south and south-western districts of this county are intersected. The downs in the vicinity of the Gogmagog Hills, are also chiefly used as sheep walks. The principal breeds kept here, are the Norfolk and west country; in the fens the most prevalent sort is a cross between the Leicester and Lincoln. The Cambridgeshire farmers think themselves unrivalled in cart-horses; they are of the large black breed; in the fens they are a source of great profit. In Cambridgeshire there is also a peculiar breed of hogs, some of which are so large as to fatten to forty stone, fourteen lbs. to the stone, at two years old.

Draining, Irrigation, and Warping.

From the nature of the northern division of the county, great attention has necessarily been paid to draining; and, in some places, advantage has been taken of the numerous rivers to irrigate and *warp* land. The interior drainage of the fens is performed principally by mills; one or two steam-engines have been erected for that purpose, and will probably answer better. There is a large tract of meadow land at Babraham, which has been irrigated from the time of Queen Elizabeth, and is supposed to be one of the oldest instances of this mode of improving land in the kingdom; it was first irrigated by Pallavicino, who was Collector of Peter's Pence at the death of Queen Mary, and who, turning Protestant, applied the money thus obtained to the purchase and irrigation of this estate. The practice, however, though evidently beneficial, has extended very little. Near Denver sluice, on the Ouse, some land has been *warped* by letting the muddy water of that river upon it, and then throwing it back by means of a wind-mill.

Manufactures.

This is by no means a manufacturing county. At Ely there is a pottery for coarse ware; and at this city, Chatteris, and Cambridge, excellent white bricks are made. Lime and chalk are a source of considerable trade and profit; the lime in the greatest estimation is that which is burnt at Reach. At Cherryhinton, at the foot of the Gogmagog Hills, are great chalk pits, noted for the marine productions they contain, and for the many rare plants growing in their vicinity. Elephants' grinders, and other animal remains have been found in a gravel pit near Chesterford, and a small tortoise in flint, at Milton. On the borders of Norfolk, a little yarn is spun for the Norwich weavers. Malt is made to a considerable amount in the north-west part of the county. There are several mills for preparing oil from cole and rape-seed, at Wittlesford, Sawston, &c., and a pretty extensive paper manufactory at the latter place. Near Cambridge is annually held one of the greatest fairs in England; it is called Stourbridge or Sturbich fair, and is under the jurisdiction of the university. It begins September the 18th, and lasts a fortnight; it has, however, been declining for many years.

Architecture.

A very curious example, and unquestionably one of the oldest in the kingdom, of Saxon architecture, occurs in the remains of the conventual church of Ely. This building is undoubtedly of as early a date as the tenth century, having been erected in the reign of King Edgar. The two transepts of Ely cathedral, afford specimens of the more massy kind of architecture introduced by the Normans; they were built towards the end of the eleventh century. St Sepulchre's church at Cambridge, affords a curious specimen of that species of architecture, which was introduced into this country, in imitation of the church of the Holy Sepulchre at Jerusalem; it is supposed to be the oldest of this form in England, and to have been built in the reign of Henry I. There are some instances in this county of the pointed arch, enriched with Saxon mouldings; this style was the immediate forerunner of the Gothic. Soham Church, the south door way of St Giles in Cambridge, and the north and south door ways of St Mary's Church in Ely, are specimens of this species of architecture. One of the most ancient buildings in this county, in which the pointed arch makes its appearance, is the great Tower at the west end

bridge-shire. of Ely Cathedral, and the south transept adjoining; they were erected between 1174 and 1189. Some traces of Saxon architecture may be observed in this part of the cathedral. The early or simple Gothic may be seen in the vestibule at the west end of Ely cathedral, in Jesus College Chapel, Cambridge, and in the chancels of Foxton, Kennett, and Cherry-hinton churches. Of the Gothic architecture of the fifteenth century, especially in the reign of King Henry VII. which was distinguished by the abundance of its rich tracery, the finest and most perfect example is found in the magnificent chapel of King's College in Cambridge.

quities. There are not many remains of antiquity in this county. The most remarkable are the ditches, which formerly extended from the woods on the east side of the county to the fens. The most entire is called the *Devil's Ditch*, and extends from Wood-ditton or ditch-town, to Reach. Near this latter place, it is most perfect, the works consisting of a deep ditch with an elevated *vallum*, the slope of which measures 52 feet on the west, and 26 on the east side. The whole of the works are about 100 feet in width. The origin and intention of these ditches are not known; they are certainly very ancient, and were probably formed for the purpose of defence.

-rates. By returns made to the Board of Agriculture in the year 1804, it appears that the poor-rates rose between 1790 and 1803 from 4s. 11d. to 5s. 8¾d. in the pound; the expence of maintaining them from Easter 1802 to Easter 1803, amounted to the sum of L.55,954, 14s. 11d. In the year ending the 25th of March 1815, the parochial rates in 131 parishes amounted to the sum of L.63,354, 13s. 1½d.; 44 parishes had made no returns.

lation. In the year 1377, the number of persons charged in this county to a poll-tax, from which the clergy, children, and paupers were exempted, was 27,350; but it seems doubtful whether it was exclusively of the town of Cambridge and city of Ely, in each of which 1722 persons were taxed. If they were taxed separately, the total number in the county would be 30,794. In the year 1700, there are supposed to have been 76,000 inhabitants: and, in the year 1750, 72,000. By the returns made under the act of Parliament, for ascertaining the population of the kingdom, in 1800, there were then 16,451 houses in Cambridgeshire, of which 16,139 were inhabited. The total number of inhabitants is stated to be 89,346, of whom 44,081 were males, and 45,265 females. Of this total number, there were 28,045 principally employed in agriculture; and 11,988 in trade, manufactures, and handicrafts. The following is the result of the population returns in 1811:

Houses inhabited,	17,232
Families inhabiting them,	21,022
Houses building,	93
—— uninhabited,	257
Families chiefly employed in agriculture,	12,831
—— in trade, manufactures, and handicrafts,	5303
All others, not included under these heads,	2888
Males,	50,756
Females,	50,353
Total in 1811,	101,109
—— in 1800,	89,346
Increase,	11,763

Cambridge-shire ‖ Camera Lucida.

It will be observed that, in the year 1800, there were 1184 more females than males in this county, whereas, in the year 1811, there were 403 more males than females.

See Gooch's *Agriculture of Cambridge*.—*Beauties of England and Wales*, Vol. II.—Lyson's *Magna Britannia*, Vol. II. Part 1. (c.)

CAMERA LUCIDA. Dr Hook's instrument of this name is described in the *Encyclopædia*, under the title CAMERA LUCIDA. The instrument which is to be spoken of here, and which differs from Hook's both in its construction and in the purpose it is designed to serve, is one of the many ingenious inventions of Dr Wollaston. Its use is to facilitate the perspective delineation of objects.

If a piece of plain glass be fixed at an angle of 45 degrees with the horizon, and if, at some distance beneath, there be a sheet of paper laid horizontally on a table, a person looking downwards through the glass will see an image of the objects situated before him; and as the glass, which reflects the image is also transparent, the paper and pencil can be seen at the same time with the image, so that the outline of the image may be traced on the paper. The image is an *inverted* one. This is the simplest form of the instrument, and may be constructed extemporaneously by fixing on a stand a plain transparent glass, with its surfaces ground parallel, or a piece of Muscovy glass, at an angle of 45 degrees with the horizon; a card with a small hole in it will serve as a sight for keeping the eye steady in one situation, whilst the pencil is tracing the image.

If there be a plain mirror at an angle of 22½ degrees with the horizon, and a piece of plain transparent glass be placed near it, at an angle of 22½ degrees with the vertical, the rays from the object will be twice reflected before they reach the eye, and consequently, on looking down through the transparent glass, an *erect* image is seen, and the pencil may be drawn over the outlines of this image so as to leave a perspective representation on the paper. This disposition is seen at fig. 1. Plate XLVI. where *bc* is the mirror, *ab* the transparent plain glass.

As the image and pencil are at different distances, they cannot be both seen in the same state of the eye. To remedy this inconvenience, a convex glass is used, of such focus as to require no more effort than is necessary for seeing the distant objects distinctly. By means of this lens, the image will appear as if it were placed on the surface of the paper. In fig. 1. *bd* is a convex glass of 12 inches focus, at *e* the eye is placed; *fghe* is the course of the rays proceeding from the object to the eye.

Those whose eyes are adapted to seeing near objects alone, will not derive advantage from the use of a convex glass, but will require a concave glass to

Camera Lucida.

be placed at *f*, in the course of the rays from the object to the reflecting surface. In fig. 2. Plate XLVI. *ik* is a concave glass placed in the above-mentioned situation; it is so disposed as to be turned at pleasure into its place, as the sight of the observer may require. Persons whose sight is nearly perfect, may use either the concave glass placed before the reflecting surface, or the convex glass placed between the paper and the eye.

Usual form of the Camera Lucida.

In the actual construction of the instrument, a prism is used instead of a mirror and a plain glass. The rays from the object fall upon the surface *bc* of the prism fig. 2. This surface *bc* is inclined $22\frac{1}{2}$ degrees to the horizon. The refractive power of the glass allows none of the rays in this situation to pass out; they are all reflected from the surface *bc* to the surface *ab*, and from that to the eye; *ab* makes an angle of 135 degrees with *bc*, and $22\frac{1}{2}$ degrees with the vertical. The eye cannot see the pencil through the prism as it does through a plain glass; therefore, in order that the pencil may be seen, the eye must be so placed that only a part of the pupil may be above the edge of the prism, as at *e*, fig. 3.; and then the reflected image will be seen at the same time with the paper and pencil. There is a small piece of brass perforated with a hole, and moving on a centre at *e*, fig. 2.; this serves to keep the eye in one position, as it must be, that the image may be steady, and also to regulate the relative quantities of light to be received from the object and from the paper.

The instrument, being near the eye, does not require to be large. The smallest size which can be executed with accuracy is to be preferred, and is such that the lens is only three-fourths of an inch in diameter. Fig. 4. shows the instrument on its stand, and clamped to a board. The joint by which the prism is attached to the stand is double. The whole instrument packs in a box eight inches by two, and half an inch deep.

Its Uses.

This instrument serves for drawing objects of all forms, and consequently also for copying lines already drawn on a plain surface. If it is required that the copy shall be of the same size as the original drawing, the distance from the drawing from the prism should be the same as the distance of the paper from the eye-hole. No lens will be necessary in this case, because the image and the paper being both at the same distance from the eye, coincide without the aid of a glass.

In order to have a reduced copy of a drawing, the drawing is to be placed at a distance from the prism greater than the distance of the paper from the eye-hole. If the distance is twice as great, a copy will be obtained, in which the lines are of one-half the size of the lines in the original, and so in proportion for other distances. A lens is necessary, that the eye may be enabled to see at two different distances; and, in order that one lens may serve, the distance between the eye-hole and the paper should be variable; to that effect, the stand is susceptible of being lengthened or shortened at pleasure.

The length of the stem is adjusted upon optical principles. When a distant object is to be delineated, the rays coming from it, and reflected by the instrument to the eye, are parallel, and it is required that the rays proceeding from the paper to the eye should also be parallel. This is accomplished by interposing a lens between the paper and the eye, with its principal focus on the paper. When the object to be delineated is so near that the rays which come from it to the eye are divergent, then it is required that the rays from the paper should likewise be divergent in the same degree, in order that the paper and the image may both be seen distinctly by the same eye; for this purpose the lens must be placed at a distance from the paper less than the distance of its principal focus. The stem of the instrument is marked at certain distances, to which the conjugate foci are in the several proportions of 2, 3, 4, &c. to 1, so that distinct vision may be obtained in all cases by placing the original drawing more distant.

If the convex lens be transposed to the front of the prism, and the proportional distances be reversed, a magnified image of the object will be obtained.

Compared with the Camera Obscura.

This instrument has deservedly come into use. Its advantages when compared with the camera obscura are, 1st, That it is small and easily carried about. 2dly, That no lines are distorted, not even those most remote from the centre, whereas, in the camera obscura, the lines which are not near the centre of the field are more or less distorted. 3dly, In the field of the camera lucida 70 or 80 degrees may be included, whilst the distinct field of the camera obscura does not extend beyond 30 or 35 degrees at most. The specification of Dr Wollaston's patent for the camera lucida is inserted in the *Repertory of Arts*, Vol. X. 1807, p. 162, and his description of the instrument in Nicholson's *Journal*, Vol. XVII.

Its Application to the Telescope.

If the camera lucida be fixed at the eye-glass of a telescope, it will reflect to the eye the image of the objects in the field of the telescope, so that a drawing of the image may be made. See Dr Brewster's *Account of some Philosophical Instruments*. A plain reflecting glass, fixed at an angle of 45 degrees with the horizon, and placed so as to receive the rays from the eye-glass of a telescope, will also give an image of the objects in the field, so situated that the image may be traced with a pencil. Varley's patent graphic telescope is upon this principle. In order that the field may be large, the magnifying power of the telescope should be small.

Various Modes of making Drawings of an Object.

The inherent qualities of all the instruments for drawing in perspective being closely allied, it will be proper to say something of the principles on which these instruments are formed, and to mention some that are not described in other parts of this work.

To make a perspective drawing of an object is to lay down on paper a section of the perspective cone, whose apex is at the eye, and whose base is the object. An experienced draughtsman can draw the figure of this section without the aid of instruments. Others who have not acquired the facility of drawing the image they see, must have recourse either to *measurement*, or to the *instruments, which bring the image under the pencil.*

Drawing by measurement is performed by actually measuring the height of the principal parts of the object, and their horizontal distance from the eye, together with the distance of the paper from the eye, and from these dimensions the drawing is constructed by the systematic rules of perspective.

Another mode of obtaining a drawing by measurement, is to measure the angles at the eye. Suited to this purpose are theodolites, astronomical quadrants, or other instruments, capable of measuring vertical and azimuthal angles at the eye. The angles to be measured are, the angles of altitude, and the angles of azimuth, between the point of sight and the principal points of the object; and if the tangents of the azimuthal angles be laid down with a radius equal to the distance of the paper from the eye, and the tangents of the angles of altitude with a radius equal to the distance of the paper multiplied by the secant of the azimuth, the situation of the principal points of the drawing will be determined. Or, if the instrument is capable of measuring angles in any plane, the angles between the principal points of the object and the point of sight are to be observed, and the azimuthal angles of these principal points with the point of sight; and the tangents of both are to be laid down on the paper, with a radius equal to the distance of the paper from the eye.

But these two modes by measurement are long, particularly the first. Usually, therefore, the instruments to which recourse is had for facilitating the operation of drawing, are such as give an image or section of the perspective cone on a plain surface, so that the pencil may be drawn over the outline of the image. These instruments may be considered under two heads. The first comprehending those in which the pencil is immediately drawn over the lines of the image. The second those in which the pencil has a motion parallel to that of the point which moves over the lines of the image.

Of the first kind are the following. 1. The tracing pane, a very simple and convenient instrument, consisting in a transparent plate of plain ground glass, or of Muscovy glass, placed vertically between the object and the eye; whilst the eye is kept fixed by a sight, the outline of the image is drawn on the glass with Indian ink. 2. Or the upright glass may be divided into small squares by lines crossing each other, and the paper on which the drawing is to be made, being similarly divided, the particular intersections on the glass that cover the principal points of the object are observed, and these points are laid down on the corresponding intersections on the paper. 3. The image seen in a plain mirror, may also be drawn on its surface with Indian ink. 4. In the camera obscura, different forms of which are described in the *Encyclopædia* under the articles Dioptrics and Optics, the image to be drawn is formed at the focus of a lens. 5. In the camera lucida the reflected image is used.

In the second division of the instruments which give a section of the perspective cone susceptible of being delineated, the pencil does not move immediately over the lines of the image, but moves parallel to these lines. 1. There is a rod which can be moved in all directions, consistent with its remaining parallel to itself. If one extremity of this rod be moved in space over the outlines of the image which the eye sees, a pencil at the other extremity will necessarily move with a similar motion, and form a drawing of the object on paper. In Sir Christopher Wren's instrument, of which he has given the description and figure in the *Philosophical Transactions*, Vol. IV., the rod is suspended by strings passing over pullies, and the ends of the strings are fixed to a counterpoise. On a similar principle is Peacock's instrument, described in the *Philosophical Transactions*, Vol. LXXV., p. 366; and the instruments treated of in the *Stockholm Transactions* for the years 1760, 1774, and 1790. 2. The pencil may delineate the base of a cone similar and opposite to the perspective cone. If the rays from the extreme points of an object cross on the ray from the centre, as they do in passing through a small hole into a dark room, and if it be supposed, that in the place of one of the rays a slender inflexible rod is substituted, moveable on a centre at the hole, when this rod is moved, so that its outer extremity goes over the outlines of the external image, a pencil fixed to its inner extremity will form an inverted drawing of the object. Of this nature is the optigraph of Ramsden and Thomas Jones, described in the *Philosophical Magazine*, Vol. XXVIII. 1807, p. 67. The image of the object is seen in a telescope. There is a piece of plain glass near *c* in the focus of the eye-glass of the telescope F, Plate XLVI., fig. 5. On the centre of this piece of glass is a dot: *a* is a plain mirror, inclined so as to reflect the image of the object down into the telescope; this mirror remains fixed, whilst the telescope is moveable on a universal joint at its object-glass *b*. Near *c* is another plain mirror, which reflects the rays to the eye-glass. The eye being placed at the eye-glass at *e*, the telescope is to be moved by the handle *h*, so that the dot in the focus of the eye-glass shall pass over the outlines of the image seen by the eye, and the pencil at L performing a similar motion to that of the dot, and sliding freely in its sheath, presses with its weight on the paper: a drawing of the object is the result. If the stand and slider H be lengthened, an enlarged drawing will be obtained. The instrument packs in a box 14 inches by 6 and 3. (Y.)

CAMPER (Peter), eminent for his extensive knowledge in the various branches of Medicine, Zoology, and Comparative Anatomy, and for his taste in the Fine Arts, was born at Leyden, May the 11th, 1722. His family had long held distinguished situations in the magistracy of that city, where his grandfather had exercised the profession of medicine. His father, Florent Camper, was a Protestant clergyman, and had officiated in that capacity for some years at Batavia; but had returned to his native country in 1713, after marrying Sarah Ketting, who was born of Dutch parents, at Surat. Florent Camper was an enthusiastic admirer of painting, and took great delight in the society of artists, whom he treated with the greatest liberality,—his purse being

Camper.

ever open to such as needed his assistance. He was much connected with the learned men who adorned the University of Leyden at the beginning of the last century; and was on terms of intimate friendship with the great Boerhaave. Young Camper has, no doubt, been greatly indebted for his success to the fortunate circumstances in which he was placed in early life; being thus surrounded by men of enlarged and cultivated understandings, eminent for their taste and learning, and having, at the same time, every incentive that a wise education could supply to emulate those excellent models; but nature had besides endowed him with that inherent desire of knowledge, that capacity, and that vigour and activity of mind, which, united as they were with a robust constitution of body, enabled him to reap the full benefit of these advantages. He gave very early proofs of his possessing those mental qualities, which lay the foundation of future eminence; and his father, discerning with delight the auspicious dawn of his genius, judiciously removed whatever might cramp its growth, and avoided imposing on him as a task those instructions and attainments, which he seemed so well inclined to acquire and pursue as an amusement.

He applied himself, at an early age, to drawing and painting, under the tuition of Moor and of his son, both of whom were celebrated artists, and soon became remarkably proficient in these accomplishments. He derived, in the course of his life, immense advantage from the skill with which he used his pencil in delineating any object in which he was interested, whether among the works of art, or the productions of nature,—or whether they were the offsprings of his own conception, in the course of his philosophical researches. The value of this acquirement, as an object of early education, is not, perhaps, in general, sufficiently appreciated. The power of conceiving readily, and with correctness, mechanical forms, is one of the most useful results that practice, in the delineation of objects, can confer, and is of incalculable advantage in a variety of pursuits, with which such a talent might not, at first sight, seem to be immediately concerned. There is no doubt, for instance, that it must remove many difficulties in the study of Geometry, by facilitating the conception of figured space, the properties of which are the subjects of that science. An accurate knowledge of Anatomy is still more directly dependant upon the same power of apprehending the relations of form. The progress which Camper made in this branch of science, and the range of inquiries to which he afterwards made his knowledge subservient, are striking illustrations of this position.

He was indebted to Labordes for his first lessons in Geometry, and was instructed in Natural Philosophy by Musschenbrock and Gravesande, who were the intimate friends of his father, and whose names will be ever illustrious in the annals of science. From these studies he was naturally led to the pursuit of Medicine, of which the elementary branches have so close an alliance with the physical sciences; and having entered the university of Leyden, became the pupil of Gaubius, Van Rooyen, and the elder Albinus; for Boerhaave was, by this time, incapacitated by the infirmities of age from continuing his exertions as public teacher in the university. Camper earned the first fruits of his academical labours by receiving, in 1746, the degree of Doctor in Philosophy and Medicine; on which occasion he published two dissertations; the one *De Visu*, the other *De oculi quibusdam partibus*, which are mentioned with commendation by Baldinger, in his *Biography of Living Physicians*, and which have been preserved by Haller. In the former he illustrates and defends Smith's *Theory of Vision*, and in the latter describes and gives plates of Petit's *Canal in the Eyes of different Animals.*

Camper.

The acquaintance he had formed at college with several foreigners of merit, had long inspired him with a desire of travelling, and of gratifying his thirst for knowledge, by visiting different countries, and conversing with men distinguished for their acquirements in the several branches of science. But the declining health of his parents, who were now advanced in years, and required the continual presence and kindest attentions of their son, long prevented him from accomplishing his wishes. Their death, however, which happened in 1748, released him from duties, which he had the consolation of reflecting had been so piously discharged; and he soon after, at the age of twenty-six, embarked for England. In London he met with the celebrated physicians Mead, Pringle, and Pitcairn, with whom he became acquainted. He pursued his medical studies under Hunter, Sharp, Smellie, and Winchester, and indulged his taste for natural history, by examining diligently the cabinets of Hans Sloane and Collinson, and the collections of Hill and Catesby. He studied Botany under Elliot, and Astronomy under Short; and was instructed in the use of the microscope by Baker, who was at that time applying this instrument with so much success to objects of natural history. He seemed determined to suffer no opportunity of amassing a store of useful knowledge to escape him; and although his views embraced a wide range of subjects, he was never satisfied with a superficial glance, nor trusted to the reports of others, when there was a possibility of seeing with his own eyes the objects of his curiosity. His attention was particularly directed to the mechanical arts; he visited the principal manufactories, and was indefatigable in collecting instructions from artists of eminence in every department; and his eager curiosity even extended to the details of naval architecture, to the study of which he devoted a considerable portion of time. He was in the habit, during all his travels, of making minutes of every thing he saw and learned; and his happy facility in the employment of the pencil, enabled him to take sketches on the spot of every object of which a delineation could be useful. Knowledge thus derived from personal observation is the more valuable, as it is more strongly impressed on the memory, and as it is less liable to inaccuracy, and less likely to be tinctured with prejudice, or distorted by the medium through which it is received. He still cultivated his taste for painting, and acquired much practical skill in the art

of engraving. After remaining about a year in London, and visiting the universities of Oxford and Cambridge, he proceeded to Paris, and devoted two months to the inspection of the principal public establishments in that capital. He then travelled onwards to Lyons and Geneva: but the prosecution of his journey in the direction of Italy was stopped by the intelligence he received of his being appointed Professor in Philosophy, Medicine, and Surgery, at Franeker, in Friseland; and he returned to Holland by Switzerland, and the banks of the Rhine, visiting, as he passed through Basle, the great Bernouilli, and examining, in the library of that city, the writings of Erasmus and the paintings of Holbein. The itinerary which he kept of his journey contains a great number of valuable remarks on agriculture and geology, and showed how well he was gifted with the talent for observation.

In consequence of a severe illness with which he was attacked in 1749, he was obliged to defer entering upon the duties of his new Professorship till the autumn of the following year, when, in conformity with the custom on these occasions, he pronounced a public inaugural discourse, choosing as his subject *De Mundo Optimo*. About the same period he was elected a Fellow of the Royal Society of London.

He had reaped so much advantage by his residence in England, and was so much attached to its inhabitants, and full of admiration for the great public establishments of that country, that he returned there during the vacation of 1752, and resumed his various pursuits, both medical and scientific, with unabated ardour. Among other objects, his attention was much directed to the method of inoculating for the small-pox, the practice of which was as yet confined to England. On his return to Franeker he resumed his lectures, which were every year more numerously attended, and gained him such increasing celebrity, that he was soon ranked as one of the ablest men of science in Holland. In 1755, he was appointed Professor of Anatomy and Surgery at the Athenæum of Amsterdam, and came, in consequence, to settle in that city, which was then the seat of opulence and learning. According to custom, he pronounced two inaugural discourses, the first, *De Anatomes in omnibus scientiis usu*; and the second, *De certo in Medicina*. In 1756, he married the widow of the Burgomaster of Harlingen.

After continuing six years in Amsterdam, his avocations were so multiplied and fatiguing, that he yielded to the strong desire which Mrs Camper had long entertained of retiring to Friseland; and once more took up his abode at his country house near Franeker. He, of course, resigned his Professorship at Amsterdam; but was allowed to retain the title of Honorary Professor of that Academy. His principal work, during the time he had held that chair, was the first volume of his *Demonstrationes Anatomico-Pathologicæ*. But the leisure he now enjoyed in his retirement in Friseland, allowed him to devote his whole time to science; and the second volume of the same work made its appearance in 1762, together with several other publications, of which notice will be taken in the sequel.

Two years thus glided by rapidly in the country, when he was again called to the active duties of an academical life, by the appointment which was conferred upon him of Professor of Medicine, Surgery, and Anatomy, in the University of Groningen. The proximity of this city to his present habitation, the natural activity of his mind, and a conscientious desire of being useful to the community, concurred with the love of fame, which retirement had not extinguished, in inducing him to undertake the office which he was now so honourably called upon to discharge. He accordingly established himself and his family at Groningen, and, at his inauguration as professor, delivered a discourse, *De admirabili analogia inter stirpes et animalia*. The great interest which he took in the improvement of agriculture, led to the establishment, under his auspices, of a society for the purpose of conducting experiments in this important art. To this society Camper was nominated Secretary. He bestowed much pains in investigating the nature of an epidemic disorder, which prevailed extensively among the cattle of Holland, and in devising the best means of diminishing its ravages. He made these the subject of several lectures, which he read, in 1769, to the Academy of Groningen; and his proposed method of inoculating the disorder, with a view of disarming it of its virulence, appears to have effectually succeeded in those districts where it was adopted. He was also much occupied, at this period, with researches in Natural History; and made a variety of important discoveries in Comparative Anatomy, of which we shall afterwards give a brief account.

The ten years that he spent at Groningen were esteemed by Camper the happiest, at the same time that they were the most laborious, of his life; and he probably would never have quitted a situation in every respect so congenial to his taste, or the circle of friends he had formed there, by whom his talents were well appreciated, and in whose approbation he found the reward of his exertions, if the wishes of his wife, and his own anxiety to superintend the education of his family, had not induced him to make the sacrifice of all these enjoyments, and once more remove to Franeker Academy, at which his sons were to be placed. He continued, nevertheless, steadily to prosecute his various philosophical and medical researches until the year 1776, when he sustained a heavy stroke of affliction in the death of his wife, in whom his affections had been centered during a union of twenty years, and whose domestic virtues, and exemplary attention to her children, had secured her the esteem and respect of all who knew her. As the most efficacious mode of soothing his grief, he determined upon varying the scene, and making occasional excursions to the neighbouring parts of the Continent. He accordingly visited all the cities that offered objects of attraction in the sciences or the fine arts; and after gratifying his taste for painting by the sight of the masterpieces of Rubens, Vandyke, and of other Painters of the Flemish School, proceeded, in search of amusement and instruction, to pay another visit to Paris. Here he enjoyed the society of Franklin, Marmontel, Di-

derot, Daubenton, Portal, and other distinguished characters in the literary and scientific world. Returning to his own country, with recruited spirits, he applied himself with fresh ardour to his favourite pursuits, and, aiming at more comprehensive views of the animal kingdom, occupied himself in pursuing the analogies which connect its several departments, and in tracing the successive links of that extended chain, by which the different orders of beings are united in one continued series of gradation. A tour through Germany, at a later period of his life, brought him acquainted with many treasures in Natural History, with which that country abounds. The anatomical preparations of Kerkringius, and the observatory of Tycho Brahe at Hamburgh; the collections of Natural History of Taube and Desrogues at Zell, and the superb cabinet of antiquities of the Count Walmoden at Hanover, particularly attracted his attention; and he explored with the eye of a geologist the volcanic district of Cassel. He formed also the acquaintance of Zimmerman, Soemmerring, and other eminent physicians. The following year he visited Prussia, and was presented to the great Frederick, who received him at Potsdam, with much affability and respect, conversing with him for a long time on the subject of the fine arts; and, on his return, had the honour of spending two days with the brother of the king, Prince Henry of Prussia, at Rhynsberg.

In 1785, Camper was chosen Member of the Royal Academy of Sciences at Paris, an honour which was the more highly prized, as the number of foreigners on whom it was conferred was limited to eight. In the same year, he paid a fourth visit to England, a country for which he had alway shown a strong partiality, and was again gratified with the society of the numerous friends he had left there, and of others whose acquaintance he then for the first time made.

His literary and philosophical occupations, numerous and important as they were, did not preclude him from taking an active part in the political concerns of his country. In 1762, he was returned as deputy in the Assembly of the province of Friesland; and in 1776, appeared there as deputy for Idaarderadeel. He persuaded the Assembly to reject a proposal for the restoration of the maritime dikes of that province. In 1783, on the recommendation of the Stadtholder, he was nominated one of the Council of State of the United Provinces, and was of course obliged to reside at the Hague. During the revolution which soon after occurred in Holland, he remained faithfully attached to the party of the Stadtholder; without, however, yielding his unqualified approbation to all their measures. The triumph of his own party was even accompanied with circumstances which gave him much concern, and embittered the latter period of his life. He died in 1789, of a violent pleurisy, on the 7th of April: and his remains were deposited in the tomb of his ancestors, in the Church of St Peter at Leyden.

To a mind enriched with vast stores of knowledge, and adorned with a taste at once elegant and refined, Camper united the most benevolent affections, and possessed all the virtues of domestic and social life. His conduct in the several relations of son, of husband, and of father, was in all respects exemplary. His manners were remarkably placid, and bespoke that habitual equanimity, which was the characteristic quality of his temper, and which, amidst strong sensibility to the affections of humanity, he constantly studied to preserve. Nature had bestowed upon him a dignified and graceful form, and a remarkably animated and expressive countenance. His voice, which was sonorous and flexible, was excellently adapted for public speaking. He had a singular facility in acquiring languages; and spoke fluently Latin, English, French, and German; and had, besides, attained a competent knowledge of Greek and of Italian.

Few men have received, during their lives, so many honourable marks of literary distinction as Camper. Besides those which have been already mentioned, he was chosen Member of the Academies of Petersburg, Berlin, Edinburgh, Manchester, Thoulouse, Gottingen, Harlem, Rotterdam, and Flushing; and was Foreign Associate of the Royal Society of Medicine at Paris. He obtained the prize of the Academy of Harlem, for his *Memoir on the Physical Education of Children*. His *Researches on Specific Remedies* gained him the prize of the Academy of Sciences of Dijon; his *Observations on Inoculation* that of the Academy of Thoulouse; and his *Memoir on Chronic Diseases of the Chest* that of the Academy of Lyons. The Royal Academy of Surgery voted him three prizes for his *Memoirs on the Influence of Different Circumstances in Regimen on the Treatment of Surgical Diseases*. To specify in detail the several subjects on which he has written, would be to extend this article to too great a length. We shall, therefore, content ourselves with enumerating those works which are of most importance; and, instead of reciting them in the order of their publication, shall arrange them according to the subjects to which they relate. His principal labours were bestowed on Comparative Anatomy and Physiology, and his discoveries in this wide field of research are numerous and important. A posthumous collection of his works on these subjects appeared at Paris in 1803, in 3 vols. 8vo, with a folio atlas of plates, under the title of *Œuvres de Pierre Camper, qui ont pour objet l'Histoire Naturelle, la Physiologie, et l'Anatomie Comparée*; to which is prefixed an Essay on his Life and Writings, by his son, and two eulogiums, one by Vicq d'Azyr, and the other by Condorcet. They contain his *Dissection and Natural History of the Orang-outang, and other Species of Apes*. He examines especially the peculiarities in the structure of the organ of voice of those animals, which deprive them of the power of uttering articulate sounds, and which alone would place an immense interval between them and the human species. His anatomical description of the two-horned rhinoceros, of the rein-deer, and of the elephant, are the subjects of separate dissertations; as also his researches on the structure of the great bones of birds, and the manner in which atmospherical air is introduced into them (of which the discovery was made by Camper, prior to the time at which Hunter published his observations on the same fact); on the

structure of the porpoise and the whale; on the classification of fishes, according to the system of Linnæus; on the anatomical structure of the organs of hearing in fishes, and of the blowing-holes of the *cetacea*; on the *dugon* of Buffon, and the *sirena lacertina* of Linnæus, both of which he pronounces to belong to the class of fishes; on the generation of the *pipa*, or American toad; on the croaking of the male frog; on the petrifactions found in the mountain of St Peter, near Maestricht, and the fossil bones of fish and other animals; on the analogies that may be traced between the several parts of the animal kingdom, especially in the structure of the human species, compared with those of quadrupeds, birds, and fishes; on the alteration of form in the human species produced by age; on the diversity of features which characterize different nations, and the mode of expressing these differences in delineating the human figure; on the mode in which the passions are indicated by the countenance; on the *beau physique*, or the beauty of forms; and on the analogy between plants and animals. In the practical branches of Medicine, he has written observations on the inoculation of the small pox, founded on experiment; on the theory and treatment of chronic diseases of the lungs, and a historical inquiry into the principal methods of cure employed by the ancients and moderns in these disorders; on the nature, employment, and mode of operation of remedies termed specifics; on the nature, causes, and treatment of dropsy, and the different indications of cure derived from the symptoms; on the nature of cancer, and on the signs denoting those of the breast that do not admit of cure; on the herniæ incident to new-born children, &c.; on ulcers in the urethra and prolapsus ani; on the fracture of the patella; on the callus of fractured bones; on lithotomy, and especially on the method of performing that operation at two different times, according to the plan of the celebrated Franco; on the construction of bandages for herniæ; on bandages in general; on the abuse of ointments and plasters, in the treatment of ulcers, and on improved methods of managing them; on the noxious effects attending the admission of air into the body, and the influence of this principle on the treatment of surgical diseases. In the department of Midwifery, he has written a letter to Dr Van Gescher on the utility of the section of the *symphysis pubis* in laborious labours, and observations on the use of the lever of Roonhuysen in difficult parturition. Several memoirs on the subject of infanticide, and the juridical questions connected with that subject, were published by him at Leenwarden. (w.)

CAMPOMANES (D. Pedro Rodrigues, Comte de), a Spanish Statesman, and Writer of great celebrity, particularly on subjects of Political Philosophy, was born in the Asturias towards the year 1710. We have sought in vain for biographical materials in regard to this eminent person, of whose life we can find no particulars but the scanty notices contained in the *Biographie Universelle*, and the Supplement to the last edition of the *Dictionnaire Universel*. From these works we learn that, in 1765 he was appointed by Charles III. Fiscal of the Royal and Supreme Council of Castille; that on the accession of Charles IV. in 1788 he was appointed President of this Council, and afterwards Minister of State; and that he was expelled from the Council, and deprived of all his employments, when Count Florida Blanca came into power. He was Director of the *Royal Academy of History*, and an honorary member of most of the other similar establishments in Europe. He supported his expulsion from office and power with firmness and dignity; and died at Madrid, according to the *Dictionnaire Universel*, in 1789, but according to the *Biographie Universelle*, not till after the commencement of the present century.

The number of his works, and the variety of subjects which they embrace, show him to have been a man of uncommon activity, as well as versatility of talent, while some of them display such a depth of political knowledge, and superiority to the prejudices of his country and age, as have ranked him in the first class of modern writers on Political Economy and Legislation. The following list contains abridged titles of his principal works, all of which, we believe, were published in the Spanish language, and none of them, so far as we know, has ever appeared in an English dress.

1. *Historical Dissertations on the Order of the Knights Templars*. Madrid, 1747. 2. *A Translation of the Periplus of Hanno, with Notes*. 1756. This translation was made from Hudson's edition of the *Periplus*, and the Notes contain a refutation of the objections urged by Dodwell against the authenticity of this celebrated Journal, which is now universally admitted to be one of the most curious relics of antiquity. The learning and ability which he displayed in support of it procured him an unsolicited place among the corresponding members of the French *Academy of Inscriptions and Belles Lettres*. 3. *A Geographical Account of the Kingdom of Portugal*. 1762. 4. Two *Memorials* relative to the means of regulating and employing *Gypsies* and *Vagrants*. 1763-4. 5. *A Memorial on the necessity of a Free Commerce in Grain*. 1764. 6. *Memorial on the provisioning of the city of Madrid*, drawn up and published by order of the Supreme Council. 1768, 2 vols. 8vo. 7. *Discourse on the Protection of Industry*. 1774, in 8vo. 8. *Discourse on the education of Artisans*. 8vo, 1775. In 1777 he gave to the world an *Appendix* to this work, containing a view of the causes which have led to the decline of arts and manufactures in Spain, in 4 vols. 8vo. Of these two great works, the *Discurso sobre el fomento de la industria popular*, and *Discurso sobre la educacion Popular de los Artesanos*, Dr Robertson speaks as follows: "Almost every point of importance with respect to interior police, taxation, agriculture, manufactures, and trade, domestic as well as foreign, is examined in the course of them; and there are not many authors, even in the nations most eminent for commercial knowledge, who have carried on their inquiries with more thorough knowledge of those various subjects, and a more perfect freedom from vulgar and national prejudices, or who have united more happily the calm researches of phi-

losophy, with the ardent zeal of a public-spirited citizen." *(History of America.)*

The above seem to be the chief productions of the pen of Campomanes; but, besides these, he was author of several other pieces on historical and literary subjects; and he published a complete edition of the voluminous works of Feyjoo, to which he prefixed an account of the life of that learned Benedictine.

CAMUS (CHARLES STEPHEN LOUIS), a mathematician and mechanician: born at Cressy en Brie, near Meaux, the 25th August 1699; son of Stephen Camus, a surgeon of that town, and Margaret Maillard.

His taste for practical mechanics was very early demonstrated by a singular ingenuity in the construction of a variety of little machines, with which he amused himself; and he soon felt so strongly the value of mathematical studies, that he urged his parents to find the means of sending him to a school where he might apply to them. In compliance with his wishes, he was placed, when he was little more than ten years old, at the College de Navarre, in Paris: and in two years he acquired knowledge enough to become an instructor of others, and to relieve his friends from all further expence in his education. He was assisted, in the pursuit of the higher departments of the mathematics, by the celebrated M. Varignon; and he particularly applied himself to civil and military architecture, and to astronomy.

1. The first result of his studies that was destined for the public eye, was an essay *On the Masts of Ships*, a subject which had been proposed in 1727 as a prize question by the Academy of Sciences. This essay was received with considerable approbation, and was inserted in the second volume of the *Collection of Prize Memoirs:* shortly after, the author was made an Adjunct, or Subassociate, of the Academy, in the department of Mechanics.

2. In 1728 he brought forwards a memoir on the *Living force* of bodies in motion, in which he concludes, from considering the actions of springs, and other similar powers, that its true measure is the product of the mass into the square of the velocity, as Leibnitz maintained: this product being also proportional to that of the force into the space through which it acts, while the momentum is proportional to the force and the time conjointly. In December 1730, M. Camus was appointed Professor of Geometry to the Academy of Architecture, and a few years afterwards he became Secretary to the same body.

3. The *Memoirs of the Academy* for 1732 contain a short paper on a *Problem proposed by M. Cramer*, respecting the determination of two curves bearing a particular relation to each other. It was the custom of the age to consider exercises of this sort as trials of strength, to which it was incumbent on all geometricians to submit, for the honour of the countries in which they lived, and of the societies to which they belonged. The author was elevated in 1733 to the rank of an Associate of the Academy, together with Clairaut, over whom he even obtained some advantage in the ballot.

4. He communicated to the Academy, in the same year, a valuable paper on the *Teeth of Wheels*. Lahire had already laid the foundation of the investigation on its true basis, and had pointed out the use of different epicycloidal curves for the forms of the teeth of wheels in different circumstances: and M. Camus, in this essay, enters into some further inquiries, particularly with regard to the best proportions for the length of the teeth, and the comparative diameters of the wheels: a discussion for which his intimate acquaintance with the art of the clockmaker made him particularly well qualified. In 1736 he accompanied Maupertuis and Clairaut in the expedition to Lapland, for the measurement of a degree of the meridian; and he was enabled to render them very essential service, not only as a geometrician and an astronomer, but also by his skill in various departments of the mechanical arts, which became particularly valuable in so remote a situation.

5. M. Camus directed his attention in 1738 to the well known but interesting mechanical phenomenon of a *Pistol ball piercing an open door*, without causing any very sensible motion in the door, and published a paper on the subject in the *Memoirs of the Academy*. He justly observes, that the effect of any force depends, not only on its magnitude, but also on the time for which it operates; and that though the impulse of the ball must tend to carry the door before it, with a force paramount to the resistance which it opposes to the ball, yet the time of the action of this force is too short to produce a sensible effect on the whole mass of the door. 6, 7. In 1739 he presented to the Academy two hydraulic memoirs, the one on *Water buckets*, the other on *Pumps*. In the latter he investigates the diameter of a valve, capable of transmitting the greatest quantity of water, within a given barrel; a valve which is too large not being at liberty to rise to a sufficient height.

8. He inserted in the *Memoirs* for 1740 a confutation of a *Mechanical fallacy*, which has misled many of the enthusiasts who have bewildered themselves in the search of a perpetual motion: demonstrating, that when a number of weights are caused to descend, in any imaginable paths, at a greater distance from the centre of a wheel than they ascend, the number of the weights descending at any one time must always be smaller than those of the weights ascending; and in such a proportion, as perfectly to compensate for the mechanical advantage apparently gained by the greater distance. In the following year he was received into the number of the Academicians, in the department of Geometry, on occasion of the resignation of M. Fontenelle. 9. He published also, in the *Memoirs* for 1741, an account of a *Gauging rule*, for measuring barrels of different forms, by simple inspection of the logarithmic scales engraved on it, observing only some easy rules for their adjustment, according to the general nature of the solid. 10. In 1746 he presented a Report, in conjunction with M. Hellot, on the *Length of the Standard Ell*, which was thought worthy of being inserted in the collection of the Academy.

11. We find among the *Memoirs* for 1747 an essay of M. Camus on the *Tangents of Curves* having several branches, crossing each other; which frequently require, for their determination, the use of fluxions of the higher orders, the first fluxions of the absciss and ordinate vanishing together. M. Saurin had before given a similar solution of the problem, but had not attempted to explain the metaphysical ground, upon which the apparent paradox is reconciled to the general principles of the differential method.

12. M. Camus also assisted in several determinations and reports which were referred at various times to committees of the Academy; and particularly in the remeasurement of M. Picard's base from Villejuif to Juvisy, which was performed by eight members, and recorded in the *Memoirs* for 1754.

13. The latter years of his life were much occupied in various engagements connected with the offices of Examiner in the schools of the Royal Engineers and in that of the Artillery, to which he was nominated by the King. He undertook, for the advantage of the students in these schools, the laborious task of reducing into a uniform system a complete course of mathematical study, in which the geometrical method was as much as possible observed, and which is considered as highly creditable to his talents and exertions: it was entitled *Cours des Mathématiques*, 4 vols. 8vo. 14. He also published an *Elementary work on Arithmetic*.

In person M. Camus was tall; his countenance was agreeable; his manners firm, and occasionally somewhat warm; but he was far from being either morose or vindictive. He was elected a foreign member of the Royal Society of London in January 1764. He married, in 1733, Mad[le]. M. A. M. Fourrier, and had four daughters, the eldest of whom was married to M. Pagin; the others died young. His last illness was supposed to have originated from a cold, taken in a professional journey, during the hard winter of 1766; and to have been aggravated by affliction for the loss of his surviving daughter: he died a few months after her, on the 4th May 1768. He left a variety of manuscripts, demonstrative of his habitual diligence, and of the extent of his researches; but not deemed of sufficient importance to meet the hazards of posthumous publication. (*Hist. Acad. Par.* 1768. P. 144.) (M. E.)

CANADA. In the *Encyclopædia* will be found an account of the settlement and early history of Canada, with other particulars relative to the nature and productions of the country. At present we propose to add such further information as we have been enabled to collect from the works of recent travellers.

Canada.

In the year 1791, the territory formerly distinguished by the general name of Canada, was divided, by an act of the British Parliament, into the two provinces of Upper and Lower Canada. These are comprehended within the 61° and 81° of west longitude from London, and between 42° 30′ and 52° north latitude; and are computed to extend from east to west about 1400 miles, and from north to south from 200 to 400 miles.

Lower Canada.

The province of Lower Canada lies between 45° and 52° of north latitude, and between the 63° and 81° of west longitude. On the north it is bounded by the territory of East Maine; on the east by the Gulf of St Lawrence, the river St John, and part of the Labrador coast, now annexed to the government of Newfoundland; on the south, by New Brunswick and the territories of the United States, namely, the district of Maine, the province of New Hampshire, the state of Vermont, and the state of New York; on the west, by a line which separates it from Upper Canada, commencing at a stone boundary on the north bank of the Lake St Francis, in St Lawrence river, thence north to Ottawa river, which it ascends to its source in Lake Temiscaming, and from thence due north, till it strikes the boundary-line of Hudson's Bay, including all the territory to the westward and southward, commonly known under the general name of Canada. This province is divided into the districts of Montreal, Three Rivers, Quebec, and Gaspé, which by proclamation of the Government were, in 1792, subdivided into the following twenty-one counties, viz. Bedford, Buckingham, Cornwallis, Devon, Dorchester, Eppingham, Gaspé, Hampshire, Hertford, Huntingdon, Kent, Leinster, Montreal, St Maurice, Northumberland, Orleans, Quebec, Richlieu, Surrey, Warwick, and York. The minor divisions are, 1*st*, The seignories, or the original grants of the French Government under the feudal system, which, in the year 1721, were again partitioned out into parishes. The limits of these last, however, have not been very strictly adhered to, portions of ancient parishes having been from time to time constituted into new ones. 2*d*, The townships or grants of land made by the English Government since the year 1796, in free and common soccage.

Upper Canada.

The following are the boundaries of Upper Canada: On the east, it is bounded, since the year 1791, by Lower Canada; on the north-east, by the Grand or Ottawa river, which is the common boundary between it and the lower province; on the north, by the territories of the Hudson's Bay Company; on the south and south-east, by the United States of America, although the common frontier between these two states is far from being well defined. It is merely an imaginary line, beginning at the village of St Regis on the St Lawrence, in the 45th° of north latitude, passing up the middle of this river, through Lake Ontario, the Niagara river, and Lake Erie, and continuing thence through the middle of the water-communication into Lakes Huron and Superior, along the middle of the chain of lakes which leads to the Lake of the Woods, and from thence due west to the river Mississippi.* The treaty of 1815 provides for the revision of this boundary-line. On

* This is the boundary fixed by the treaty of 1783, when the country was little known, and it is therefore erroneous; the Lake of the Woods being to the north of the sources of the Mississippi. A line drawn due west from this lake would never strike the Mississippi.

Canada.

the west and north-west, no limits have been assigned; and Upper Canada may be supposed, therefore, to extend, in this direction, as far as the Pacific and Northern Oceans.

Upper Canada is divided into eight districts, namely,

Eastern,	The Home,
Johnstown,	Niagara,
Midland,	London, and
Newcastle,	The Western.

These again are subdivided into twenty-three counties, namely,

Glengary,	Prince Edward,
Stormont,	Northumberland,
Dundas,	Durham,
Prescott,	York,
Russel,	Norfolk,
Grenville,	Oxford,
Leeds,	Middlesex,
Carleton,	Lincoln,
Frontenac,	Haldimand,
Lenox,	Kent, and
Addington,	Essex.
Hastings,	

These contain 159 townships, exclusive of Indian lands, and certain other portions that are reserved for the Crown, and the maintenance of the Protestant clergy. The quantity of land in each township is computed by Bouchette, in his valuable and elaborate work on Canada, to amount, on an average, to 61,600 acres, making the whole amount to 9,694,400 acres; of which 3,000,000 of acres are granted in feu and common soccage, 2,769,828, are reserved for the Crown and clergy, and 3,924,572 still remain to be granted.

General Aspect of the Country.

The country of Canada is intersected by mountainous ridges, which extend from the coast far into the interior, and between these lie extensive valleys, which are generally pleasant and fertile. On the southern shore of the St Lawrence, a ridge of heights rises near the eastern extremity of Lower Canada, which runs close to the river for upwards of 100 miles, and forms its rugged banks as far as Cape Tourment, about 30 miles below Quebec. Here the ridge, taking a direction west south-west, terminates on the river Ottawa, about 38 leagues above its confluence with the St Lawrence; extending westward from Cape Tourment along the course of the river about 300 miles. The tract of country lying between it and the St Lawrence, which may be estimated at from 15 to 30 miles in breadth, is beautifully picturesque, well watered, and level. Towards the westward, more especially, it may be considered, both in respect to population, soil, and skilful cultivation, as the choicest part of the province.

That part of Canada which lies on the north side of this ridge, is comprehended within the Ottawa river on the north-west, the 81st parallel of west longitude, and the 52d of north latitude. It is intersected by another and higher range of mountains, which runs into the interior in a north-west direction, at the distance of about 200 miles from the former ridge, and which forms the height of land by which the tributary streams of the St Lawrence are divided from those that fall into Hudson's Bay. Of this extensive wilderness, which has been but imperfectly explored, all that we know is, that it is covered with immense forests, whose dreary solitudes are only interrupted by hunting parties of wandering savages.

On the south side of the river St Lawrence, a ridge commences nearly 100 miles below Quebec, taking a south-west direction; and, opposite to this city, it is about 10 leagues distant from the river. The intervening country is a fertile and well-cultivated level, with several insulated hills, or rather rocks, of a singular form, and thinly covered with small trees near their summits. The same chain, continuing in a south-west direction, crosses the boundary-line between Canada and the United States to the west of Lake Memphremagog, and proceeds in the same course until it meets with the Hudson river. The tract between this ridge and the St Lawrence, with the exception of some occasional ridges, is nearly level; and, from the richness of its soil, is covered with populous and flourishing settlements.

Beyond this ridge, at about the distance of 50 miles, is another and a higher ridge, generally denominated the Land's Height, as it divides the tributary streams of the St Lawrence from those which flow towards the Atlantic Ocean, and its summit is also supposed to constitute the boundary-line between the territories of Great Britain and the United States. This range of mountains commences near Cape Rosier, in the Gulf of St Lawrence, and, running into the interior in a direction nearly parallel with the course of the river, and with the former chain, it terminates upon the eastern branch of Connecticut river, being in length nearly 400 miles. The country lying between these two ridges, varies in its quality and fruitfulness, according to its peculiar situation. From the 45th degree of north latitude, which is the boundary-line between Canada and the United States, to the river Chaudiere, within a few miles of Quebec, there is a tract of excellent and fertile land, divided mostly into townships, many of which are settled and under cultivation. This part of the country, both from its luxuriant soil, and from the great advantage of its being contiguous to the United States, and its comprehending the main roads and principal points of communication between the two territories, will probably become the most flourishing portion of the province. From the river Chaudiere eastward to Lake Temiscouata, the land is broken, irregular, and of an indifferent quality; interspersed, however, with some good and productive tracts, of which the returns would amply repay the expences of cultivation.

From Lake Temiscouata eastward to Cape Rosier, in the Gulf of St Lawrence, the country has been but partially explored. But it appears generally to be of a rugged and mountainous character, and such parts of it as are known exhibit an appearance of sterility which holds out no encouragement to the labours of the farmer. On the banks of the St Lawrence, however, some fertile spots are to be found, on which settlements might be established with advan-

tage. On the south side of the ridge, down to the shores of Gaspé and Chaleur Bay, the country is generally barren and mountainous, interspersed with occasional spots of excellent land, some of which, especially those on the shores of Chaleur Bay, are well settled. They contain about 3000 inhabitants, most of whom, being employed in the fisheries, bestow comparatively little attention on agriculture.

That portion of Upper Canada which has been laid out into townships, extends from its eastern frontier along the north shore of the river St Lawrence, Lake Ontario, Lake Erie, Lake St Claire, and the communication between it and Lake Huron, in length about 570 miles, and its breadth towards the north varies from 40 to 50 miles. Through the whole of this track the soil is excellent, and is not exceeded by any other part of the American Continent. It generally consists of a fine dark loam, mixed with a rich vegetable mould; but it is so happily varied as to present situations adapted to every species of produce. For about 170 miles from the eastern frontier of the province to the head of the Bay of Quinté, on Lake Ontario, the land is spread out into an almost uniform level of great beauty, which rises only a few feet from the bank of the St Lawrence. It is well watered in almost every direction by numerous streams, which are generally navigable for boats and canoes, and which, at the same time, present the most desirable situations for the erection of machinery. From the Bay of Quinté, about 40 miles from the eastern shores of Lake Ontario to its western extremity, runs a longitudinal ridge of no great elevation, and of inconsiderable breadth. Another ridge, called the Queenstown Heights, extends eastward along the southern shores of Lake Ontario, between these and Lake Erie, into the State of New York. This range never rises in any part more than 160 yards above the level of the lake. The country which lies between the two lakes of Ontario and Erie, and which extends round the western extremity of Lake Ontario to the Bay of Quinté, comprehending the Newcastle, the Home, and the Niagara districts, or nearly one-third of that portion of the province which has been surveyed, and laid out into townships, is watered by a number both of large and small streams. The land throughout is uncommonly rich and fertile, and already contains a number of flourishing settlements.

The remaining part of the tract we have been describing, which extends along the southern shores of Lake Erie, from the river Ouse to the Lake and River of St Clair, is a complete level, abounding in the most advantageous situations for settlements; and those places which are already occupied and under tillage, equal any part of either province, for the plentiful crops and thriving farms with which they abound. That portion of the country which lies between Lake Erie and Lake St Clair is, perhaps, the most delightful in the whole province. The fertility of the soil,—the diversified and luxuriant scene which everywhere opens to the view,—the excellent fish which abound in the rivers, and the profusion of game in the woods, combine to attract a continual supply of new settlers to this highly favoured tract.

Beyond these cultivated parts of Upper Canada, there are large tracts of land, stretching far to the northward, covered with immense forests, the haunt of wild animals and of wandering savages. But these regions, though they have never been explored by the Europeans, are known to spread out into valleys of a rich and fertile soil, more especially in the country skirting the south-west shore of the Ottawa river. They are also watered by many streams, some of a large size, which flow both into Lake Huron, and into the Ottawa river. The course of these rivers is not, however, sufficiently known, to be traced with accuracy on the map. In those unexplored countries all sorts of timber are found in the greatest profusion. The oak, beech, walnut, ash, hickery, maple, elm, pine, sycamore, birch, and many other sorts, grow to the largest dimensions, which is the best proof of the fertility and vigour of the soil in which they have taken root.

Rivers.

The rivers and lakes of Canada are stamped with a peculiar character of grandeur. The great river St Lawrence issues from Lake Superior, and flowing successively through Lakes Huron, Erie, and Ontario, falls into the ocean after a course of 2000 miles. Its course is through a long and narrow valley, in which, also, are contained the great lakes from which it derives its ample stream. This valley seems to have taken the form of the immense collection of waters of which it is the depository; it is closely encompassed on every side, except on that through which the river makes its way to the sea, by different ranges of mountains, which completely encircle the great lakes at the distance, in some points, of not more than sixty miles, and shutting them up from the interior, form the dividing ridge between the tributary streams of the St Lawrence, and those which flow north and south into Hudson's Bay and the Mississippi. The prodigious volume of water which the St Lawrence rolls into the ocean, and the extent to which it is navigable, give it the pre-eminence over all the other great rivers of the American Continent. Its breadth, at its mouth, may be reckoned 90 miles, and at Saguenay river, 260 miles higher up, it is still 18 miles broad. It is navigable with safety for ships of the line 400 miles from its mouth, and, to Montreal, 160 miles further, it is navigable, with very little difficulty, for ships of 600 tons burden. For vessels of a larger size the navigation is intricate and dangerous. The St Lawrence is diversified by numerous islands, and its shores alternately present the pleasing view of flourishing settlements, and of sublime and picturesque scenery.

The tract of country which the St Lawrence drains of its waters, is confined, both on the north, and more especially on the south, by ranges of mountains which run along its whole extent; so that there is no adequate space for the formation of such immense tributary rivers as pour their waters into the Amazons, the Plata, or the Mississippi. It will, accordingly, be found that the main stream of the St Lawrence is not increased by such vast accessions from the tributary waters of the territory through which it flows, as those last mentioned rivers. The

Canada.

principal rivers which it receives from the north, are the Ottawa, the Masquinongé, the St Maurice, the St Ann, the Jacques Cartier, the Saguenay, and the Manicouagan. From the south, it receives the Salmon river, the Chateaugay, the Chambly or Richlieu, the Yamaska, the St Francis, the Becancour, the Du Chene, Chaudiere, and Du Loup. Of these, the Ottawa and Saguenay are important rivers, and bring a great accession to the stream of the St Lawrence. The Saguenay is a broad, deep, and uncommonly rapid river. At its mouth it is only one mile broad, but is said to be of unfathomable depth, attempts having been made to find the bottom with 500 fathoms of line, but without effect. About two miles higher it has been found to be from 130 to 140 fathoms deep. The Ottawa is also a large and important river. It has its rise from several lakes in Upper Canada, and, rushing over a bed of remarkable declivity, falls into the St Lawrence a few miles above Montreal.

Lakes.

No country in the world contains such immense depositories of fresh water as Canada. Its lakes are not only numerous, but they are unequalled in magnitude by those of any other country in the world. Lake Superior, which is of a triangular form, is 381 miles in length, and 161 broad. Its circumference is above 1100 miles, and it is equally remarkable for the transparency of its waters and for their extraordinary depth. Lake Huron yields but little, in point of extent, to Lake Superior. Its greatest length from west to east is 218 miles; at its western extremity it is less than 100 miles, and at about 100 miles from its eastern shore it is scarcely 60 miles broad; but near the centre it extends southward to the breadth of 180 miles. Its circumference, measuring all the bendings of the coast, is about 812 miles. At the western angle of Lake Huron is Lake Michigan, which is 262 miles in length by 55 in breadth, and whose circumference is 731 miles. Lake Erie, which is connected with Lake Huron by the river Detroit, extends from south-west to north-east 231 miles. It is $63\frac{1}{2}$ miles in breadth where it it is broadest, and is 658 miles in circumference. From the north-east extremity of Lake Erie, the communication to Lake Ontario is by the Niagara river, and is 36 miles in length. This lake is 171 miles in length, its greatest breadth is $59\frac{1}{2}$, and its circumference is 467 miles. In the interior, the country is covered with numerous smaller lakes, which are so connected, that, by the help of short pontages, and other expedients, a navigable communication, by means of canoes, is carried to the Lake of the Woods, Lake Winnipeg, and onwards to the distance of several thousand miles in the remote regions of the north-west country.

Climate and Seasons.

In Canada, the opposite extremes of heat and cold are felt in all their excess. The greatest heat experienced during the summer is from 96 to 102 degrees of Fahrenheit in the shade; but the usual summer heat varies from 75 to 80. In the winter, the mercury sometimes sinks to 31°, and it has even been known to fall so low as 36° below 0. It never continues, however, above one or two days at these extremes, and it is not above once or twice in a season that this excessive cold is felt. The medium temperature of winter may be estimated, in general, to be from 20 degrees above to 25 degrees below 0. The pure air and cloudless sky, which always accompany this intense frost, make it both pleasant and healthy, and render its effects on the human body much less severe than when the atmosphere is loaded with vapours. In the vicinity of the sea, towards the eastern coast of Lower Canada, fogs are frequently brought from the gulf of Lawrence, by the easterly wind. But to the westward they seldom prevail, and even at Quebec they are almost unknown. In Canada, the spring, summer, and autumn are comprehended in five months, from May to September. The rest of the year may be said to consist wholly of winter. The summer commences in May, and ends with September. In October, frost begins to be felt, although during the day, the rays of the sun still keep the weather tolerably warm. In the succeeding month of November, the frost increases in rigour, and one snow storm succeeds another, until the whole face of the country is covered, and the eye looks in vain for one solitary spot of verdure whereon to rest. These storms are generally accompanied by a violent tempest of wind, which, driving along the snow with immense velocity, renders them tenfold more gloomy and terrific. The most severe snow storms occur in November. They generally come from the north-east, from the frozen regions of Hudson's Bay and Labrador. This gloomy and disagreeable weather frequently continues to the middle or latter end of December, when the atmosphere clears; an intense frost succeeds—the sky becomes serene, pure, and frosty, and of a bright azure hue, and this cold and clear weather generally lasts till the month of May. The snow covers the ground to the depth of several feet, so that wheel-carriages can no longer be used. Their place is supplied by *carioles*, a sort of sledges, which, being placed on iron-runners, resembling in their form the irons of a pair of skaits, pass over the hardened snow without sinking deep. Those carriages are generally light open vehicles, drawn by one horse, to which the snow, after it is trodden for some time, and hardened by the frost, offers very little resistance. In these vehicles, the Canadians travel in the most agreeable manner, and with inconceivable rapidity. So light is the draught, that the same horse will go in one day 80, and sometimes 90 miles, and the inhabitants of this cold climate always take advantage of the winter season, when they can travel so easily and expeditiously, to visit their friends who live at a distance. Covered *carioles* are sometimes used to protect the travellers from the weather. But, in general, open carriages are preferred.

About the beginning of December, all the small rivers are completely frozen over and covered with snow. Even the great river St Lawrence is arrested in its course, and from the beginning of December till the middle of April, the navigable communication is interrupted by the frost. During this period, the river from Quebec to Kingston, and between the great lakes, except the Niagara and the rapids, is wholly frozen over. The great lakes are

Canada. never entirely covered with ice; but it usually shuts up all the bays and inlets, and extends many miles towards the centre of those inland seas. In Lake Superior, which is furthest to the north, the ice extends 70 miles from the shore. It is seldom that the river is frozen over below Quebec. But the force of the tides is continually detaching the ice from its shores, and those immense masses are kept in such constant agitation that navigation is rendered quite impracticable. In some seasons, though rarely, the river is frozen completely over below Quebec; and this happens when large masses of ice come in contact, and fill the whole space between one side of the river and the other, in consequence of which the whole becomes stationary. If this takes place at neap tides, and in calm weather, the intense frost gives it solidity before it can be deranged by the rising tides; and when it has stood some days, it remains firm and immoveable, till it is dissolved and broken up by the warmth of the April sun. When the river is frozen over, it is of great advantage, both to the inhabitants of Quebec, and to those of the adjacent country, as it affords an easy mode of transporting into the town all sorts of bulky commodities, such as fire-wood, and other produce. It thus reduces the price of those necessary articles in Quebec, while by diminishing the price of carriage, it opens to the produce of the most distant parts of the country, a quick and easy access to all the most eligible markets.

The snow begins to melt in April, and the thaw is so rapid that it is generally gone by the second or third week. Vegetation then resumes its suspended powers; the fields are clothed with verdure, and spring can scarcely be said to exist before summer is at hand. In Upper Canada, the winters are much shorter than in Lower Canada, nor is the cold so intense. The spring opens, and the labours of the farmer commence six weeks or two months earlier than in the neighbourhood of Quebec. The climate is not liable to the same extremes either of heat or cold, and the weather in autumn is usually favourable for securing all the late crops.

Commerce. The exports from Canada consist chiefly of oak and pine timber, deals, masts, and bowsprits, spars of all denominations, staves, pot and pearl ashes, peltry, wheat, flour-biscuit, Indian corn, pulse, salt provisions, furs of various descriptions, and other miscellaneous articles. The imports are wines, rum, sugar, molasses, coffee, tobacco, salt, coals, and all sorts of manufactured articles from Great Britain. The commerce of Canada has been progressively increasing since it became a British colony. In the year 1769, the value of produce exported amounted to L. 163,105; and it employed 70 vessels belonging to Great Britain and to her subjects in the different colonies of North America. Not more than twelve vessels were engaged at this period in the fisheries of the St Lawrence, and about six were sent to the West Indies. In the course of the next ten years, the trade appears to have greatly improved; and the number of vessels employed in 1775 was increased to 97, containing 10,841 tons. In the succeeding ten years, the number of vessels which entered the St Lawrence was diminished to 57. But in the course of another period of ten years, about the year 1795, not less than 128 vessels were employed in the commerce of Canada. This increase was occasioned by the scarcity of grain which prevailed at that time in Britain, and in other countries of Europe; to supply the augmented demands from this quarter, there were exported from Canada in that year 395,000 bushels of wheat, 18,000 barrels of flour, and 20,000 cwts. of biscuit. The high prices which were procured for those necessary articles, gave a powerful stimulus to industry in all its branches, and by increasing the capital of the colony, gave it the means of carrying on a more extended commerce. The following is an account of its exports and imports:

For 1797, from Quebec, furs and other produce	L. 295,063
Wheat, biscuit, and flour	45,445
Oak and pine timber, planks and staves	32,144
Pot and pearl ashes	29,866
Fish, lumber, oil, &c. from Labrador and Gaspé	88,900
	491,419
Imports from England of manufactured goods, and West India produce	338,214

In 1799 and the three following years, large exportations of grain took place. In 1802, 1,010,000 bushels of wheat, 38,000 barrels of flour, and 32,000 cwts. of biscuit were sent abroad; and the number of vessels engaged in the trade of the colony was 211, the aggregate burden of which amounted to 36,000 tons. Agriculture in Canada has since been greatly extended,—the surplus produce has of course increased, and we find the exports amounting for 1807 to L. 813,900; the imports to L. 467,294. In 1808 the exports had increased to L. 1,156,060, and the imports to L. 610,000.

The following is an account of the value of the exports to the British colonies in North America during four years previous to 1814:—

	British Produce.	Foreign.	Total.
1810,	L.1,484,383	L.263,733	L.1,748,116
1811,	1,578,464	266,095	1,844,559
1812,	1,658,531	251,158	1,909,689
1813,	1,134,987	284,032	1,419,019

This includes the exports to Nova Scotia and Newfoundland, which being deducted, the annual value of the exports to Canada will not be found to amount to more than one million. Since the year 1808, therefore, its trade does not appear to have materially increased. In 1808, the number of vessels which cleared outwards from Britain to Canada was 179, and the number of arrivals from Canada, in the same year, was 202. In 1815, those which cleared outwards amounted only to 132, and those which entered inwards only to 138. This, however, is probably owing to accidental circumstances; since it cannot be doubted that as the interior ad-

Canada.

vances in population and improvement, there will be a corresponding increase of external trade.

Population.

For a long period after its original settlement, the colony of Canada was neglected by the court of France, and its administration was left, in a great measure, to the discretion of individuals. In 1663, it was raised to the dignity of a royal government, and from this period its governors were appointed by a regular commission from the king. Its inhabitants amounted to about 7000, who, possessing the advantages of a free trade and of regular government, began rapidly to increase; and, in 1714, their numbers had risen to 20,000. The colony would even have increased more rapidly, but, by the rashness of its governors, it was engaged in almost perpetual hostility with the native tribes, by whose continued incursions the attention of the settlers was distracted from agriculture to war. Under these disadvantages, however, its population had increased, in 1759, when it was conquered by the English, to 70,000. The conquest of a country must be regarded as a serious evil, even in circumstances the most favourable; and the revolution which took place, in consequence of this event, in the government and political institutions of Canada, tended, for some years, to retard its progress. The change of allegiance from one sovereign to another, was rendered as easy as possible to the inhabitants, by the lenient measures of the conquerors. Their laws were allowed to remain unaltered. They were secured in the undisturbed possession of their lands under their ancient tenures, and in the free possession of their religion. All religious property was respected, and every concession was made by the British Government in favour of the peculiar customs and manners of its new subjects. Under this judicious management, the country soon began to improve, and, in the year 1775, its population, including the new settlers in Upper Canada, who could not amount to above some thousands, had increased to 90,000. In 1814, according to a regular census, the province of Lower Canada contained 335,000 inhabitants. Of this number 235,000 may be reckoned native Canadians, descendants of the original French settlers. The remainder is composed of emigrants from various nations, chiefly English, Scotch, Irish, and American. In the year 1783, the settlers of Upper Canada were estimated at 10,000, of which the numerous frontier posts and garrisons constituted by far the greatest part. After this period, the number of settlers was augmented by a great accession of loyalists and disbanded soldiers, and by emigrants from the United States, and from Great Britain, so that in the year 1814 the inhabitants of the province had increased, according to the most accurate returns, to 95,000. Since the year 1793, the progress of this colony has been particularly rapid. In that year a solitary Indian wigwam stood where the town of York, the capital of Upper Canada, is now built. In the succeeding spring, the ground was marked out for the future metropolis of the country, and it now contains 2500 inhabitants, and is fast increasing. It is the residence of the chief officers of government, both civil and military, and affords many of the more refined comforts and conveniencies of life. A newspaper is printed once a week, and its markets are well supplied with every necessary from the adjacent lands, which are in a high state of cultivation. The other towns of Upper Canada are Kingston, Johnstown, and Cornwall. The two latter contain only sixty or seventy houses, built of wood. The town of Kingston was founded in 1784, and it now presents a front of nearly three quarters of a mile in length, and extending in breadth about 600 yards. It contains 370 houses, and the streets are regularly planned, crossing each other at right angles, though they are not paved.

State of Landed Property.

At the time when Canada was conquered by Britain, the lands throughout the country were universally held by feudal tenures, all of which being confirmed by the British Government, still remain in force. But the townships and tracts subsequently disposed of, have been, with two or three exceptions, granted in free and common soccage. Under the French Government, the lands were held immediately from the King, either *en fief* or *en roture*; each proprietor being bound to render homage to the sovereign, on his accession to the seignorial property. The revenues of the seigneurs arise from various sources. They are entitled to certain fines from their vassals, which are paid on the alienation of any part of the property. In the event of a sale, a sum of money equal to a twelfth part of the price, is payable to the seignior, and he has also the right, within forty days after the sale, to take the property sold at the highest price offered,—a right, however, which is seldom exercised. In the event of new lands being granted, a fifth part of the whole purchase money is payable to the seigneur, which, if paid immediately, entitles the purchaser to a deduction of two-thirds of the fine. The vassals are also bound to grind their corn at the lord's mill, and this condition is found on many occasions to be exceedingly irksome. In a large seigniory, for example, there may not be more than one mill; and though it should be ten miles distant from the tenant's farm, and although he might have his corn ground on better terms at some adjoining mill, he is, nevertheless, bound to carry it to the seignior's mill, under a heavy penalty. Another evil of these seignorial rights is, that they are by no means well defined, and that the vassal is, in consequence, subjected to exorbitant and unjust demands, when the superior happens to be of a rapacious disposition. In the provincial assembly, the propriety of setting bounds to these undefined privileges has been frequently urged by the English members. But the French party, attached to old habits, which they found conducive to their interest, have hitherto strenuously and successfully resisted any alteration of the established laws. The seignior is entitled to receive a tithe of the produce of all the fisheries which are established within the bounds of his seigniory. He has also the privilege of felling the timber which grows in any part of his seigniory, for the purpose of erecting mills, repairing roads, or constructing new ones, or for any other purpose of general utility. Many proprietors of seigniories have acquired wealth from these revenues, as the sales

nada. and transfers of landed property have of late years become numerous.

Lands held by Roman Catholics, under any of the aforementioned tenures, are still further subject to the payment of one twenty-sixth part of all the grain produced upon them, for the maintenance of their curates, and to occasional assessments for building and repairing churches. The lands of the province, which are not held under these tenures, are subjected to a reservation out of the produce of two-sevenths, one of which goes to the Crown, and the other is set apart for the maintenance of the Protestant clergy.

and ern-. The laws of England, both civil and criminal, were introduced into Canada after its conquest in 1759; and the criminal code of Britain, which freed the Canadians from the tyrannical modes of procedure to which they were formerly exposed, was generally considered as a most important improvement. But the civil code of England was not received with equal satisfaction. The inhabitants were attached by habit and prejudice to the ancient system by which property was regulated; and, by the act of 1775, therefore, that system was restored. The government of the country was, at the same time, vested in a council, composed of certain individuals, chosen by the sovereign. In 1792, by the 31st Geo. III., all the advantages of the British Constitution were extended to Canada. Two houses of legislature were at the same time appointed, namely, a legislative council and assembly. The legislative council of Upper Canada consists of not fewer than seven members; and that of Lower Canada of not fewer than fifteen, appointed by the King. The house of assembly is composed of fifty-two members, who are generally extensive proprietors of land. In the districts and counties, the possessors of a property of the annual value of forty shillings are qualified to vote; and in the city of Quebec and the other towns, the voters must either be possessed of a dwelling-house, and a piece of ground, of not less annual value than L. 5 Sterling; or they must have been settled for a year, and have paid one year's rent, not under L. 10. There exists no disqualification in this country for any office, or for the exercise of any political privilege, on account of religious tenets; and great practical benefit is found to result from this unreserved toleration, which has the effect of reconciling the different sectaries to each other, and of abating that mutual rancour necessarily arising from a system of exclusion. The executive government consists of a Governor, who is generally a military officer, and Commander of the forces, a Lieutenant-Governor, and an Executive Council, amounting to seventeen, appointed by the King, and exercising an influence in the affairs of the province, similar to that of the Privy Council in the affairs of England. The Governor has the power to prorogue and to dissolve the assembly. He is also invested with the prerogative of giving the royal assent or refusal to all acts which have been approved by the two houses of legislature.

The expence of travelling post in Lower Canada is 1s. currency *per* league. The American packets on Lake Champlain, charge from three to four dollars for the passage from St John's to Skenesburgh, a distance of nearly 160 miles, and from Skenesburgh the traveller proceeds to New York, in a waggon or stage, at the rate of 3d. Sterling *per* mile.

Bouchette, Esq. 1815.—Weld's *Travels through the States of North America in* 1795, 1796, 1797.—Heriot's *Travels through the Canadas*, 1807. —Grey's *Letters from Canada*.—Lambert's *Travels in North America*, 1814. (o.)

CANARY ISLANDS. In the *Encyclopædia* will be found some account of this Archipelago, so far as known at the time of its publication. Since that time, M. Bory de St Vincent has published his *Essay on the Fortunate Islands*, in which, besides giving the result of his own observations, he has collected, with great industry, all that is to be found in the Spanish writers on the subject. M. Humboldt also, who, in his way to South America, ascended the Peak of Teneriffe, has communicated, in his *Personal Narrative*, a number of learned and curious remarks. From these sources we have derived a considerable accession of new materials.

Original Inhabitants.

It is not proposed to follow M. Bory into his speculation concerning the ancient Atlantic Continent, of which the Canaries appear to him to have composed a fragment; because the whole theory appears to us destitute of any solid foundation. He has collected, however, from the early Spanish historians, a variety of particulars respecting that singular people, called the Guanches, by whom the Canaries were originally inhabited. They appear to have considerably surpassed in civilization, both the inhabitants of the West India Islands, and those of the opposite Continent of Africa. The most remarkable of their customs, and of which monuments still remain, was that of embalming the bodies of their dead. This operation was performed by extracting the intestines, washing the whole body with salt water, and filling the large cavities with aromatic plants. The bodies were then dried in the heat of the sun, or, if that were wanting, in a stove. Where this method was too expensive, corrosive liquids, calculated to destroy the intestines, were merely poured down the throat previous to desiccation. The embalment being completed, usually in about fifteen days, the body was sewed up in several folds of goat skin, was placed in a chest or coffin, cut out from a single piece of wood, and was finally lodged in a grotto excavated from the rock, and the entrance of which was carefully guarded. These mummies or *xaxos*, as they are called, when found at the present day, are of a tanned colour, and usually of an agreeable odour. They are often perfectly well preserved, particularly the hair; the features are distinct, but drawn back; the belly sunk. On being taken out of the goat skins, and exposed to the air, they fall gradually into dust.

The Spanish authors have translated some specimens of the poetry of the Guanches, which display considerable imagination and sensibility. The females appear to have been treated with a respect very unusual among savage tribes. In the island of Lancerota, a plurality of husbands is said to have prevailed, as in Thibet. There were a species of vestal priestesses called *Malgades*, who were held in the utmost veneration, and supposed to enjoy peculiar communication with the divinity. The form of government was highly aristocratic. A tradition prevailed, that the nobles were created first, and had the property of the earth, and of all its productions vested in them; after which a supplementary creation took place of beings destined solely to perform the office of slaves. They had a king, however, but of limited power. There are reports of the existence, among the Guanches, of a race of giants; and the Spanish annals mention one chief who was nine, and another who was fourteen feet in height; but these are evidently fables, such as are found in the early traditions of every nation.

The Guanches have long been entirely extinct. They made a vigorous resistance to the invaders; but the sword of the Spaniards, aided by a pestilential disorder, soon swept entirely this ancient population from the face of these islands.

Physical Aspect of Teneriffe.

The information furnished by Humboldt relates chiefly to the physical aspect and present state of the Canaries. In ascending the Peak of Teneriffe, he found five zones of vegetation. The first was that of vines, rising about two or three hundred toises above the sea. It forms the only part of the island which is much inhabited, or carefully cultivated. Here corn, the vine, the olive, the fruit trees of Europe, the date, the plantain, the Indian fig, the *arum colocasia*, are found in a flourishing state. The bread-fruit, cinnamon, coffee, and cocoa, have been tried with success. The second zone, or that of the laurels, contains the wooded part of Teneriffe. It contains four species of laurel, an oak resembling the *quercus Turneri* of Thibet, a native olive, the largest tree of this zone, and several species of myrtle. The third zone, beginning at the height of 900 toises, and extending 400 upwards, consists entirely of a vast pine forest. The tree resembled the Scotch fir; but M. Humboldt, not having an opportunity of examining the fructification, could not determine whether there was any thing peculiar in the species. The fourth and fifth zones, called those of the Retama and the Gramina, consist of an immense plain, or rather sea, of sand, covered with pumice stones and large blocks of obsidian. In its lower part, are scattered tufts of the retama (*spartium nubigenum* of Aiton), a beauti-

Canary Islands.

ful plant, whose odoriferous flowers render delicious the flesh of the goats who feed upon them. At the upper end of the plain, grasses and lichens faintly struggle against the volcanic matter. At 1530 toises above the sea, they reached a station commonly called *the English Halt*, consisting of a cavern inclosed between two rocks. Here they spent the night, suffering considerably from cold. Next morning, after two hours walk, they came to a small plain called *Alta Vista*, where persons called *Neueros* were collecting snow for the use of the inhabitants of the coast. Then began the *Malpays*, a tract entirely destitute of mould, covered with fragments of lava, which, sinking beneath the feet, rendered the ascent very laborious. The guides now earnestly dissuaded them from proceeding farther, and were found, on examination, never to have themselves reached the summit. At the extremity of the Malpays, however, the travellers came to a small plain, whence they saw rising the cone of the *piton*. This hillock is extremely steep, and is so covered with volcanic ashes and fragments of pumice stone, as to render the ascent scarcely possible. They succeeded only by following a current of old lava, the wrecks of which formed a wall of scorious rocks, by grasping the points of which, in half an hour, they reached the top. This volcano appeared to Humboldt the most difficult to ascend of any he had seen, except that of Jorullo in Mexico.

On arriving at the summit, our traveller was surprised to find scarcely room to sit down. The crater was inclosed with a small circular wall of porphyritic lava, with basis of pitchstone. This wall, at a little distance, has the appearance of a small cylinder or a truncated cone. It would have entirely blocked up the approach to the crater, had there not been a breach on the east side, through which they descended into the funnel. They found it of an elliptic form, 300 feet in length, and 200 in breadth. It is remarkable, that these dimensions are only a fifth part of those of the crater of Vesuvius. In fact, very lofty volcanoes usually throw out the matter by lateral openings, so that some of the greatest among the Andes have very small apertures at the summit. The inside of the funnel indicated the appearance of a crater which had not thrown out fire for thousands of years. There were none of those layers of scoriæ and ashes, which mark recent volcanic action; the floor was strewed with fragments of stony lavas, which the action of time had detached from the sides. The strata along the edges were very irregularly piled over each other, exhibiting various grotesque ramifications. The inclosing wall is snow white at its surface, owing to the action of sulphuric acid gas on pitchstone porphyry. The aspect of the whole is rather curious than awful. "The majesty of the site consists in its elevation above the level of the ocean, in the profound solitude of those lofty regions, and the immense space over which the eye ranges."

The view from this point is described by Humboldt as interesting in a very peculiar manner. He observes, "Travellers have learnt by experience, that views from the summit of very lofty mountains are neither so beautiful, picturesque, or varied, as those from the summit of heights which do not exceed that of Vesuvius, Rigi, or Puy-de-Dome. Colossal mountains, such as Chimboraço, Antisana, or Mount Rosa, compose so large a mass, that the plains, covered with rich vegetation, are seen only in the immensity of distance, where a blue and vapoury tint is uniformly spread over the landscape. The Peak of Teneriffe, from its slender form and local position, unites the advantages of less lofty summits to those which arise from very great heights. We not only discover from its top a vast expanse of sea, but we see also the forests of Teneriffe, and the inhabited part of the coasts, in a proximity fitted to produce the most beautiful contrasts of form and colouring. The volcano seems as if it crushed, with its mass, the little isle which serves for its basis, and shoots up from the bosom of the waters to a height three times loftier than the region where the clouds float in the summer." The remarkable transparency of the atmosphere increases greatly the apparent proximity in which the hamlets, vineyards, and gardens on the coast are beheld.

The Peak appeared to Humboldt to be composed entirely of volcanic products, without any mixture of primitive rocks. It is peculiarly distinguished by the vast quantity of obsidian, a substance not found in the immediate vicinity of almost any other volcano. It alternates with, and passes into pumice, in a manner which convinced our traveller that pumice was merely tumefied obsidian. These two rocks, together with a porphyry consisting of vitreous lava in a basis of pitchstone, composed the whole upper part of the Peak. Although the crater was entirely silent, yet, near the summit, vapour, which condensed into pure water, issued from different spiracles, called the Nostrils of the Peak.

The active volcanos of Teneriffe are considered by Humboldt to be merely lateral eruptions of the great volcano. The only one recently in operation, is the volcano of Cahorra, situated on the west side of the Peak. After a long silence, it began its discharge on the night of the 8th of June 1798. A hollow and stifled sound was first heard, like that of distant thunder; then a louder noise, like that of matter in violent ebullition; after which another sound, which resembled a great discharge of artillery. A short interval still elapsed, till the liquified substances began to ascend. Four mouths were opened, of which the two highest threw up only red-hot stones. The third poured out lava, but slowly; and it is fortunately surrounded by a rampart of rocks, the interval between which and the volcano must be filled up, before the stream could reach the cultivated fields.

Aspect of the other Islands.

Humboldt observed the other islands merely by sailing along their coasts. Lancerota exhibited every mark of having been recently overwhelmed by volcanic agency. This appears to have taken place in 1730, when nine villages were entirely destroyed. The summit of its great volcano did not appear to exceed 300 toises. The coast of Graciosa is distinguished by rocks of basalt 500 or 600 feet high, which frown in perpendicular walls over the ocean,

Canary Islands.

like the ruins of vast edifices. One of them so exactly resembled a castle, that the French captain saluted it, and sent a boat on shore to make some inquiries of the governor.

All the rocks which Humboldt observed, were thus either volcanic, or of very recent trap formation. M. Broussonnet, however, who spent a long time upon these islands, stated, that Gomera was composed of the primitive rocks of granite and mica slate. The Grand Canary has never been explored; but it struck Humboldt as wearing a different aspect from the rest, its mountains being disposed in parallel chains.

Present state of Teneriffe and the other Islands.

The eastern side of the Island of Teneriffe is entirely naked and barren; but the northern and western sides are beautiful and fertile. It does not produce two-thirds of the corn necessary for its own consumption, but is supplied from the other islands. Santa Cruz, the capital, is situated on the eastern side; the convenience of the harbour and situation compensating for the barrenness of the surrounding country. It supports itself by trade, forming, as it were, a great caravansary between Spain and the Indies. English ships often touch at this port for fresh provisions, which are obtained of excellent quality, though chiefly from the neighbouring island of Canary. The appearance of this city, which exhibits houses of dazzling whiteness, with flat roofs, and windows without glass, stuck against a perpendicular wall of basaltic rocks, appeared very unpleasing to Humboldt. The streets, however, are neat, with foot-walks on each side. The houses within are remarkably spacious; the halls and galleries so extensive as, in M. Bory's opinion, to exclude the comfortable feeling of a house, and rather to suggest that of an open space. The road is excellent, and forms the chief recommendation of Santa Cruz. The harbour is well built, but the landing difficult and even dangerous. The population is estimated at 8000 souls.

Laguna is the nominal capital of Teneriffe, and contains the tribunals belonging to the island; but since the volcano of 1706 destroyed its port of Garachico, then the finest on the island, its commerce has been supplanted by that of Santa Cruz, and it has been in a state of rapid decline. It still, however, contains 9000 inhabitants. The situation is beautiful, about 350 toises higher than Santa Cruz, and crowned by a wood of laurel, myrtle, and arbutus, which maintains a delightful coolness. The situation of Orotova is still finer, and it is refreshed by numerous rivulets passing even through the streets. Its aspect, however, is gloomy and deserted, and it is chiefly inhabited by a haughty race of nobility. The population amounts to 7000, with 3000 in its port of Santa Cruz. The road is bad.

The other islands have been very little examined. The Grand Canary is said to surpass Teneriffe in fertility, but has been much neglected. Its chief town, Cuidad de las Palmas, contains upwards of 9000 inhabitants, and is the ecclesiastical capital of the islands. Lancerota and Fortaventura are the most arid, and their soil so nearly resembles that of the African continent, that the camel has been introduced with success.

The following statement is given by Humboldt of the progressive population of the different islands.—

	Surface in Nautical Leagues.	POPULATION in			
		1678.	1745.	1768.	1790.
Teneriffe . .	73	49,112	60,218	66,354	70,000
Grand Canary	60	20,458	33,864	41,082	50,000
Palma . . .	27	13,892	17,580	19,195	22,600
Lancerota .	26		7,210	9,705	10,000
Fortaventura	63		7,382	8,863	9,000
Gomera . .	14	4373	6,251	6,645	7,400
Terro . . .	7	3297	3,687	4,022	5,000
Total	270		136,192	155,866	174,000

The inhabitants are said to be of an active and industrious disposition. They have emigrated in great numbers to the different parts of South America, where they are supposed to be as numerous as in their native islands. They are fond of considering these as a portion of European Spain, to whose literature they have made some not unimportant additions, by the labours of Clavijo, Vieyra, Yriarte, and Betancourt. A most formidable list of prohibited books is exhibited at Laguna, but this only whets their avidity after these forbidden treasures.

The chief article of export is wine; of which the average produce in Teneriffe is estimated by M. Bory at 22,000 pipes. Lord Macartney reckons 25,000, and Mr Anderson (in Cook's *Third Voyage*) 40,000; but this last amount is doubtless greatly exaggerated. A large proportion is consumed in the island; the export, chiefly to Britain and America, amounts to 8000 or 9000 pipes. The other exports are brandy, raw silk, soda, and some fruits, which, however, are not equal in quality to those of Portugal. The revenue amounts to 242,000 piastres. (B.)

CANNON, THE ART OF CASTING. Formerly the mould for casting cannon was of loam, and now is usually made of dry sand. Loam for making moulds, is an earth consisting principally of clay. It is passed through sieves and then mixed, whilst wet, with horse dung, cow's hair, chopped straw, or tow cut short; the loam being mixed up with one of these substances, they are well beat up together on a wooden board with an iron bar; by this addition, the loam becomes susceptible of being dried rapidly without cracking. The most attenuated loam is used for the surface of the mould that is to come in contact with the metal, to the end that the surface may come off smooth. The loam-moulders are a particular class of workmen different from the common sand-moulders. The business to which they are bred, consists in making of loam and of dry sand, the moulds for steam-engine cylinders, pipes for conveying water, boilers, guns and other large articles.

Moulds.

Formerly on a tapering wooden spindle, entwined with straw ropes, a model was made of loam, copied

exactly from the pattern gun; this model was painted over with a coat of wood ashes mixed with water. By means of this coat, no adhesion took place between the convex model and the loam which was afterwards applied; over this coat of ashes, successive coats of loam were applied, each being dried by fire before the next was laid on; the whole was bound externally with longitudinal iron bars, and with hoops transversely. Over this carcass of iron, a coat of plaster of Paris was applied. This was dried, and then the spindle and its envelope of straw was taken out. The interior convex model being thus deprived of its core and support, fell to pieces and was picked out; and then a hollow mould of the gun remained. In this way the mould for the body of the piece was formed; the moulds for the breech and head were made separately; these three parts were joined together so as to form a complete mould. This method of moulding guns required the construction of a new convex model for every gun that was moulded; It was used in the French Government founderies of Douai, Ruelle, near Paris, and Strasburg, in 1794.

Method of forming Loam-moulds.

Other Method.

The following method of constructing the loam-mould, is an improvement on that just mentioned: A model of wood, or to prevent change of form by moisture, a model of brass or pewter is made and formed on the turning lathe, with its exterior surface exactly resembling that of the gun, with its head and the square piece at the cascabel; if the model is of metal, it is made hollow for the sake of lightness. This model is laid with its longitudinal axis horizontal, and one half immersed in a bed of sand; upon that part of the model which projects above the sand, successive coats of loam are applied and pressed on the model. When the first layer is dried by fire, a second layer is applied and dried, and so on till the model is covered with a coat of loam four or five inches thick. Over this an iron carcass is applied, and over the carcass another coat of loam. The mould with the model in it is now turned, so that the half already covered with loam shall be lowermost. The plain surface of the loam which had been in contact with the sand, is painted over with a coat of blacking, composed of finely powdered charcoal mixed with clayed water; this prevents the adhesion of the flat surface with the loam that is to be laid on it. A layer of loam is applied upon the naked half of the model. This is dried, and several more layers are applied successively. A carcass is put over the loam corresponding to the carcass of the first half, so that these two carcasses can be bound together with bolts and wedge-formed keys, with screw-bolts and nuts, or tied with iron-wire. When the loam is dry, the upper half of the mould is lifted off, the model is taken out, and the interior surfaces of both parts of the mould are painted over with blacking; this prevents the loam from being melted, and from adhering to the hot metal. The two halves of the mould are then put together, and the carcasses are firmly connected by their bolts; the whole is thoroughly dried by fire. When dried, the mould is placed vertically in the pit of the casting house, with the breech lowermost, sand is beat round it for support, and the metal is poured in at the top of the head. This method was practised in the Arsenal of Paris in 1794.

Dry Sand Moulding.

The most approved method of constructing the mould of a gun is in dry sand, and this is the method now practised in Britain. Guns cast in loam do not come from the mould with a surface so correctly resembling that of the model as those cast in dry sand, and in order to render the surface correct, and to remedy defects, it was always necessary to subject them to the process of turning. In guns carefully cast in dry sand, the process of turning might be dispensed with, the gun would then be strengthened by the outer skin of metal which, having cooled more rapidly than the other parts, is the hardest; this outer skin is also less liable to rust than the surface laid bare by turning. The mould of a gun in dry sand, at the same time that it is more accurate, is also sooner made and dried than a loam-mould. Dry sand-moulding is a part of the business of the loam-moulder.

The sand for dry sand-mouldings is made by mixing a quantity of sharp refractory sand with water in which clay has been diluted. After the mixture is thoroughly made, if a handful is grasped, and on opening the hand the sand retains the form given it, then the consistence of the mixture is good. The sand should have the following qualities: *1st*, It should not be fusible by the heat of melted cast-iron; if it were, it would adhere to the metal, and make the surface of the gun rough. *2dly*, It must be sharp, and composed of angular particles; if the particles of the sand were round, it would not hold together on taking out the model. *3dly*, It must not contain too much clay, for in that case it would crack in drying. *4thly*, It must contain a certain proportion of clay to retain the form that the model impresses on it.

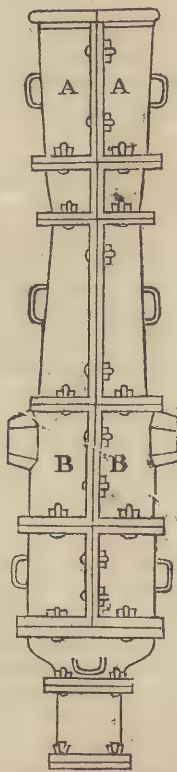
The Model.

For dry sand-moulding, a pattern of wood may be used, turned exactly to the form of the gun; or to avoid expansion from humidity, the model or pattern, as it is termed in the founderies, may be of metal. Brass or pewter are preferable to iron for making patterns, as a smooth surface may be more easily given them, so that they may leave a correct impression and may come out well from the sand. The metallic pattern is hollow, that it may be lighter and more easily handled; it is in different pieces; each piece fits into the adjacent piece by a rabbet.

The length of each piece of the model should be a very little greater than the given length of the corresponding part of the gun; because the length of the mould is the length of the gun whilst hot; and this is longer than the length of the gun when it comes to the temperature of the atmosphere, at which temperature the dimensions of the guns are given. It has been estimated that some kinds of cast-iron contract six-hundredths of an inch in a foot, in passing from the liquid state to the temperature of the atmosphere. This contraction is not considerable enough to be taken into consideration in the diameter of the pattern. The shrinking of the sand in drying, though not considerable, tends like-

Cannon. wise to make the piece shorter, and is another motive for making the pattern a little longer than the dimensions taken from a gun at the usual temperature. The patterns of the trunions are attached to the pattern of the second reinforce by screws, so as to be unscrewed and separated when the pattern is to be lifted out of the sand.

Gun-Boxes. The gun-box, in which the dry sand mould is to be formed, is of cast-iron, and cast in sand. It consists of several portions; each of these portions has flanges by which it is fixed to the others, and the whole, when connected together, form the gun-box. In the flanges are holes through which bolts are passed; the bolts are secured by wedge-formed keys; thus the different parts of the box are firmly held together. The two portions of the gun-box which contain the breech-ring and cascabel are single, not being divided longitudinally. Each of the other five transverse portions is divided longitudinally into two. A handle is fixed to each portion of the box, for the purpose of moving it. The upper transverse portion AA contains the gun-head. In each of the two portions BB, which contain the second reinforce, there is a lateral projection for the trunions. The figure represents the gun-box with the breech lowermost, in the position in which it is placed when the metal is poured in.



Forming the mould. To make the mould, the pattern of the breech is first placed on a board, and the corresponding portion of the gun-box is put over it, and sand is rammed between the pattern and the box. The flat exposed surface of the sand is painted over with blacking, which consists of charcoal and clayed water, that there may be no adhesion with the sand of the next portion of the mould. The pattern of the first reinforce is now fitted into the pattern of the breech, and the corresponding portions of the first reinforce box adjusted on the flange of the breech box. Sand is well rammed, in small quantities at a time, between the pattern and the box; and the upper flat surface of the sand is painted over with blacking. The mould is completed by adding the remaining pieces of the model and of the box, one above another, ramming the sand, and painting the transverse surface of the sand at the top of each division of the box with blacking. The sand must be strongly rammed and equably, that every part of its surface may be able to resist the pressure of the liquid metal. Three little wedges are interposed between the two adjacent transverse portions of the box, that the sand may project a little, so that after it is dry it may be flush with the box; if this were not done, there would be an interval between the adjacent surfaces of the sand, through which the metal would pass and form a fin.

Drying-Stove. When every part is moulded, the box is taken to pieces, and the parts of the pattern are carefully taken out of the sand, for which purpose they are first struck with a wooden mallet. Each part of the mould is then carried separately to the stove to dry. The stove is a room 12 or 15 feet square, with large iron doors on one side; the fire is made in a large conical grate placed on the middle of the floor; the smoke issues by an aperture in the brick ceiling. The heat in this stove is considerable, but it must not be so great as to make the boxes red-hot, for then, by the expansion of the iron, the mould would be injured; the moulds take about 15 hours to dry in this situation. When the moulds are taken out of the stove, their interior surface is painted over with a coat of blacking, that there may be no adhesion between the mould and the metal.

Putting together the Mould. The pieces of the gun-box containing the mould are then taken to the pit, and being carefully placed the one upon the other by the crane, they are put together and secured by their bolts. The mould is placed with the breech undermost; the axis of the mould is made perpendicular to the horizon by a plumb-line, that the weight of the melted metal may press equably, and not more on one side of the mould than on another. It is not necessary that sand should be rammed round the mould, the box being strong, and its parts firmly bound together, so as to require no additional support. The mould is now in a position for the metal to flow into it through its open end, which is the extremity of the head. Whether the gun is to be of cast-iron or brass, the construction of the mould is the same.

Air-furnace. The pig iron from which the gun is to be made is melted in a furnace, called an air-furnace in the iron-founderies, and termed by some authors a reverberatory furnace. The flame of pit coal is carried by a current of air, so as to play upon the pig iron. The stack of the chimney is 40 feet high. By the pressure of the unrarified external air on the lower part of the rarified column of air in the furnace and chimney, the current of air through the furnace is produced. The grate G is larger than any other transverse section of the furnace. (See figure next page.) The furnace has three openings, one C, for introducing the coals; the second P, which has a sliding brick door, with a counterpoise, serves for introducing the pig iron. The third I is for the purpose of stirring the metal, and taking out the melted iron for small castings by iron ladles coated with clay, and made red-hot. This third opening has a door of fire brick, the joints between the door and the door-frame are luted. In the middle of the door is a hole, through which the state of the melted metal may be seen. There is likewise a smaller opening T for letting out the melted metal.

The furnace and stack are of brick. The interior of the furnace is a coating of fire brick, 9 inches thick, detached and separate from the outer coat, and the other parts of the building, in order that the

heat may not melt the common brick of which the outer parts are composed. The fire-brick is made of refractory clay, which, containing little iron, and little or no calcareous matter, burns white, and sustains a great heat without melting. These bricks are made of Stourbridge clay, or of a light blueish grey stratified clay found in the strata that accompany coal. The clay is first ground, the pieces of ironstone picked out, and then made into bricks. In making the interior coating of the furnace, the bricks must be built with moistened fire-clay, and not with lime mortar. The quantity of metal put into the furnace should be equal to the weight of the solid unbored gun with its head, and something more in case of need. It requires a large air-furnace to contain metal enough for one large gun.

lity of Iron.

The pig-iron for guns should be grey, that kind having most tenacity; white pig-iron is too brittle, and so hard that the head cannot be cut off, nor the gun bored.

rging Fur-

A bed of sand N is made in the furnace on which the pig-iron is to be laid. The furnace is heated to a white heat, till the sand is vitrified, which is known to have taken place by touching the surface of the sand with an iron ringard. The brick door is then lifted up, and the pig-iron is laid on the bed of sand. The heat should be applied so as to produce a speedy fusion, for if the iron is long exposed to heat before melting, a portion of its carbonaceous matter is burnt, and it passes from the state of grey cast-iron to that of white. In situations where pit-coal cannot be had, wood may be used in the air-furnace, but the heat given by wood is not so great as that produced by pit-coal. To obtain the most heat that the wood is capable of affording, it should be well dried, cut into small logs, and the logs should be placed with their end upon the grate.

The pig-iron melted by the flame playing on it, flows down into a cavity L, which has a hole T opening outwardly, and stopped with clay. When the hole is forced open by a workman, the metal issues and is conveyed by a gutter formed of sand to the gun-mould, into which the melted metal falls through the open end of the head. The sand forming the gutter should be in a proper state of moisture. If it is too dry, some pieces of it will be carried away by the metal. Across the gutter is a dam composed of an iron-plate luted, and dipping a little below the surface of the metal to retain the scoriæ. This dam is driven down to stop the current of metal when the mould is full. The metal is also skimmed, as it passes along, by a skimmer, composed of a rod of iron terminated by a flat semi-elliptical piece luted and made red hot. It is sometimes the practice to plunge a piece of green wood for a short time into the head whilst liquid. This is with a view to prevent honeycombs, and its action may be to metallize any oxidated particles of the metal; and that the vapour from the green wood rising to the surface of the metal may carry with it small air bubbles, or other extraneous bodies that would, if they remained, occasion cavities in the metal.

anation e Fi-

F is the mass of building which forms the foundation built below the surface of the ground to support the weight of the furnace and stack. R the surface of the ground out of doors. C P N L H is the course that the flame takes.

Air-furnace preferable for Guns.

It is better to cast the guns from the air-furnace than from the blast-furnace; for in the blast-furnace, where the ironstone is smelted, the quality of the metal is uncertain, and it may vary from one cast to another, by causes either unknown, or not under the control of the iron-master. On the other hand, in the air-furnace, pig-iron of a quality proper for making guns is put in, and the quality of the iron is not materially altered by the process of melting.

The Head.

The head of the gun is like the jet (gate or geet of the workmen) of any other casting. Whilst the whole is liquid, the head is a column of liquid metal that acts by its height, exerting pressure on the metal that forms the body of the gun. The metal subjected to this pressure whilst liquid, is less subject to porosity when cooled. The head also furnishes metal to fill up the cavities that occur in the piece by the contraction and crystallization of the metal whilst it is passing to the solid state. All the great contractions and crystallizations are thus transferred to the surface of the head, which is found to be composed of large cavities, sometimes containing cast-iron crystallized in a fern-leafed shape. The head

Cannon.

also serves to receive any impurities that may have escaped the attention of those appointed to skim the iron as it flows along the gutter.

In ten or twelve hours, the piece is sufficiently cool to be removed. It is then stripped of the mould, and taken to the boring-mill, to undergo the operations described under our article BORING OF CANNON. Mortars, howitzers, and carronades are moulded, cast, and bored in the same way as long guns.

The English Board of Ordnance is supplied with iron guns by contract. The contractors are those iron-masters who offer the guns at the lowest price, and the guns are cast at their works in the country. The guns are sent to Woolwich to be examined in respect to their dimensions, the coincidence of the axis of the bore with that of the piece, the position of the touch-hole, and to undergo a proof by powder. It is also tried whether water can be forced through the substance of the gun. If any cavities called honey-combs be found in the bore, the piece is rejected. The proofs are at the risk of the contractors, who generally examine and prove the guns at their works, before sending them to Woolwich. Unserviceable guns are taken to the triangle, where a large mass of cast-iron is let fall upon the gun, from a height of 40 or 50 feet. It is thus broken into pieces of a size fit for being introduced into the air-furnace to be re-cast. Some brass guns are cast and bored in the foundery of the Board of Ordnance at Woolwich.

Brass Guns.

Cast-iron guns have the advantage of not suffering any injurious alteration from the heat of repeated firing. Brass guns, when fired rapidly in succession, droop at the muzzle. Cast-iron guns alone are used on board British ships; brass guns are now principally used for field-pieces. Brass guns, in strict and precise language, might be called bronze guns, as the word brass is most commonly used to denote a composition of copper and zinc, whereas, in gun-metal, there is generally little zinc, and often none. Copper alone is too soft, so that the guns that have been made of it were cut and furrowed by the ball in firing. Use is made, therefore, of a mixture of copper and tin; this composition being harder than copper. Copper and tin separately are soft and malleable; when combined they form a composition that is hard and brittle; and these two qualities are increased by augmenting the relative quantity of tin. Different proportions have been employed for guns; 10 parts by weight of copper, and 1 of tin, is a proportion that is found to give the requisite hardness, and not too much, nor too great brittleness. The copper is first melted, and the tin is added. If the tin were melted first, and the copper added, much of the tin would be oxidated before the combination took place; the metal, during the process, is stirred with a rod of green wood.

Bell-metal is a combination of copper and tin in other proportions. It is made hard by means of tin, in order that it may be sonorous. It contains 25 *per cent.* of tin, and is too brittle and too hard for making guns. In the year 1794 the Revolutionary Government of France obtained gun-metal by depriving bell-metal of a part of its tin. Bell-metal was heated with the contact of air, and stirred to oxidate the tin; the bell-metal was thus reduced to the state of a coarse powder; this powder was thrown into another quantity of bell-metal in fusion; the metallic and oxidated copper in the powder melted, and was mixed with the already fused bell-metal; the oxide of tin of the powder remained on the surface. A melted mass was thus obtained, containing a larger proportion of copper than the bell-metal, and fit for making guns.

The mould for brass guns is formed of dry sand, in the same way as the mould for cast-iron guns already described. The furnace for melting brass for guns is a reverberatory furnace, the metal being exposed to the flame. It has no high chimney like the air furnace for melting iron, the heat required not being so great as that for melting cast-iron.

Brass guns are subject to melt at the interior extremity of the touch-hole, by the heat of quick firing; and the melted parts are driven out by the explosion, so as to render the touch-hole too wide. To prevent this, there is sometimes a bush of copper inserted, and in this bush the touch-hole is drilled. The copper being less fusible than the brass, is not melted by the heat of firing the piece. To form the bush, a cylindrical piece of copper is hammered cold, and made into the form of a male screw. A hole is then bored, reaching from the surface of the gun into its bore; the diameter of this cylindrical hole is equal to the diameter of the cylinder of copper measured from the bottom of the threads of the screw. The piece of copper is then screwed into the cylindrical hole, and the touch-hole is drilled in it.

Progress of the Art of casting Cannon.

The improvements in casting cannon, as in other arts, have been gradual. Formerly cannon were cast with a core, and this was practised in some founderies in Flanders, even in the year 1794. But they are now always cast solid, experience having shown that guns cast solid are stronger, and less liable to burst, and the bore is freer from honeycombs, and more likely to have the same axis with the piece. The second of these qualities is still more certainly attained by the practice now in use, of making the gun itself revolve whilst boring; in this way, as long as the boring bar remains unmoved, the axis is right; but if the boring bar has a conical motion, then the point of the bit is out of the axis; when the boring bar was made to revolve, the bore might deviate greatly from the axis. The improvements in the casting of cannon have kept pace with the improvements in the manufacture of cast-iron.

The art of casting iron was known to the ancients, as appears from a small antique statue of Hercules, of cast-iron, dug up at Rome. In China it appears to be practised with a dexterity visible in the Chinese specimens of many other arts. In modern Europe it has grown with the general advancement of society, and has latterly attained to a high degree of improvement in this Island, where individuals having the command of capital, and the power of making advances for the salaries of workmen and the construction of buildings, were induced to form large establishments for the smelting of ironstone, and for the manufacture of cast-iron. In

Cannon.

France cast-iron is little used; many of the articles which in England are of cast-iron, being there of wrought-iron, copper, earthenware, or wood. In the Prussian dominions, the art of casting statues and small medals, in cast-iron, is successfully practised. But in none of the other countries of Europe is cast-iron so generally used, and nowhere is it manufactured on so large a scale, and with the employment of so much capital, as in Britain.

Pit-coal has been the main instrument in this extensive manufacture. As it gives a better heat for the melting of cast-iron, and saves the great extent of ground required for rearing wood, the greatest part of the cast-iron in Britain is now extracted from the ironstone, and made into castings by pit-coal. Pit-coal began to be used in smelting of ironstone in 1619. This first operation was performed in Worcestershire, by Dudley, who describes his process in a book, entitled, *Metallum Martis*. The manufacture of cast-iron was not much advanced one hundred years after; for in the first half of the eighteenth century, cast-iron goods were imported into some part of Britain from Holland. And the Dutch chimney-backs, with the figure of a parrot, are to be seen in old country houses in Scotland to this day.

Two kinds of mineral are smelted for iron in Britain. The first is the hæmatites of Ulverstone and the neighbourhood of Whitehaven, which, as it contains much iron (60 *per cent.*), is carried by sea to smelting furnaces in different parts of Britain. The second is the argillaceous ironstone, which constitutes some of the strata that accompany pit-coal. This is more generally used than the hæmatites. And it is in the vicinity of the masses of stratified minerals, which yield coal and ironstone, that the principal iron-works in Britain are set down. These strata are found in various parts of the island, and are portions of that class of depositions called by geologists the coal-formation. A stratum of coal or of ironstone of considerable extent, is termed, by the coal and iron masters, a coal-field, or an ironstone-field.

Pit-coal cannot be employed entire in the blast-furnace; the bituminous part would be conglutinated by the heat, and the furnace would be choked, and the materials would no longer descend gradually as they ought to do. The coal is, therefore, burnt to drive off its bitumen, and it is then in a state of cinder and called coak. It requires a larger mass of coak than of charcoal to smelt ironstone. Hence the coak blast-furnaces are large, and the machines employed to blow them are more powerful than the wooden spring bellows invented in Germany, in 1620, and which continue to be employed in the charcoal iron furnaces in Germany and France. Bellows connected by leather, and worked by water, were used to blow the blast-furnaces at Carron, at the commencement of that establishment in 1760. Sometime after, these bellows gave place to blowing machines, composed of pistons working in iron cylinders, constructed by the celebrated Smeaton, and described in his Reports. The blowing machines of the blast-furnaces in Britain are now always composed of pistons moving in iron cylinders. The improvements in the steam-engine have rendered practicable the working of blast-furnaces in situations where there is no fall of water; and, on the other hand, the manufacture of the various parts of numerous steam-engines, has called forth the abilities and ingenuity of the iron founder.

In consequence of the advanced state of the English cast-iron manufacture, several foreign nations have been desirous of introducing the English method, and have procured English workmen for that purpose. In this way, iron-works, on the English plan, were erected in Russia, about 1780, in Silesia in 1790, and in France, at Creusot, near Montcenis, there were three English coak blast-furnaces, begun about 1790.

Strength, Calibre, and Dimensions of Cannon.

The strength of guns depends on the strength of the metal of which the gun is composed, and on the quantity of metal and the manner in which it is disposed. This subject is considered in the article Gunnery of the *Encyclopædia*. The nature of the subject does not admit of determining with precision the best weight and length that can be given to a gun fitted for exploding a ball of a given weight. Guns of the same calibre are consequently made of different dimensions, even in the same country. The four tables that follow contain the weight, length, and other dimensions of British and of French guns:

Capillary Attraction || Caraccas.

CAPILLARY ATTRACTION. We had intended, in this place, to examine at some length the different theories which have been proposed in this branch of Natural Philosophy; but we find that we must defer this inquiry till we reach the article Tubes, Capillary.

CAPMANY (D. Antonio de), one of the most eminent of the later writers of Spain, was born in Catalonia in 1754. He lived for a considerable time in Barcelona, and latterly in Madrid, where he died in 1810. He ranks high both as a general scholar, and as a political writer, and has, indeed, in the latter character, manifested much more sound and extensive views than belong to most of his countrymen. In particular, it is to be remarked of him, that he is almost the only native who has endeavoured to expose the exaggerations of the earlier writers in regard to the immense population, and highly advanced state of agriculture, commerce, and manufactures, in that country, in former times. His principal works, as noticed in the *Biographie Universelle*, and *Dictionnaire Universel*, are as follows: 1. *The art of translating the French into the Spanish language.* 1776, in 4to. 2. *The Philosophy of Eloquence.* 1777, in 8vo. 3. *History of the Marine, Commerce, and Arts of the ancient City of Barcelona.* The two first volumes of this work were published in 1779; the two last, which consist of a variety of curious and important documents copied from the archives of Barcelona, in 1792. " This excellent work is marked throughout with a spirit of liberality and good sense, and distinguished by an attention to philosophical and general views, but seldom displayed by those who ransack archives, and compile papers for the use of future historians. We consider it a most valuable addition to the history of the commerce and manufactures of the middle ages." (*Edinburgh Review*, Vol. X.) 4. *Historical and Critical Theatre of Spanish Eloquence.* 1786—94. 5 vols. 4to. 5. *A Dictionary, French and Spanish.* 1805, in 4to. This dictionary is prefaced with a critical examination of the two languages.

Besides these, and some other pieces, noticed in the Biographical Dictionaries already mentioned, there is a collection of tracts by Capmany, not alluded to in either of them, entitled *Questiones criticas sobre varios Puntos de Historia Economica, Politica y Militar*, published in 1807, and of which there is an interesting account in the tenth volume of the *Edinburgh Review*. All Capmany's works were published in the Spanish language, and we are not aware that any of them has been translated into any other tongue.

Boundaries and Divisions.

CARACCAS, an extensive province of South America, forming part of the Spanish dominions in that country. It comprehends five other subordinate provinces or governments; namely, the province of Venezuela in the centre, the government of Maracaibo on the west, Guiana on the south, the government of Cumana on the east, and the Island of Margaretta on the north-east. It is bounded on the north from the Cape de la Vela to the point of Paria, by the Carribbean sea; on the east by the Atlantic from the 12th to the 8th degree of north latitude;

on the south by Dutch Guiana and Peru, and on the west by the kingdom of Santa Fé.

This country, extending from the 12th degree of north latitude towards the equinoctial line, might be expected, from its geographical position, to be subject to the utmost violence of the tropical heats, and to be reckoned almost uninhabitable by a scorching sun. But throughout the whole continent of America, the general law of the climate is modified by the elevation of the ground; and, owing to this circumstance, the inhabitants of many parts of the Caraccas enjoy the temperature of perpetual spring. For this happy singularity in its climate, the province of the Caraccas is indebted to a chain of the Andes, which, commencing near the province of Quito, traverses the country in its whole extent, and, gradually diminishing in height in its progress to the east, finally loses itself in the Island of Trinidad. This chain of mountains, which varies in breadth from ten to twenty leagues, is generally of moderate elevation. In some points it rises to the height of 8000 feet, but its average height is not more than 4500 feet above the level of the sea. These inequalities of height give rise to a corresponding diversity of temperature; owing to which the vegetable productions of distant countries, here meeting with a congenial climate, are frequently found concentrated within a comparatively narrow compass. At intervals rich vallies open, and the sides of the mountains are covered with the finest trees. In travelling into the interior from the coast, the European experiences a great and enlivening change from the hot air of the low countries to the pure and cool atmosphere which prevails in these mountainous regions. The city of Caraccas, according to Depons, is 3000 feet above the level of the sea, and though it is situated in 10° 31′ north latitude, so far from being oppressed by the insupportable heats of the torrid zone, it enjoys the mild and temperate climate of the southern countries of Europe. The highest range of the thermometer in summer is 85°, and in winter 76°, and the minimum of heat in winter is 52°.

To the south, these mountains are bounded by the valley of the Orinoco. The country is here extended into immense plains, known by the general name of *Las Llanos*. Those plains afford pasturage to innumerable cattle, the proprietors of which reside in the towns, leaving them to the care of slaves or people of colour. This race of men, accustomed to be almost continually on horseback, and being almost in a state of nature, in these immense and uninhabited plains, contract the most disorderly and lawless habits. Many of them are professed robbers; they are already beginning to form themselves into bands, and to infest the roads, so as to render travelling dangerous. In these plains the heat is intense, the thermometer frequently rising to 110 and even 115 degrees.

The seasons here are divided into winter and summer, which are not so much distinguished by cold or heat, as by rainy and dry weather. The rainy season commences generally in April and continues till November. These rains are not, however, without intermission. There are some days in which no rain falls, and there are others, though they are not frequent, in which it rains incessantly. It may be calculated that, during the rainy season, it rains, on an average, three hours each day, and oftener in the morning than in the evening. The long continued and drizzling rains of the polar regions are not known here. But notwithstanding of this, the rains which in the torrid zone rush down with the violence of a torrent, produce in one hour about six times the quantity of water which is ever known to fall in Europe within the same space. During the rainy season, the rivers are consequently in a continual state of inundation; the channels which, during the rest of the year, remain parched and dry, are now filled with overflowing streams; and the plain through which flows the Orinoco, is inundated by a sea of fresh water for a space extending 150 leagues in length and 40 in breadth.

For about a century after the acquisition of *Terra Firma* by the Europeans, no attempt was made to raise any sort of produce from the soil. Gold and silver were the great objects of research, and the pursuit after these superseded every other species of industry. The adventurers, however, who settled in the country, not finding a sufficient quantity of the precious metals to gratify their rapacity, turned their thoughts towards the pearl fisheries. Being speedily disappointed in their expectations of wealth from this source, they had recourse to agriculture, and, on trial, they found the soil of the Caraccas extremely fertile, and capable of producing ample returns. They began with cultivating cacao, plantations of which were multiplied throughout the country, and the labours of the planter were so admirably seconded by a favourable soil, that the produce was both abundant and of an excellent quality. Cacao was almost exclusively cultivated till a very late period. About the year 1774, the culture of indigo was begun, and it was speedily ascertained, that the soil was equally well adapted to raise this valuable produce. Most of the new plantations were, therefore, prepared for this new species of culture, and immense plains, till then uncultivated, were covered with plantations of indigo. The profits derived from this trade, and the great concourse of traders and cultivators, occasioned villages to spring up in the desert, and gave to many towns, such as Maracay, Tulmero, and Victoria, which were before in a state of decay, the aspect and consistence of cities. About the same time the cotton plant was introduced. The cultivation of sugar, tobacco, and generally of all the other products of the tropical regions, was also commenced. In this fine country, however, blessed as it is with all the advantages both of soil and of climate, agriculture still languishes. There is a want of enterprise and active industry among the planters;—their plantations are committed to the care of ignorant overseers; and the Spanish proprietor, who generally resides in town, seldom visits his estates above once in a year. This carelessness frequently produces embarrassments; the land is mortgaged for the purpose of raising money, and the capital which ought to be laid out in improved cultivation, is thus forestalled for the purposes of extravagance. "It is a matter of astonishment," says Depons, "that in the most beautiful country in nature, where everything concurs to promote luxuriance of vegetation, the plantations should be so inconsider-

Caraccas. able in magnitude. A planter, whose income amounts to 4000 or 5000 dollars *per annum*, is considered rich. There cannot be enumerated twenty plantations in the Caraccas which yield a greater revenue. It is not, however, that the property is too much divided. It is rare to see a plantation of which one-tenth part of its extent is cultivated. It is a cheerless and painful sight to behold the labour of three successive centuries crowned with such pitiful results. On a soil two hundred times less spacious, incomparably less watered, and less fertile, and with not more than one-half the white population, the French have succeeded in raising, at St Domingo, ten times more produce than is raised at this day in the vast province of the Caraccas."

Abundance of Wood of various kinds. Besides the colonial commodities already enumerated, this country produces vanilla, wild cochineal, gums, resins, roots, barks, and plants, many of which are prized for their medicinal virtues. In the mountains of the interior are found the same kinds of wood as in the Antilles, and many other kinds peculiar to the country. The vast forests by which the country is covered, contain abundant supplies of timber for the most extensive ship-yards. All those inexhaustible resources are, however, useless, owing to the difficulty of transporting the wood over the trackless paths of the mountains. These difficulties might be considerably diminished, if due exertion were made to clear the channels of the rivers from occasional obstructions, so as to facilitate the intercourse with the interior. But there is neither enterprise nor industry in the country adequate for such improvements. Besides large timber for the construction of vessels and other purposes, their forests contain materials for the work of the carpenter and cabinet-maker, so various, as to embarrass them in their choice. The beams and joists of houses are, in general, made from the wood which the Spaniards call Pardillo, and in some places they use a species of very hard oak. Cedar is used for doors, windows, tables, &c.; and, for ornamental furniture, they have several kinds of wood susceptible of the highest polish. Among these is distinguished the black ebony, found in great abundance in the forests in the neighbourhood of Lake Maracaibo. Yellow and red ebony is also common; but mahogany is not so abundant as in the West India islands, and it is, besides, inferior both in respect to its shades and gloss. Iron wood, which abounds in different parts of the country, is used for shafts to the wheels of water-mills; for the rollers of the cylinders used for pressing sugar-canes; and, generally, on all occasions for which wood of extraordinary hardness is required. The red ebony is also applied to the same uses as the iron wood, and is even thought to surpass it in hardness. No wood has yet been found fit for dyeing, except the Brasil wood. But the immense forests which overspread the mountainous parts of this country have not been explored to any extent. They still continue, for the most part, to be the exclusive domain of ferocious animals and venomous reptiles, and we cannot be certain, until they are more fully known, what hidden resources they may afford for the extension of commerce, or the improvement of art.

Pearl-fishery. On the first discovery of *Terra Firma*, the pearl-fishery formed a considerable branch of trade as well as of revenue. The *pearla ronde* was found to abound in the shoals which extend from Cape Paria to that of Vela; and the island of Margaretta, Cubagua, Coche, Punta Araya, and the mouth of the Rio la Hacha, were celebrated for the quantity of pearls which they produced. The fifth of the produce was claimed by the king, and it was estimated in the beginning of the 16th century to amount to about 15,000 ducats, which, considering that an extensive contraband trade was at the same time carried on, shows the whole amount to have been considerable. Till the year 1530, the annual value of the pearls sent to Europe amounted on an average to 800,000 piastres. Towards the end of the 16th century, the produce of the American pearl-fisheries diminished rapidly, and, according to some accounts, they were altogether abandoned by the year 1683. Various causes were assigned for the decline of this trade. But the chief cause seems to have been the increasing scarcity of the oysters which yielded these precious stones. With such persevering rapacity was this lucrative trade pursued, that the shells were destroyed faster than they could be multiplied. It is known that the animal which inhabits the pearl-shell does not live above nine or ten years, and it is only in the fourth year that the pearls begin to show themselves. Of these shells, a boat will collect in about two or three weeks more than 35,000. At Ceylon, the government only permits the pearl-fishing to be continued for one month in the course of a year; but on the coasts of the Caraccas there was no restriction. The pearl banks were fished at all seasons, and the consequence is, that they have been abandoned for nearly two centuries. At Cumana it is supposed, that, during such a long period of reprieve, the pearl-shells must have been greatly increased; and, in 1812, some attempts were made to revive the fishery. But it is generally observed, that the few pearls which are now accidentally found are both extremely small, and devoid of brilliancy, while those found among the Indians on the arrival of the Spaniards on *Terra Firma*, were particularly distinguished for these two properties. It is difficult to account for this change. Humboldt conjectures that the earthquakes to which this country is peculiarly subject, may have altered the bottom of the sea, or that the changes in the submarine currents may have so far influenced the temperature of the water, as to diminish the sustenance necessary for the support of the animal which produces the pearl. The small pearls which are still occasionally found on the coasts entangled in the fishermen's nets, are sold to the retail dealers of Cumana, at the ordinary price of a piastre, or 4s. 2d. *per* dozen.

Mineral Springs. Mineral springs abound in these provinces, both warm and cold; and they are of various qualities, namely, the ammoniacal, the ferruginous, the nitrous, and the acidulous. Some of these waters have a degree of heat which nearly approaches to that of boiling water. Owing to their situation, however, generally in uninhabited places, far from any frequented path, they are not of the same advantage to medicine as if they were differently situ-

ated, because the patient cannot enjoy the benefit of those waters, and, at the same time, all those domestic comforts which are equally necessary to his recovery. He must sacrifice the one to procure the other; so that, in many cases, the disadvantage of the change is greater than the benefit.

All that portion of the coast which is north of the province of Venezuela, furnishes a considerable quantity of salt, of a beautiful whiteness. But the most abundant salt-pit is that of Araya, which consists of a mixture of the fossil and marine salts. Its produce, under the regime of the mother country, was monopolized for the benefit of the Crown, the consequence of which was, that the working of the pits was little attended to, and that they did not yield anything like the quantity of salt which, under better management, they were capable of producing.

The aspect of this country is agreeably diversified by lakes and rivers. Of the lakes, those of Maracaibo and Valencia are the most deserving of notice. The lake of Maracaibo is of an oblong form, lying north and south, and communicating by a narrow neck with the sea. Its length, from the bar to its southern extremity, is 150 miles. Its greatest breadth is 90, and it is 450 miles in circumference. It is navigable for vessels of the greatest burden; and though it is not liable to tempests, there is always an undulation on its surface; and when strong breezes blow, more especially from the north, its waves become sufficiently agitated to bury under them canoes and small craft. Its waters are, in general, fresh and fit for drinking; but, at times, the waters of the sea are forced, by means of storms, towards the lake, and it then becomes brackish as far as the town of Maracaibo. All the different species of fish which are found in the rivers of South America, with the exception of the tortoise, abound in this lake; but the general sterility of the adjacent country, and the unhealthy atmosphere which is occasioned by noxious exhalations from its waters, are unfavourable to the progress of cultivation; so that the Indians, in place of making their abode on its shores, have generally dwelt on the lake itself, in wooden huts, constructed for the purpose. To the north-west of the lake is an inexhaustible mine of mineral pitch, which is of so inflammable a nature that during the night, and especially in hot weather, phosphoric fires are continually seen, which have the appearance of lightning. These fires are known by the name of the *lanterns of Maracaibo*, and they serve as a light-house and compass to guide the course of the Spaniards and Indians who are navigating the lake.

The lake of Valencia, though not of the same magnitude as Lake Maracaibo, presents a far more agreeable and interesting spectacle. Its shores, in place of being arid and unhealthy, are clothed with all the luxuriant vegetation of the tropical regions, and the temperature is mild and salubrious. This lake is about one league distant from the city of Valencia, and about 18 miles from the sea. It is of an oblong form, stretching north-east and south-west, and is about 40 miles in length, and about 12 in the broadest part. It is situated in a valley surrounded with high and inaccessible mountains, excepting on the west, where it extends into the interior; and it receives the waters of twenty rivers, without any visible outlet. This circumstance has given occasion to the conjecture, that its waters must be discharged by a subterraneous passage; and, in confirmation of this hypothesis, it is stated by Depons, that the boats which navigate the lake sail with rapidity from the shores to the centre, but that it requires longer time and greater exertion to return from the centre towards the shore. How far this conjecture is well-founded, seems extremely doubtful. The contributions from so many rivers may be no more than sufficient to supply the drain occasioned by the constant and intense evaporation of a tropical sun; and, at any rate, until this question is determined by accurate investigation, it seems idle to have recourse to the supposition of subterraneous channels to account for what may be the result of more obvious causes. One fact is certain, that, of late years, the waters of the lake have experienced a considerable depression, and they still continue receding within a narrower space. This is sufficiently accounted for by the progress of cultivation throughout the country, in consequence of which the cultivators draw an increased supply of water from the streams which flow into the lake, in order to irrigate and refresh their different plantations. In proportion as the waters recede, tracts of ground are left uncovered, which, having received for centuries past the deposited slime and substances of the lake, have thence acquired a prodigious fertility. These spots are eagerly selected for cultivation, and they reward the labours of the planter with a large return. The eastern shores of the lake are laid out for the culture of tobacco in five plantations, which occupy 15,000 persons, and the remainder of the lands which surround it are employed in raising other productions peculiar to the country. The woods in the vicinity afford a haunt to numerous varieties of birds, which are equally distinguished by the brilliancy of their plumage, and the melody of their notes. Reptiles are also common. Among these are two species of lizards, which are considered by the Indians and Spaniards as delicious food, and which are eagerly sought after. The waters of the lake are thick and of a nauseous taste, which is ascribed by Depons to the putrefaction of animal and vegetable substances. Its surface is diversified by numerous islands, by which its navigation is somewhat impeded. Most of these are inhabited, and yield abundance of provisions, fruits, and vegetables.

Rivers.

The abundant rains, which fall in the Caraccas, find their way to the ocean by a variety of channels, and there is, accordingly, no country which is watered by more numerous streams. Every valley has its rivers, and if they are not all of sufficient size to answer the purposes of navigation, they afford ample supplies of water for the necessary purpose of irrigating the grounds which are cultivated along their shores. All the streams which rise on the northern ridge of the mountains in the interior run from south to north, and fall into the Carribbean Sea, while those which have their sources in the southern declivity of the same range of mountains, traverse in a southern direction the whole ex-

Caraccas.

tent of the intermediate plain, till they reach the majestic stream of the Orinoco. The principal rivers which flow northward into the Carribean Sea are the Guiges, Tocuyo, Aroa, Yaracuy, Tuy, Unara, Neveri, Manzanares. These are so strongly fenced in by the natural barriers of high banks, and the ground at the same time forms such a continued declivity, that they seldom overflow the adjacent country to any extent, so as to occasion damage. The most considerable rivers which fall into the Orinoco are the Mamo, the Pariagon and Pao, the Chivata and Zoa, the Cachimamo, the Aracay, the Manapira and Espino, and, lastly, the great river Apure, which enters the Orinoco by several channels. This river receives an immense variety of smaller streams, and is, indeed, the only channel by which all the lesser rivers, which rise in the extensive tract of country through which it flows, are conveyed to the Orinoco. During the rainy season, its waters, near its mouth, are spread over the flat country, which it traverses to an extent of nearly 96 miles; and, in general, all the rivers of this province, which flow through level grounds, overflow, during part of the year, a large tract of the adjacent country. This inundation covers a larger space as the rivers approach the ocean. Near the mouth of the Orinoco, one vast sea of fresh water is spread over the country to an extent, according to Depons, of nearly 200 leagues. The rise of the rivers commences in April, and ends in August, and during the subsequent month of September, there is no perceptible fall in the waters of the Orinoco. About the beginning of October they begin to retire from the flat country, and by the end of February the river has reached its lowest point.

Commerce of this Colony, and Policy of the Mother Country.

In the settlements which they established in different parts of South America, the Spaniards, it is well known, were actuated solely by the desire of procuring the precious metals, and every other less valuable produce was regarded as unworthy of consideration. Under the influence of this spirit, the first adventurers in *Terra Firma* directed all their researches, as we have already observed, to the discovery of mines. These, however, proved so unproductive, that they were soon abandoned, and the colonists were, in this manner, compelled to have recourse for their subsistence to the cultivation of the soil. But it does not appear that their early efforts were favoured by the superintending care of the mother country. No Spanish vessel ever approached the desert shores of this new settled colony; and it was only at the special request of the colonists, that one vessel from the mother country was annually freighted to this part of America, to supply them with the necessaries of life. In this languishing state, the Caraccas continued during the whole of the 16th century. The faint hope of discovering mines, joined to the prosecution of the pearl fishery, which was at this time carried on with singular perseverance and cruelty, still continued to stifle every idea of agricultural industry; and it was not till the year 1634, when the Dutch took possession of the island of Curacoa, that the inhabitants of Terra Firma were encouraged, by the vicinity of those industrious settlers, to devote their attention to agriculture, for the purpose of providing themselves with the means of commercial exchange. Cacao and hides constituted for a long period the two staple articles which they exchanged with the Hollanders for such other commodities as they were in want of.

The commencement of a trade with foreigners, however inconsiderable, excited the jealousy of the mother country, which, though it gave no seasonable aid to the early efforts of those colonists, was resolved to claim the dominion over them, as soon as their industry could be made subservient to its profit. Two vessels were accordingly allowed to sail from Spain, freighted with merchandise for the colonies, on which enormous duties were charged. The consequence was, that the Spanish merchants were undersold by the Dutch traders, and those foreigners were left during the remainder of the century in quiet possession of the trade, which was carried on both more openly and to a greater extent. During the first thirty years of the subsequent century, the intercourse with Spain was revived; but the trade with the mother country bore no proportion to the contraband trade. The annual produce of the province amounted to 65,000 quintals * of cacao; the legal exports were estimated at 21,000 quintals, so that 44,000 quintals still remain for the contraband trader. The Spanish Government, viewing with increasing dislike the growing connection of its colony with foreigners, resolved to stop the intercourse by the violence of power; and, with this view, confiscations, fines, and the most degrading punishments, were inflicted on those who engaged in it. Numerous families were ruined by these severities, but the trade continued as before. It originated in the necessities of the country, and such encouragements to evasion were held out, as covered all the risks of detection.

These violent measures not being found to answer their intended purpose, several Biscayan merchants offered to the government, in 1728, to destroy the contraband commerce, on condition of being allowed the privilege of supplying the wants of the colony, and of exporting its produce. To this proposal the government acceded, after imposing several burdensome conditions on the company. These, however, were complied with, and with such activity, prudence, and economy, were the affairs of the company carried on, that they succeeded in supplanting the contraband trade, while their management gave complete satisfaction to the colonies. From the year 1730 to 1748, 858,978 quintals of cacao were shipped from the colonies to the mother country, which amounted to one-third more than had been exported for the last thirty years. In 1742, the company had acquired such credit with the government, that they applied for and obtained the monoply of the colonial trade. Great jealousies were excited in the colonies by this concession; and to appease the universal discontent which prevailed, it was agreed, in 1750, that a board should be appointed, composed of an

* A quintal is 1600 ounces.

equal number of members of the company, and of cultivators in the colony,—the Governor-General to be President, who should regulate the prices at which the colony and the company should respectively exchange their merchandise. It was, at the same time, permitted to those planters who were not satisfied with the established price, to send one-sixth part of their cacao to Spain, on their own account, and in the vessels of the company. Under this regulated monopoly, the colonial trade was carried on with less of injustice to individuals than might have been expected, and with great prudence and success. For the destruction of the contraband trade, the company maintained, at an annual expence of 200,000 dollars, an armament of ten vessels, which carried 86 guns and 518 men; besides, 102 men employed on shore. Superb warehouses were constructed in the different ports to which its vessels traded, for the accommodation of its agents; and advances, without interest, were made to different planters to the amount of 640,000 dollars, on the security of the produce of their estates, at a fixed price. By the encouragement thus given to the trade of the colony, cultivation was extended,—flourishing villages arose in different parts,—and in addition to cacao, formerly the only staple of the country, other species of colonial produce were now cultivated. About the year 1735, the whole cacao produced in the province was estimated at 65,000 quintals, while, in 1763, there were embarked,

	Quintals.
For Spain,	50,319
Vera Cruz,	16,864
the Canaries,	11,160
St Domingo, Porto Rico, and Havannah,	2316
Local consumption,	30,000
Total,	110,659

During the same period the cattle multiplied rapidly on the extensive plains which stretch to the south of Caraccas, and hides were added to the other articles of exportation. By the increase of cultivation and trade, the various duties, which were hitherto insufficient to defray the expences of government, became perfectly adequate to every charge; and the government of the mother country was freed from the burden to which it had been subject for a period of 200 years, of sending remittances from Mexico, for the purpose of supporting the civil and military establishments of Venezuela.

Such were the beneficial effects produced by the moderate and prudent conduct of the Company. It was evident, however, that no security existed for the continuance of this good management, farther than the discretion of the directors, who, in process of time, were corrupted by the temptations held out to them; and, in place of trading with the colonies upon the equitable principles of commercial exchange, became eager to obtain all the unfair advantages of the most rapacious monopolists. Bribery was resorted to, in order to procure a regulation of prices favourable to their interests,—the duties were evaded,—the contraband trade was encouraged,—and by all those transactions the planters were injured, while the mother country was deprived of the trade which the Company had engaged to carry on for her benefit. The natural remedy for these abuses was a free trade. A regulation was accordingly issued in 1778, by which all the chief ports of the Caraccas and of Spain were reciprocally opened to each other's produce, and the trade between them was, in effect, declared free. A scale of duties was at the same time established, by which the articles exported to the colonies were divided into three classes. The first of these consisted of articles the growth or manufacture of Spain, which were charged at the lowest rate, namely, $9\frac{1}{2}$ *per cent.* on leaving Spain, and the same on being landed in America. All goods, likewise, of which the value was doubled by domestic industry, were placed in the same class. In the second class were comprehended such articles as had received a certain augmentation of value from domestic industry, but not such as to raise their value one half. These paid, on their shipment to the colonies, and on their arrival, $12\frac{1}{2}$ *per cent.* The third class of articles, which were of foreign workmanship, were liable to a duty of 22 *per cent.* on leaving Spain. The colonial produce, on its importation into Spain, was made subject to moderate duties.

From the year 1793 to the year 1796, and from 1796 to 1800, Depons, in his account of the Caraccas, gives the following comparative statement of the value of the produce exported.

Exportations from 1793 *to* 1796.

			Dollars.	
367,819 quintals	cacao,	at 18 dollars,	6,620,742	12,252,415
2,955,963 libs.	indigo,	12 reals,	5,172,937	
1,498,332 libs.	cotton,	20 reals,	299,666	
1,325,584 libs.	coffee,		159,070	

Exportations from 1796 *to* 1800.

			Dollars.	
239,162 quintals	cacao,	at 18 dollars,	4,304,916	6,442,318
793,210 libs.	indigo,	14 reals,	1,386,117

1,536,967 libs.	coffee,		184,435	

Diminution on the four last years, 5,810,097

Caracca.

This diminution of exports is ascribed by Depons to the defects of the internal administration, and partly also to the war which, after this period, was begun between Great Britain and Spain. This writer does not specify particularly the faults to which he alludes; but, in the mean time, no such change had taken place in the domestic administration of the country, as will account for such an enormous defalcation in the value of the produce exported. The war between Britain and Spain appears to be the most probable and satisfactory cause of this diminution. By that event, the whole colonial trade of Spain became the prey of the British cruisers; and such was their unremitting vigilance, that the intercourse between the colonies and the mother country was almost entirely interrupted. In these circumstances, the rigour of the colonial monopoly was relaxed; the ports of the colonies were thrown open to neutrals; and, in addition to this intercourse, a contraband trade, to a great extent, was carried on with the British colonies. But of this illicit traffic no return would of course be made in the general account of the colonial trade; and it is possible, therefore, that the apparent defalcation of exports pointed out by Depons may have arisen from the circumstance of an illicit having taken the place of a contraband trade. In the year 1800, the Court of Spain, swayed by the selfish representations of the Spanish merchants, revoked the liberty granted to the colonies of trading with neutrals; and the consequences of this order were injurious in the extreme, and would have been ruinous to the colonies, had they not resorted, as before, to the necessary remedy of the contraband trade. This trade was carried on to a great extent with the British colonies, and was either connived at, or, as was affirmed, was in some cases formally licensed, by the British cruisers. During this period, therefore, and generally indeed during the whole course of the war, no custom-house account of imports and exports can be considered as affording any accurate view of the foreign trade of this colony.

Revenues.

The public revenues of the Caraccas arise from various taxes, namely, from the alcavala, which is a tax of 5 *per cent.* collected on all sales, whether of moveables, or of landed property. Every species of merchandise or territorial production is made subject to this impost, the moment it is exposed to sale; and retail dealers are in the habit of compounding with the Government, by the payment of an annual sum on their whole stock. This tax produced, in 1793, 150,862 dollars, and, in 1797, only 10,248, owing to the suspension of maritime commerce. A revenue is also derived from export and import duties, from duties on all distillers of intoxicating liquors, and on the shops where they are sold; from the sale of titles and offices, from stamps, from the sale of bulls granting spiritual indulgencies, from the monopoly of tobacco, and from various other local imports. The tithes, which are rigorously levied throughout the Caraccas, form a branch of the public revenue; two-ninths belonging to the Crown, and the remaining seven-ninths being appropriated to the payment of the ecclesiastics, and to the building and upholding of religious edifices.

The Fo[reign trade.] Articles [in] greatest request.

The cargoes exported from Spain to the Caraccas do not, generally, contain above one-fourth of Spanish produce and manufactures, the other three-fourths being supplied chiefly from Britain, France, the Hanse Towns, and part occasionally by Italy. The articles in the greatest demand at the Caraccas are linens, laces, black stuffs, principally serges, prunellas, satins, and taffeties. These are used for the cassocks and mantles of the priests, and for the dresses used by the women in their devotional exercises. Thick cloths are also in demand, and most of the whites are dressed in cassimere or in French cloths. Hats are also a saleable article, and French hats are universally preferred to those manufactured in other countries. No round hats are worn except by the lowest classes, or by boys, all the civil and military officers wearing cocked hats. A considerable quantity of boots, for the wearing of which the young Spaniards have acquired a taste, have been lately imported from the British colonies, and have met with a ready sale. As the shoemakers of the country cannot imitate the fashion and the make of these articles, the importer is free from competition, and he is therefore enabled to charge a high price. Shoes, however, are made in the country of a sufficiently good quality, and at a moderate price. They do not, therefore, form so profitable an article of importation. Among the coarse goods, the linens of Brittany, Rouen, Morlaix, and of Russia, are universally used.

Populat[ion.]

The population of the Caraccas is stated by Depons to amount to 728,000, and he assigns the following proportions to the different provinces:

To the province of Venezuela, including Varinas, a population of -	500,000
To the Government of Maracaibo, -	100,000
To that of Cumana, - -	80,000
To Spanish Guiana, - -	34,000
To the Isle of Margaretta, -	14,000
	728,000

Of this population the whites form two-tenths, the slaves three-tenths, the descendants of freedmen four, and the Indians compose the remainder. Some writers are of opinion that this account of the population is rather exaggerated.

Principal Towns.

The principal towns of the Caraccas are, Caraccas the capital, containing 34,000 inhabitants, Cumana 24,000, Porto Cavello 7500, Valencia 6500, Maracay 8400, Guayra 6000, Tulmero 8000, Victoria 7800, Coro 10,000, Carora 6200, Barquisimeto 11,300, Tocuyo 10,000, Guanara 12,300.

History, a[nd] late Revolution.

This country was first discovered by Columbus in the year 1498, in the course of his third voyage to America. Several attempts were made to settle it by means of missionaries, all of which proved unsuccessful. The natives were at last subdued by a military force, and the management of the Spanish settlements in this province were, for a pecuniary consideration, consigned by Charles V. to a German mercantile company named the Welsers. Under their government, the country experienced the most cruel oppression. The company were, in consequence

deprived of the sovereignty in the year 1550, and a supreme government was appointed by the Crown. Since this period, these provinces continued under the government of the mother country, until the year 1810, when Spain was nearly overrun by the armies of France, and when no reasonable expectation could be entertained that she would be able to resist the invading force. In these circumstances, the colonies being aggrieved by useless restrictions on their commerce, and by other oppressions, a strong party was formed, ostensibly to protect them from the yoke of France, but really, it is supposed, with a view to detach them entirely from the dominion of the mother country. At last, on the 4th July 1811, the congress of Venezuela published a formal decree for their independence. A declaration of rights was afterwards issued, and with such severity was the new system enforced, that the jails were crowded with persons suspected of disaffection to the revolutionary measures adopted; great numbers were proscribed; some were banished and imprisoned; others were executed, and their heads stuck upon poles, as examples of terror to others. Several towns, and among others Coro and Valencia, declared against the new system. Troops were immediately dispatched to reduce the former city by force; these were beaten back with considerable loss. General Miranda was at the same time sent against the town of Valencia, and after some sanguinary encounters, he obtained possession of the place, from which, however, he was soon driven with loss by the determined resistance of the inhabitants. Being reinforced, he renewed the attack, and finally succeeded in his object. Since this period, the war between the two parties has been carried on with various success; and, from the latest accounts, it would appear that the cause of the independents is gaining ground. At present we have no information by which we can decide as to the issue of the contest; and we must, therefore, defer any farther account of it till we arrive at the general article of SOUTH AMERICA.

See Semple's *Sketch of the Present State of the Caraccas*, 1812.—*Travels in South America, by* F. Depons, 2 vols 8vo, 1807.—Humboldt's *Personal Narrative of Travels in the Equinoctial Regions*, 2 vols. 8vo, 1814. (O.)

CARDIGANSHIRE is divided from Caermarthenshire and Pembrokeshire, along the greatest part of its southern side, by the Tivy; on the north it is divided from Merionethshire by the river Dory; and from Montgomeryshire by an artificial boundary. The boundaries on the east, between it and Radnorshire and Breconshire, are also artificial. On the west, it stretches along the sea-coast in a bending line, from north-east to south-west, forming part of the shore of Cardigan Bay. Its extent, measured along the shore, is nearly 40 miles. Its breadth does not average 20. It contains 726 square miles, or 464,640 acres. It is divided into five hundreds. The market towns are Aberystwith, Cardigan, Llanbodarnvawr, Llanbeder, and Tregaron. The number of parishes, according to the last Parliamentary returns respecting the poor's rates, is 97. It sends one member to Parliament; lies in the province of Canterbury, and diocese of St David's; and is in the North Wales circuit. The coast of Cardigan Bay (which is formed by the projecting counties of Caernarvon on the north, and Pembroke on the south, with the coasts of Merioneth and Cardigan in the centre), according to tradition and appearance, have suffered greatly from the depredations of the sea, especially on the Cardigan shore. The tradition of the country is, that there was formerly a sixth hundred, which is now covered by the sea; and there are still to be seen, at low water, several ridges of rocks, called causeways, which seem to confirm the truth of this tradition. Of these the most remarkable is St Patrick's Causeway, which extends from within a mile of the point of Mochras, south of Harlech, 22 miles into the sea, in a serpentine line. It is formed of rough stones, 24 feet broad; and at the extremity there is a round head, formed of sixteen great stones, one of which is four yards in diameter. Trunks and roots of trees are also found at a considerable distance from the shore.

Rivers. The principal rivers are the Tivy, the Rydiol, the Ystwyth, and the Aeron. The Tivy rises in Llyn Teefy, or Tivy Pool, in a mountain in the north-east of the county. On the top of this mountain there are five lakes, of which Tivy Pool is the principal. It is about one mile and a half in circumference, is surrounded by high and perpendicular rocks, and is said never to have been fathomed. The Tivy at first flows through a rocky district; afterwards, forming a regular channel, it passes Tregaron; and, at Llanbeder, becomes the boundary between Caermarthenshire and Cardiganshire. It falls into the sea about two miles below Cardigan. The Rydiol rises on the south-west side of Plinlimmon; its course is about south-west; and it falls into the sea near Aberystwyth. About 12 miles above this town is the Devil's Bridge, called by the Welch, Pont y Monach, or the Monks' Bridge, and Pont ar Fynach, from the confluence here of the Fynach with the Rydiol. There are two arches, one above the other. The uppermost is between 20 and 30 feet in the chord; and the other less than 20. The upper one was built in 1753; the date of the building of the lower one is not known. Near this bridge are the falls of the Fynach. The first fall takes place where the river is much confined by the rocks. The water is carried about six feet over them, into a basin 18 feet below. The next fall is 60 feet, the third fall is 20, and the last is 110 feet. Near this is the fall of the Rydiol, the scenery round which is considered very striking and grand. The Ystwyth rises among the hills on the eastern side of the county, and falls into the sea at Aberystwyth. The Aeron is between six and seven miles in extent, receives six tributary streams, and forms, during the whole of its course, nearly the arc of a circle. It falls into the sea at Aberaeron.

Surface and Soil. That part of the country which lies along the sea is level, especially the south-western extremity; but the northern and eastern parts are very rugged and mountainous. The soil of the low lands is either a light or a strong loam, lying on slate. The soil of

Cardiganshire.

Agriculture.

the mountainous division is in general thin and poor, except in the narrow vallies, where it consists of clay or peat. The tract along the sea coast produces good crops of wheat, barley, turnips, potatoes, and oats. The quality, as well as the produce of the barley grown in some parts of this tract, are very remarkable. Between Aberaeron and Llanrysted, is an extensive flat, extending from the sea to the east mountains, which produces from sixty to eighty bushels of fine barley *per* acre. This land is constantly under this crop, and has been so for at least half a century. It is manured every three years with sea-weed. Potatoes are grown on the peat mosses in such a manner as at once to secure good crops, and to drain the land. The potatoe sets are laid on the surface of the bog, a little manure is spread over them, and they are afterwards covered with earth dug out of the trenches.

Very few sheep are kept on the low land; but on the mountains they are numerous. They are, in general, the native breed, very inferior both for wool and carcase. Cattle are kept in all parts of the county; in the low lands, and in the vales of the mountainous district, principally for butter and cheese; in the other parts they are bred for the English drovers. Of the 464,640 acres which this county contains, it is calculated that 100,000 are in tillage; 145,000 in pasture, and the rest waste land.

Mines.

Cardiganshire formerly was famous for its mines of lead, but at present they are not very productive; the principal are two, in the vicinity of Cwmystwith. Near Tal-y-bont are some that used to be very productive, but now are almost exhausted; the matrix of the ore is carbonate of lime. There are also veins of copper, but they are not wrought. The want of coal, of which there is none in the whole county, the rugged nature of the country, and the badness of the roads, are probably the chief causes why the mines are not worked.

Slate Quarries.

Near Aberystwith are large slate quarries; the slates lie in alternate strata with shale, and are in compact masses, of a coarse texture; the inclination of the strata varies very much, following the general irregularity of shale. The slate that is found near the sea coast, not being mixed with shale, lies in perpendicular strata.

Peat.

There are some very extensive tracts of peat, especially on the coast beyond Aberystwith, bordering on the river Dovy; and from Strata Florida, near the Tivy, to Llyn y Maes, or the lake of the flood; the latter tract is one continued marshy bog, abounding in Turbaries, as far as Tregaron: according to tradition, a town once stood in this marsh. As connected with the natural history of this county, it may be remarked that Mr Aikin observed near the banks of the Rydiol, a moor-buzzard, and the horse-ant, the largest species of ants that are natives of Britain. The angel-fish is found in the bay of Cardigan.

Manufactures and Exports.

There are few manufactures in this county; at Llechwydol, near Cardigan, are iron and tin works. Black cattle, pigs, butter, barley, oats, flannels, Welsh-webs, bark, iron, tin, slates, and ale, are exported from Aberystwyth, and Cardigan. There is a great fair for cattle and sheep at Rhos, near the source of the Tivy.

Cardiganshire is celebrated in the literary history of Wales, for having given birth to David ap Gwyllim, who flourished between 1330 and 1370. From the poems of this author, the modern literary dialect of Wales has been chiefly formed, and this dialect is spoken with greater purity in this county than in any other part of the principality.

In Cardiganshire, a custom prevails resembling the penny-weddings among the peasantry of Scotland. Before marriage a *bidder* goes from house to house, inviting the inhabitants to come to the wedding, and to bring money and cheese and butter. The marriage always takes place on the Saturday, and the guests assemble on the Friday with their presents. All these are set down on paper, that, if demanded, they may be repaid, but this seldom happens. The furnishing of the woman is also brought home on this day. On Saturday, ten or twenty of the man's friends who are best mounted, go to demand the bride, who is placed on a horse behind her father, and rides off as fast as she can. She is soon, however, overtaken. Presents are continued to be received on the Saturday and Sunday; on Monday they are sold, frequently making, with the money presented, the sum of L. 50 or L. 60.

In 1803, the poor's rates amounted to L.10,167. In 1815, there was collected from 92 parishes L.15,409, 8s. 6d.

In 1800, the number of houses was 9040, and of inhabitants 42,956. The males were 20,408; the females 22,548. In 1811, there were

CARLOW, the account of which in the *Encyclopædia*, under the name of CATHERLOUGH, occupies only a very few lines, lies almost entirely between the rivers Barrow and Slaney. It is about 33 English miles long, from north to south, and about 29 miles broad at its greatest breadth; but it narrows in very much from east to west, between Kilkenny and Wexford. It is divided into five baronies, and into fifty parishes. According to Dr Beaufort, its area is 214 square miles Irish, or 344 English, equal to 137,050 Irish or plantation acres, and 220,098 English acres. The principal towns are

Carlow, Tublow, Leighlin-Bridge, Rutland, Palatine Town, Hackets-town, and Gousbridge.

The surface of the greater part of this county is pleasantly undulated; and, with the exception of the high and rough hills which occupy the small portion of it that lies to the west of the Barrow, and the mountainous district in the south-east, on the borders of Wexford, the hills yield little in fertility to the vales. The prevailing soil of the lowlands is a strong fertile loam, mixed with limestone, and incumbent upon it; and that of the uplands is generally a light gravel.

Mr Wakefield gives the following statement of the cultivated and uncultivated land in this county:

Baronies.		Cultivated Land.	Mountains and Bogs.
		Acres Irish.	*Acres Irish.*
Ruthvilly,	-	28,510	
Carlow, -	-	18,487	
Forth, -	-	21,601	1937
Idrone, -	-	38,615	7100
St Mullins,	-	16,303	3171
		123,516	12,217

The principal rivers are the Barrow and the Slaney; the former runs along the whole of the western borders of the county, with the exception of a jutting part of Idrone barony, which it separates from the main body. The Barrow is navigable for barges as far as the town of Carlow, and thence there is a communication with Dublin by means of the Grand Canal. The Slaney, which rises in Wicklow, crosses the eastern part of the county.

The mineralogy of Carlow is very imperfectly known. The river Barrow seems to separate the soil in this part of Ireland; to the west of it there is limestone in abundance, whereas there is none in Wexford and Wicklow; the best in Ireland is found near Carlow. Marl and a great variety of clays are also found in this county. The mountains, called Black Stairs, from their black appearance at a distance, and their perpendicular height, which separate Carlow from Wexford, are chiefly composed of granite. It also contains iron ore, and a considerable quantity of oxide of manganese. In the time of Charles I. there appears to have been a large iron-foundery near Idof, in which, ordnance, pots, and small round furnaces, were cast. It belonged to Mr Christopher Wandsworth, Master of the Rolls in Ireland, and afterwards Deputy of that kingdom, under the Earl of Stafford (*Natural History of Ireland*, p. 73, Dublin, 1726.) By the same authority we are informed, that the first coal mine was found out in Ireland, a few years before 1726, in the same hill, where the iron mine was. "In that iron mine, after that for a great while they had drawn iron-ore out of it, and that, by degrees, they were gone deeper, at last, in lieu of ore, they met with sea-coal, so as ever since, all the people dwelling in those parts have used it for their firing, finding it very cheap; for the load of an Irish car, drawn by one garron, did stand them, besides the charges of bringing it, in nine pence only, three pence to the digger, and six pence to the owner."—"These coals are very heavy, and burn with little flame, but lye like charcoal, and continue to the space of seven or eight hours, casting a very great and violent heat." (*Natural History of Ireland*, p. 84.) The same author informs us, that "little smith coals were dispersed every where in great quantity, and had been used by the smiths, even before the mine was discovered." At present, this mine is either forgotten, or not deemed worth working, as the county is chiefly supplied with coals from Kilkenny.

Agriculture.

There are no large estates in this county; and very little minute division of property. The hiring tenant is generally the occupier, except of small pieces. The fee has been more transferred here than in any other part of Ireland. Carlow was formerly noted for the extent and luxuriance of its pastures, being one of the greatest sheep counties in the kingdom; but in consequence of the bounty which was granted about the year 1768, on corn conveyed by land-carriage to Dublin, Mr Young calculated that sheep-feeding had declined so much, when he was there in 1776-8, that four farmers had a greater number of sheep twenty years before, than were kept in the whole county at that period. There are still, however, some excellent flocks of large woolled sheep. Four sheep of the Irish breed, and five of the English are called a "collop," and three collops are allotted to two acres of the best land.

Dairies.

But it is for its dairies that Carlow is famous; and, in this respect, it is not excelled by any county in Ireland. The farmers spare no trouble or expence to procure good cattle for their dairies. From twenty to fifty are generally kept; and, during the season, each cow produces on an average about $1\frac{1}{2}$ cwt. of butter. The dairy system pursued in Devonshire, Dorsetshire, and some of the northern counties of Ireland, of letting cows to dairymen, is followed here; but this custom was more prevalent when the Catholics could not legally purchase land, as they then employed their capital in hiring cows. The butter made in Carlow is divided into three sorts, according to its quality. The first in point of quality is sent to Dublin and England, and thence exported to the East and West Indies. It is highly esteemed in the London market, where it is often sold as Cambridge butter. That of the second quality is exported to Spain, and the worst to Portugal. It is all packed in large casks, weighing upwards of three hundred weight.

Increase of Tillage.

From the following statement, given by Mr Young, it appears that the bounty on land-carriage corn soon operated to the increase of tillage in Carlow. No great additional quantity of corn was brought from this county to Dublin till 1769, when the bounty had risen from about L. 150 to L. 849. In the years 1770 and 1771, it declined. In 1772, it rose to L. 1025; and in 1773 to L. 2676. In 1774, to L. 2813. In 1777, the last year Mr Young quotes, it was L. 2479.

Barley.

There is not, however, much wheat grown, and it is not of a bright colour, or a very good quality.

But the barley of Carlow is excellent; according to Mr Young, the best in Ireland. At the time of his tour, it was the only interior county which produced it; and at present more is grown here than in any other part of the kingdom. It is principally consumed by the illicit distilleries in the north of Ireland, being carried to Dublin by the canal; by the breweries and distilleries at Cork; or by the malting-houses at Wexford. The potatoes grown in Carlow are excellent. There is little or no flax. The county is tolerably wooded. In the vicinity of Carlow, a great many onions are grown, which are sold all over Ireland.

Manufactures. Carlow is not distinguished as a manufacturing county. In Carlow, coarse cloth, reaping hooks, scythes, shears, &c. are, however, made. At Leighlinbridge is one of the largest corn-mills in Ireland, capable of grinding more than 15,000 barrels a-year.

Population. According to Dr Beaufort, in the year 1792, there were 8763 houses, and 44,000 inhabitants; 15.6 Irish acres to a house; and 40.94 inhabitants to an Irish square mile. The Catholics are reckoned to be ten to one Protestant. The Catholic farmers are becoming wealthy, and have considerable property in leases and farming stock.

In 1792, there were 5503 houses of one hearth; 484 of two; 128 of three; 69 of four; 50 of five; 31 of six; 15 of seven; 8 of eight; 7 of nine; 3 of ten; none were returned above 44: 268 were exempted as new, and 1822 as inhabited by paupers. The total, according to this return, was 8394.

Carlow county sends two members to Parliament, and the town one. The number of registered freeholders of fifty pounds, to February 1815, was 359; of twenty pounds, 295; and of forty shillings, 3263: in all, 3917.

See Young's *Tour in Ireland*.—Beaufort's *Memoir of a Map of Ireland*.—Wakefield's *Statistical Account of Ireland*. (c.)

CARLYLE (Joseph Dacre), a distinguished orientalist, and general scholar, was the son of a Physician at Carlisle, and was born there in the year 1759. He received his early education, in the learned languages, at the grammar-school of that city. In 1775 he proceeded to Cambridge, obtained his bachelor's degree in 1779, and was elected a fellow of Queen's College in that University. He left College in 1783, after taking his master's degree, and returned to his native city, where he obtained some church preferment. In 1793, upon the resignation of Dr Paley, he succeeded to the Chancellorship of the Diocese of Carlisle. *(Gentleman's Magazine*, 1804.)

Mr Carlyle had early devoted much of his attention to an accurate study of the Arabic language, in which pursuit he had been assisted by a native of Bagdad, who resided sometime with him at the University. Having thus attained to great proficiency in the language and literature of the Arabians, he in 1792 appeared before the Public as the Translator of an inedited historical work in that language, known under the name of the *Maured Allatafet*. The author of this work was Jemaleddin, a person of the rank of Emir, and distinguished among the Eastern writers by the title of *Historiographer of Egypt*, on account of his great attention to the improvement of its history. The *Maured Allatafet* is an Epitome, made by Jemaleddin himself, of a larger work, which comprised a complete history of that country, from the first establishment of the Arabian Government, to the eight hundred and fifty seventh year of the Hegira. In reviewing the Epitome with a view to its publication, Mr Carlyle thought proper to retrench that part of it which relates to the Caliphs of Bagdad, their history being, as he conceived, sufficiently illustrated in other writings; so that his publication commences with the first of the *Fatimite* Caliphs who reigned in Egypt; and it ends, where the original Epitome also terminates, with the reign of Almalec Alashrof, the twelfth of the Circassian race of Sultans, thus comprising a period of nearly five hundred years. However creditable to Mr Carlyle's attainments in Eastern learning, this treatise is not thought to have added much to the stock of historical knowledge, or to suggest any high ideas of the merit of that larger work from which it was abridged, and which procured Jemaleddin so much renown in the East. The title of Mr Carlyle's publication is as follows: *Maured Allatafet Jemaleddini, filii Togri Bardii*, seu rerum Egypticarum Annales, ab anno Christi 971, usque ad annum 1453. E Codice MS. Bibliothecæ Academiæ Cambrigiensis. Arab. et Lat. 4to.

In 1794, Mr Carlyle was elected Professor of Arabic in the University of Cambridge; and, in 1796, he gave to the world another, and more pleasing proof of his zealous endeavours to illustrate the literature of the East, in a work entitled, *Specimens of Arabian Poetry from the earliest time to the extinction of the Caliphat, with some Account of the Authors*. Arab. and Eng. 8vo. His object was, by arranging the pieces in chronological order, and accompanying each with some account of the author, and of the occasion of the composition, to exhibit a sort of history of Arabian poetry, during the most splendid period of the Mohammedan empire. Many of these pieces possess considerable beauty; but as Mr Carlyle had it in view to exemplify the different species of poetic composition, he has accordingly translated some specimens, in which he was himself sensible there was nothing to be prized, either in the thought or the execution. Like most of those who have become eminent in Eastern learning, Professor Carlyle is thought to have formed too high an estimate of its merits; but all must admit that his *Specimens*, with their prefaces, form an elegant and interesting work; one which, to use his own words, cannot but prove acceptable to "those who wish to gain an insight into the history of manners, and who love to trace the operations of the human mind in distant countries and various situations." A second edition of this work was published in 1810.

When the Earl of Elgin was appointed Ambassador to the Porte, in 1799, Professor Carlyle was invited to accompany him as an accredited agent of the British government, for the purpose of literary research; and in that capacity he accordingly proceeded to the East. After remaining some time in Constantinople, he left that capital in January 1800, and proceeded through Asia Minor and Cyprus to

Palestine; in which tour he was employed till the following July, when he returned to Constantinople. He again quitted this city in March 1801, and visited the Troad, the convents of Mount Athos, and several parts of Greece. He appears to have spent three weeks amongst these celebrated convents, where, being furnished with recommendations from the Government, and the Patriarch of Constantinople, he was received with marked kindness, and enjoyed every opportunity for literary research. From Athens, where he spent some time, assisted in his inquiries by the artists employed by Lord Elgin, he proceeded in a Ragusan vessel to Malta, and afterwards to Naples, where he arrived in July 1801. He soon thereafter set out for England, and reached his native city early in the month of October. (*Addenda to the* Remains *of John Tweddall.* 1816. 4*to.*)

Soon after his return, he was presented by the Bishop of Carlisle to the living of Newcastle-upon-Tyne; but which he did not long enjoy; for he fell into bad health, and died in the prime of life, in April 1804 (*Gent. Mag.* 1804). His premature death cut short some useful literary undertakings, and deprived the world of the full fruits of his observations on many interesting scenes, which he had surveyed with the eye of a scholar and the feeling of a poet; for all that the public has derived from his travels, is a posthumous volume of poems, with remarks suggested by these scenes, and which, though bearing testimony to his learning and taste, is but a poor substitute for such a work as, with his knowledge and means of information, he could not have failed to produce. The title of this posthumous volume is as follows: *Poems, suggested chiefly by scenes in Asia Minor, Syria, and Greece, with Prefaces extracted from the Author's Journal.* It was published in 4to, in 1805, and is embellished with some fine engravings.

CARNATIC, the name of an extensive maritime province on the eastern side of the peninsula of India, which, according to Mr Hamilton's *East India Gazetteer*, stretches from the 8th to the 16th degree of north latitude. In Dr Heyne's *Tracts on India*, it is said to extend from the 10th to the 15th degree. The average breadth of this tract is about seventy-five miles. It comprehends the former dominions of the Nabot of Arcot, which were transferred to the East India Company, by a treaty concluded in 1801.

The Carnatic is reckoned one of the hottest portions of India. The soil varies, but is generally sandy, and in many parts water is scarce, the supplies being wholly derived from what is preserved in tanks filled during the periodical rains. There are, however, some rivers which flow through the country from the high mountains called the Ghauts. In the inland parts, there are large spots of salt ground, containing, says Dr Heyne, either common salt, or a mixture of that salt and soda, which, from the use to which it is applied in India, is known by the name of *Washermen's earth.* Rice constitutes the principal produce of this country, and in those places where water is scarce, great labour is employed to obtain the necessary supplies for the rice fields. The cultivators raise four different crops in the year, two of them from the same ground. In good seasons the first crop produces fifty fold. Sugar is cultivated, but in very small quantities, the soil not being rich enough for the cane. The indigo plant might be cultivated to advantage, if the demand for it were greater. The common *dwarf cotton* is cultivated on the coast, but not extensively.

The capital of this province is Madras, of the present state of which city we shall give some account when we reach that head. The other principal towns are Tanjore, Trichinopoly, Madura, Tranquebar, and Negapatam, in the division called the *Southern* Carnatic; Madras, Pondicherry, Arcot, Wallajahbad, Vellore, Cuddalore, Ginjee, Pullicat, Chandgherry, and Nelloor, in the *Central* Carnatic; and Ongole, Carwaree, and Samgaum, in the *Northern* Carnatic. Vellore is well known as one of the principal stations of the Company's forces. The sons of Tippoo Sultan were placed here, and palaces on a large scale built for them, but since the well known mutiny of 1807, they have been removed to Bengal.

The great mass of the population profess the Hindoo religion, the Mahommedans being but thinly scattered through the country. It contains about 40,000 Christians of all descriptions. The whole population of the Carnatic, in its most extensive sense, may be estimated at five millions. The natives are considered inferior in bodily strength to the other natives of Hindostan Proper. In no part of India are the genuine Hindoo manners more purely preserved than among the majority of the natives of the Carnatic.

CARPENTRY.

It has been judged most expedient to reprint the article Carpentry from the *Supplement* to the *third* Edition of the *Encyclopædia*, in order that it may form, with the articles Roof and Strength of Materials, * a uniform system of the most useful departments of practical mechanics, deduced, in

* It is proper to mention here, that these two articles, first printed in the *third*, were incorporated in the subsequent editions of the *Encyclopædia*, but that the connected article Carpentry, first published in the *Supplement* to that edition, was not; owing to this circumstance, that the copyright of the Encyclopædia, and of that Supplement, was for some time held by different Proprietors.—Ed.

the same familiar and elementary manner, from the simple principles of the composition of forces: premising some Introductory Observations, which may be considered as a retrospective summary of the doctrine of Passive Strength, accompanied by some of the most useful propositions respecting the resistance of elastic substances, derived from the principles which have been already laid down in our article BRIDGE: and subjoining a few notes, on such passages as may appear to require further illustration or correction. Some of the demonstrations will be partly borrowed from a work which has been published since the death of Professor Robison, the able author of these three articles: but others will be more completely original: and of the remarks, the most important will probably be those which relate to the form and direction of the abutments of rafters; a subject which seems to have been very incorrectly treated by former writers on Carpentry.

I. ABSTRACT OF THE DOCTRINE OF PASSIVE STRENGTH.

The effects of forces of different kinds, on the materials employed in the mechanical arts, require to be minutely examined in the arrangement of every work dependent on them; and of these effects, as exhibited in a solid body at rest, we may distinguish seven different varieties: the extension of a substance acting simply as a tie; the compression of a block supporting a load above it; the detrusion of an axis resting on a support close to its wheel, and resisting by its lateral adhesion only; the flexure of a body bent by a force applied unequally to its different parts; the torsion or twisting, arising from a partial detrusion of the external parts in opposite directions, while the axis retains its place; the alteration or permanent change of a body which settles, so as to remain in a new form, when the force is withdrawn; and lastly, the fracture, which consists in a complete separation of parts before united, and which has been the only effect particularly examined by the generality of authors on the strength of materials.

The analogy of the laws of extension and compression has been demonstrated in a former article of this volume, and their connexion with flexure has been investigated: but it is not easy to compare them directly with the resistance opposed to a partial detrusion, the effects of which are only so far understood as they are exhibited in the phenomena of twisting: and these appear to justify us in considering the resistance of lateral adhesion as a primitive force, deduced from the rigidity or solidity of the substance, and proportional to the deviation from the natural situation of the particles. The resistance exhibited by steel wire, when twisted, bears a greater proportion to that of brass than the resistance to extension or compression; but the forces agree in being independent of the hardness produced by tempering.

Flexure may be occasioned either by a transverse or by a longitudinal force: when the force is transverse, the extent of the flexure is nearly proportional to its magnitude; but when it is longitudinal, there is a certain magnitude which it must exceed, in order to produce or rather to continue the flexure, if the force be applied exactly at the axis. But it is equally true that the slightest possible force applied at a distance from the axis, however minute, or with an obliquity however small, or to a beam already a little curved, will produce a certain degree of flexure; and this observation will serve to explain some of the difficulties and irregularities which have occurred, in making experiments on beams exposed to longitudinal pressure.

Stiffness, or the power of resisting flexure, is measured by the force required to produce a given minute change of form. For beams similarly fixed, it is directly proportional to the breadth and the cube of the depth, and inversely to the cube of the length. Thus a beam or bar two yards long will be equally stiff with a beam one yard, provided that it be either twice as deep, or eight times as broad. If the ends of a beam can be firmly fixed, by continuing them to a sufficient distance, and keeping them down by a proper pressure, the stiffness will be four times as great as if the ends were simply supported. A hollow substance, of given weight and length, has its stiffness nearly proportional to the square of the diameter: and hence arises the great utility of tubes, when stiffness is required, this property being still more increased by the expansion of the substance than the ultimate strength. It is obvious that there are a multiplicity of cases in Carpentry where stiffness is of more importance than any other property, since the utility as well as beauty of the fabric might often be destroyed by too great a flexibility of the materials.

If we wish to find how much a beam of fir will sink when it is loaded in the middle, we may multiply the cube of the length in inches by the given weight in pounds, and divide by the cube of the depth, and by ten million times the breadth: but on account of the unequal texture of the wood, we must expect to find the bending somewhat greater than this in practice, besides that a large weight will often produce an alteration, or permanent settling, which will be added to it: a beam of oak will also sink a little more than a beam of fir, with the same weight.

With respect to torsion, the stiffness of a cylindrical body varies directly as the fourth power of the diameter, and inversely in the simple proportion of the length: it does not appear to be changed by the action of any force tending to lengthen or to compress the cylinder: and it may very possibly bear some simple relation to the force of cohesion, which has not yet been fully ascertained: but it appears that, in an experiment of Mr Cavendish, the resistance of a cylinder of copper to a twisting force, acting at its surface, was about $\frac{1}{100}$ of the resistance that the same cylinder would have opposed to direct extension or compression.

Alteration is often an intermediate step between a temporary change and a complete fracture. There are many substances, which, after bending to a certain extent, are no longer capable of resuming their original form: and in such cases it generally hap-

pens that the alteration may be increased without limit, until complete fracture takes place, by the continued operation of the same force which has begun it, or by a force a little greater. Those substances which are the most capable of this change, are called ductile, and the most remarkable are gold, and a spider's web. When a substance has undergone an alteration by means of its ductility, its stiffness, in resisting small changes on either side, remains little or not at all altered. Thus if the stiffness of a spider's web, in resisting torsion, were sufficient at the commencement of an experiment, to cause it to recover itself, after being twisted in an angle of ten degrees, it would return ten degrees, and not more, after having been twisted round a thousand times. The ductility of all substances, capable of being annealed, is greatly modified by the effects of heat: hard steel, for example, is incomparably less subject to alteration than soft, although in some cases more liable to fracture; so that the degree of hardness requires to be proportioned to the uses for which each instrument is intended: although it was proved by Coulomb, and has since been confirmed by other observers, that the primitive stiffness of steel, in resisting small flexures, is neither increased nor diminished by any variation in its temper.

The strength of a body is measured by the force required completely to overcome the corpuscular powers concerned in the aggregation of its particles, and it is jointly proportional to the primitive stiffness, and to the toughness of the substance; that is, to the degree in which it is capable of a change of form without permanent alteration. It becomes however of importance in some cases, to consider the measure of another kind of strength, which has sometimes been called resilience, or the power of resisting a body in motion, and which is proportional to the strength and the toughness conjointly, that is, to the stiffness and the square of the toughness. Thus if we double the length of a given beam, we reduce its absolute strength to one half, and its stiffness to one eighth; but since the toughness, or the space, through which it will continue to resist, is quadrupled, the resilience will be doubled, and it would require a double weight to fall from the same height, or the same weight to fall from a double height, in order to overcome its whole resistance. If we wish to determine the resilience of a body from an experiment on its strength, we must measure the distance through which it recedes or is bent, previously to its fracture; and it may be shown that a weight, which is capable of breaking it by pressure, would also break it by impulse if it moved with the velocity acquired by falling from a height equal to half the deflection. Thus if a beam or bar were broken by a weight of 100 pounds, after being bent 6 inches without alteration, it would also be broken by a weight of 100 pounds falling from a height of 3 inches, or moving in a horizontal direction with a velocity of 4 feet in a second, or by a weight of 1 pound falling from a height of 300 inches. This substitution of velocity for quantity of matter has however one limit, beyond which the velocity must prevail over the resistance, without regard to the quantity of matter, and this limit is derived from the time required for the successive propagation of the pressure through the different parts of the substance, in order that they may participate in the resistance. Thus if a weight fell on the end of a bar or column with a velocity of 100 feet in a second, and the substance could only be compressed $\frac{1}{200}$ of its length, without being crushed, it is obvious that the pressure must be propagated through the substance, with a velocity of 20,000 feet in a second, in order that it might resist the stroke; and, in general, a substance will be crushed or penetrated by any velocity exceeding that which is acquired by a body falling from a height, which is to half that of the modulus of elasticity of the substance, as the square of the greatest possible change of length is to the whole length. From the consideration of the effect of rigidity in lessening the resilience of bodies, we may understand how a diamond, which is capable of resisting an enormous pressure, may be crushed with a blow of a small hammer, moving with a moderate velocity. It is remarkable that, for the same substance in different forms, the resilience is in most cases simply proportional to the bulk or weight, while almost every other kind of resistance is capable of infinite variation by change of form only.

The elaborate investigations of Mr Lagrange, respecting the strength and the strongest forms of columns, appear to have been conducted upon principles not altogether unexceptionable; but it is much easier to confute the results than to follow the steps of the computations. One great error is the supposition that columns are to be considered as elastic beams, bent by a longitudinal force; while, in reality, a stone column is never slender enough to be bent by a force which it can bear without being crushed: and even for such columns as are capable of being bent by a longitudinal force, Mr Lagrange's determinations are in several instances inadmissible; he asserts, for example, that a cylinder is the strongest of all possible forms, and that a cone is stronger than any conoid of the same bulk; but it appears to be demonstrable in a very simple manner, and upon incontestable principles, that a conoidal form may be determined, which shall be stronger than either a cone or a cylinder of the same bulk.

When a column is crushed, its resistance to compression seems to depend in great measure on the force of lateral adhesion, assisted by a kind of internal friction, dependent on the magnitude of the pressure, and it commonly gives way by the separation of a wedge in an oblique direction. If the adhesion were simply proportional to the section, it may be shown that a square column would be most easily crushed when the angle of the wedge is equal to half of a right angle; but, if the adhesion is increased by pressure, this angle will be diminished by half the angle of repose appropriate to the substance. In a wedge separated by a direct force from a prism of cast iron, the angle was found equal to $32\frac{1}{2}^\circ$, consequently the angle of repose was $2 \times 12\frac{1}{2}^\circ = 25^\circ$, and the internal friction to the pressure as 1 to .466, the tangent of this angle: there was, however, a little bubble in the course of

the fracture, which may have changed its direction in a slight degree. The magnitude of the lateral adhesion is measured by twice the height of the wedge, whatever its angle may be: in this instance the height was to the depth as 1.57 to 1, consequently the surface, affording an adhesion equal to the force, was somewhat more than three times as great as the transverse section, and the lateral adhesion of a square inch of cast iron would be equal to about 46,000 pounds: the direct cohesive force of the same iron was found by experiment equal to about 20,000 pounds for a square inch. It is obvious that experiments on the strength of a substance in resisting compression ought to be tried on pieces rather longer than cubes, since a cube would not allow of the free separation of a single wedge so acute as was observed in this experiment; although, indeed, the force required to separate a shorter wedge on each side would be little or no greater than for a single wedge. The same consideration of the oblique direction of the plane of easiest fracture would induce us to make the outline of a column a little convex externally, as the common practice has been: for a circle cut out of a plank possesses the advantage of resisting equally in every section, and consequently of exhibiting the strongest form, when there is no lateral adhesion; and in the case of an additional resistance proportional to the pressure, the strongest form is afforded by an oval consisting of two circular segments, each containing twice the angle formed by the plane of fracture with the horizon. If we wish to obtain a direct measure of the lateral adhesion, we must take care to apply the forces concerned at a distance from each other not greater than one sixth of the depth of the substance, otherwise the fracture will probably be rather the consequence of flexure than of detrusion. Professor Robison found this force in some instances twice as great as the direct cohesion, or nearly in the same proportion, as it appears to have been in the experiment on the strength of cast iron; Mr Coulomb thinks it most commonly equal only to the cohesion: and in fibrous substances, especially where the fibres are not perfectly straight, the repulsive strength is generally much less than would be inferred from this equality, and sometimes even less than the cohesive strength.

It is well known that the transverse strength of a beam is directly as the breadth, and as the square of the depth, and inversely as the length: and the variation of the results of some experiments from this law can only have depended on accidental circumstances. If we wish to find the number of hundred weights that will break a beam of oak, supported at both ends, supposing them to be placed exactly on the middle, we may multiply the square of the depth, in inches, by 100 times the breadth, and divide by the length; and we may venture in practice to load a beam with at least an eighth as much as this, or in case of necessity, even a fourth. And if the load be distributed equally throughout the length of the beam, it will support twice as much: but for a beam of fir, the strength is somewhat less than for oak. A cylinder will bear the same curvature as the circumscribing prism, and it may be shown that its strength, as well as its stiffness, is to that of the prism as one fourth of its bulk is to one third of the bulk of the prism. The strength of a beam supported at its extremities may be doubled by firmly fixing the ends, where it is practicable; and we have already seen that the stiffness is quadrupled; but the resilience remains unaltered, since the resistance is doubled, and the space through which it acts is reduced to a half. It is therefore obviously of importance to consider the nature of the resistance that is required from the fabric which we are constructing. A floor, considered alone, requires to be strong; but in connexion with a ceiling, its stiffness requires more particular attention, in order that the ceiling may remain free from cracks. A coach spring requires resilience, for resisting the relative motions of the carriage, and we obtain this kind of strength as effectually by combining a number of separate plates, as if we united them into a single mass, while we avoid the stiffness, which would render the changes of motion inconveniently abrupt.

In all calculations respecting stiffness, it is necessary to be acquainted with the modulus of elasticity, which may be found, for a variety of substances, in the annexed table.

Height of the Modulus of Elasticity in Thousands of Feet.

Iron and steel,	10,000	Fir wood,	10,000
Copper, -	5,700	Elm, -	8,000
Brass, -	5,000	Beech,	8,000
Silver, -	3,240	Oak, -	5,060
Tin, -	2,250	Box, -	5,050
Crown glass,	9,800	Ice, -	850

II. Propositions relating to Flexure.

A. *The stiffness of a cylinder is to that of its circumscribing rectangular prism, as three times the bulk of the cylinder is to four times that of the prism.*

We may consider the different strata of the substance as acting on levers equal in length to the distance of each from the axis; for although there is no fixed fulcrum at the axis, yet the whole force is the same as if such a fulcrum existed, since the opposite actions of the opposite parts would relieve the fulcrum from all pressure. Then the tension of each stratum being also as the same distance x, and the breadth of the stratum being called $2y$, the fluxion of the force on either side of the axis will be $2x^2y\dot{x}x$, while that of the force of the prism, the radius being r, is $2rx^2\dot{x}$. Now z being the area of half the portion included between the stratum and the axis, of which the fluxion is $y\dot{x}$, the fluxion of $z - \frac{y^3x}{rr}$ will be $y\dot{x} - \frac{y^3\dot{x}}{rr} - \frac{3y^2x\dot{y}}{rr}$, or since $\frac{xx}{rr} = 1 - \frac{yy}{rr}$, $\frac{xxy\dot{x}}{rr} - \frac{3yy}{r}\left(-\frac{x\dot{x}}{y}\right)$, or $\frac{xxy\dot{x}}{rr} + \frac{3xxy\dot{x}}{rr} = \frac{4xxy\dot{x}}{rr}$; consequently the fluent of $^2x^2y\dot{x}$ is $\frac{1}{2}r^2z - \frac{1}{2}y^3x$, which, when $y=0$ becomes $\frac{1}{2}r^2z$, or one fourth of the product of the square of the radius by the area of the section, while the fluent of $2rx^2\dot{x}x$,

that is, $\frac{2}{3} rx^3$, the force of the prism, becomes $\frac{2}{3} r^4$ or $\frac{1}{3} r^2 \times 2r^2$, one third of the product of the same square into the area of the section of the prism.

Hence the radius of curvature of a cylindrical column, instead of $\frac{\mathrm{M}aa}{12fy}$ (Art. BRIDGE, Prop. G), will be $\frac{\mathrm{M}aa}{16fy}$, the weight of the modulus M decreasing in the same proportion as the bulk, when the prism is reduced to a cylinder. The force is supposed in this proposition to be either transverse or applied at a considerable distance from the axis: but the error will not be material in any other case.

B. *When a longitudinal force f is applied to the extremities of a straight prismatic beam, at the distance b from the axis, the deflection of the middle of the beam will be* $b\left(\text{SECANT}\left[\sqrt{\left(\frac{3f}{\mathrm{M}}\right)}\cdot\frac{e}{a}\right]-1\right)$; *M being the weight of the modulus, e the length of the beam, and a its depth.*

The curvature being proportional to the distance from the line of direction of the force, or to the ordinate, when that line is considered as the absciss, the elastic curve must, in this case, initially coincide with a portion of the harmonic curve, well known for its utility in the resolution of a variety of problems of this kind. Now if the half length of the complete curve be called k, corresponding to a quadrant of the generating circle, and the greatest ordinate y, c being the quadrant of a circle of which the radius is unity, the radius of curvature r corresponding to y will be $\frac{kk}{ccy}$, that is, a third proportional to y and $\frac{k}{c}$ the radius of the generating circle; consequently $\frac{\mathrm{M}aa}{12fy} = \frac{kk}{ccy}$, $kk = \frac{\mathrm{M}aacc}{12f}$, and $k = \frac{1}{2}\sqrt{\frac{\mathrm{M}}{3f}}\,.\,ac$; but, by the nature of the curve, $y : b = 1 : \text{ç}\,\frac{ec}{2k} = \text{SEC.}\,\frac{ec}{2k} : 1$ and $y = b\ \text{SEC.}\,\frac{ec}{2k} = b\ \text{SEC.}\sqrt{\frac{3f}{\mathrm{M}}}\cdot\frac{e}{a}$, which is the ordinate at the middle; and the deflection from the natural situation is $y - b$.

It follows that, since the secant of the quadrant is infinite, when $\sqrt{\frac{3f}{\mathrm{M}}}\cdot\frac{e}{a}$ becomes equal to c, the deflection will be infinite, and the resistance of the column will be overcome, however small the distance b may be taken, provided that it be of finite magnitude: and since in this case $\frac{3fee}{\mathrm{M}aa} = cc$, $f = \frac{\mathrm{M}aacc}{3ee} = .8225\ \mathrm{M}\frac{aa}{ee}$, which is the utmost force that the column will bear: and for a cylinder we find, by the same reasoning, $f = \frac{\mathrm{M}aacc}{4ee} = .6169\ \mathrm{M}\frac{aa}{ee}$. If b be supposed to vanish, we shall have in theory an equilibrium without flexure, but since it will be tottering, it cannot exist in nature.

By applying this determination to the strength of wood and iron, compared with the modulus of elasticity, it appears, that a round column or a square pillar of either of these substances cannot be bent by any longitudinal force applied to the axis, which it can withstand without being crushed, unless its length be greater than 12 or 13 times its thickness respectively: nor a column or pillar of stone, unless it be 40 or 45 times as long as it is thick. Hence we may infer, as a practical rule, that every piece of timber or iron, intended to withstand any considerable compressing force, should be at least as many inches in thickness as it is feet in length, in order to avoid the loss of force which necessarily arises from curvature.

C. *When a beam, fixed at one end, is pressed by a force in a direction deviating from the original position of the axis in a small angle, of which the tangent is t, the deflection becomes* $d = at\sqrt{\frac{\mathrm{M}}{12f}}\ \text{TANG.}\left(\sqrt{\frac{12f}{\mathrm{M}}}\cdot\frac{e}{a}\right)$.

The inclination of the curve to the abscis being inconsiderable, it will not differ sensibly from a portion of a harmonic curve; and supposing the quadrantal length of this curve k, we have again, as in the last proposition, $k = \frac{1}{2}\sqrt{\frac{\mathrm{M}}{3f}}\cdot ac$, or, for a cylinder, $k = \frac{1}{4}\sqrt{\frac{\mathrm{M}}{f}}\cdot ac$. Now, the tangent of the inclination of the harmonic curve varies as the sine of the angular distance from the middle, consequently as $\text{ſ}\,\frac{k-e}{k}\cdot c$, or $\text{ç}\,\frac{ec}{k}$ is to the radius, so is the tangent t, expressing the difference of inclination of the end of the beam and the direction of the force, which is also that of the middle of the supposed curve, to the tangent of the extreme inclination of the curve to its abscis, which will therefore be $t\ \text{SEC.}\,\frac{ec}{k}$: consequently the greatest ordinate will be $\frac{kt}{c}\ \text{SEC.}\,\frac{ec}{k}$, and since the ordinates are as the sines of the angular distances from the origin of the curve, the ordinate at the fixed end of the beam, corresponding to the angle $\frac{ec}{k}$, that is, the deflection, will be $\frac{kt}{c}\ \text{SEC.}\,\frac{ec}{k}\cdot\text{ſ}\,\frac{ec}{k} = \frac{kt}{c}\ \text{TANG.}\,\frac{ec}{k} = \frac{1}{2}\sqrt{\frac{\mathrm{M}}{3f}}\cdot at\ \text{TANG.}\,\frac{2e}{a}\sqrt{\frac{3f}{\mathrm{M}}}$, or, for a cylinder, $\frac{1}{4}\sqrt{\frac{\mathrm{M}}{f}}\cdot at\ \text{TANG.}\,\frac{4e}{a}\sqrt{\frac{f}{\mathrm{M}}}$.

By means of this proposition we may determine

the effect of a small lateral force in weakening a beam or pillar, which is at the same time compressed longitudinally by a much greater force; considering the parts on each side of the point, to which the lateral force is applied, as portions of two beams, bent in the manner here described, by a single force slightly inclined to the axis.

D. *A bar fixed at one end, and bent by a transverse force applied to the other end, assumes initially the form of a cubic parabola, and the deflection at the end is* $d = \frac{4e^3 f}{\mathrm{M}aa}$.

The ordinate of a cubic parabola varying as x^3, its second fluxion varies as $6x\,(\mathrm{d}x)^2$, or since the first fluxion of the absciss is constant, simply as the absciss x, measured from the vertex of the parabola, which must therefore be situated at the end to which the force is applied, and the absciss must coincide with the tangent of the bar. But if we begin from the other end, we must substitute $e-x$ for x, and the second fluxion of the ordinate will be as $6\,(e-x)\,(\mathrm{d}x)^2$, the first as $6ex\mathrm{d}x - 3x^2\mathrm{d}x$, and the fluent as $3ex^2 - x^3$, which, when $x=e$, becomes $2e^3$, while it would have been $3e^3$ if the curvature had been uniform, and the second fluxion had been every where $6e(\mathrm{d}x)^2$. Now the radius of curvature at the fixed end being $r = \frac{\mathrm{M}aa}{12ef}$, and the versed sine of a small portion of a circle being equal to $\frac{ee}{2r}$, this versed sine will be expressed by $\frac{6e^3 f}{\mathrm{M}aa}$; and two thirds of this, or $\frac{4e^3 f}{\mathrm{M}aa}$, will be the actual deflection.

E. *The depression of a bar, fixed horizontally at one end, and supporting only its own weight, is* $d = \frac{3e^4}{2maa}$; *m being the height of the modulus of elasticity.*

The curvature here varies as the square of the distance from the end, because the strain is proportional to the weight of the portion of the bar beyond any given point, and to the distance of its centre of gravity conjointly, that is, to $(e-x)\,\frac{1}{2}\,(e-x)$, so that if the second fluxion at the fixed end be as $e^2(\mathrm{d}x)^2$, it will elsewhere be as $(e-x)^2\,(\mathrm{d}x)^2$; and the corresponding first fluxions being $e^2x\mathrm{d}x$ and $e^2x\mathrm{d}x - ex^2\mathrm{d}x + \frac{1}{3}x^3\mathrm{d}x$, the fluents will be $\frac{1}{2}e^2x^2$, and $\frac{1}{2}e^2x^2 - \frac{1}{3}ex^3 + \frac{1}{12}x^4$, or, when $x=e$, $\frac{1}{12}e^4$, and $(\frac{1}{2} - \frac{1}{3} + \frac{1}{12})\,e^4 = \frac{1}{4}e^4$; consequently the depression must be half the versed sine in the circle of greatest curvature. Now the radius of curvature $\frac{\mathrm{M}aa}{12fy}$ becomes here $\frac{\mathrm{M}aa}{6ef}$, the force being applied at the distance $\frac{1}{2}e$: and since the weight of the bar is to that of the modulus of elasticity in the proportion of the respective lengths, we have $\frac{f}{\mathrm{M}} = \frac{e}{m}$, and $r = \frac{maa}{6ee}$, and the versed sine for the ordinate e will be $\frac{3e^4}{maa}$, half of which is the actual depression.

F. *The depression of the middle of a horizontal bar, fixed at both ends, and supporting its own weight only, is* $d = \frac{5e^4}{32maa}$.

The transverse force at each point of such a bar, resisted by the lateral adhesion, is as the distance x from the middle (Art. BRIDGE, under Prop. L.); but this force is proportional to the first fluxion of the strain or curvature, consequently the curvature itself must vary as the corrected fluent of $\pm x\mathrm{d}x$, taking here the negative sign, because the curvature diminishes as x increases; and the corrected fluent will be $\frac{1}{4}e^2 - x^2$, since it must vanish when $x = \frac{1}{2}e$; the first fluxion of the ordinate will then be $\frac{1}{4}e^2x\mathrm{d}x - \frac{1}{3}x^3\mathrm{d}x$, and the fluent $\frac{1}{8}e^2x^2 - \frac{1}{12}x^4$, or for the whole length $\frac{1}{2}e$, $\frac{5}{192}e^4$, instead of $\frac{1}{32}$, or $\frac{6}{192}$, which would have been its value if the curvature had been equal throughout. Now the strain at the middle is the difference of the opposite strains, produced by the forces acting on either side; and these are the half weight, acting at the mean distance $\frac{1}{4}e$, and the resistance of the support, which is equal to the same half weight, but acts at the distance $\frac{1}{2}e$, the difference being equivalent to the half weight, acting at the distance $\frac{1}{4}e$, so that the curvature at the middle is the same as if the bar were fixed there, and loose at the ends, that is, as in the last proposition, substituting $\frac{1}{2}e$ for e, $r = \frac{2maa}{3ee}$; and the versed sine at the distance $\frac{1}{2}e$ being $\frac{e^2}{8r}$, or $\frac{3e^4}{16maa}$, $\frac{5}{6}$ of this will be $\frac{5e^4}{32maa}$. This demonstration may serve as an illustration of two modes of considering the effect of a strain, which have not been generally known, and which are capable of a very extensive application.

It follows that where a bar is equally loaded throughout its length, the curvature at the middle is half as great as if the whole weight were collected there, the strain derived from the resistance of the support remaining in that case uncompensated. The depression produced by the divided weight will be $\frac{5}{8}$ as great as by the single weight, since $\frac{5}{6} \times \frac{1}{2}$ is to $\frac{2}{3}$ as 5 to 8. Mr Dupin found the proposition by many experiments, between $\frac{2}{3}$ and $\frac{3}{5}$; and $\frac{5}{8}$ is a very good mean for representing these results.

III. ELEMENTS OF CARPENTRY.

Defini-

"Carpentry is the art of framing timber for the purposes of Architecture, Machinery, and, in general, for all considerable structures.

It is not intended in this article to give a full account of Carpentry as a mechanical art, or to describe the various ways of executing its different works, suited to the variety of materials employed, the processes which must be followed for fashioning and framing them for our purposes, and the tools

which must be used, and the manner in which they must be handled: This would be an occupation for volumes; and though of great importance, must be entirely omitted here. Our only aim at present will be to deduce, from the principles and laws of mechanics, and the knowledge which experience and judicious inferences from it have given us concerning the strength of timber, in relation to the strain laid on it, such maxims of construction as will unite economy with strength and efficacy.

This object is to be attained by a knowledge, 1st, of the strength of our materials, and of the absolute strain that is to be laid on them; 2dly, of the modifications of this strain, by the place and direction in which it is exerted, and the changes that can be made by a proper disposition of the parts of our structure; and, 3dly, having disposed every piece in such a manner as to derive the utmost advantage from its relative strength, we must know how to form the joints and other connections in such a manner as to secure the advantages derived from this disposition.

port- anch chani- ence.

This is, evidently, a branch of mechanical science which makes Carpentry a *liberal* art, constitutes part of the learning of the ENGINEER, and distinguishes him from the workman. Its importance in all times and states of civil society is manifest and great. In the present condition of these kingdoms, raised, by the active ingenuity and energy of our countrymen, to a pitch of prosperity and influence unequalled in the history of the world, a condition which consists chiefly in the superiority of our manufactures, attained by prodigious multiplication of engines of every description, and for every species of labour, the SCIENCE (so to term it) of Carpentry is of immense consequence. We regret therefore exceedingly, that none of our celebrated artists have done honour to themselves and their country, by digesting into a body of consecutive doctrines the results of their experience, so as to form a system from which their pupils might derive the first principles of their education. The many volumes called COMPLETE INSTRUCTORS, MANUALS, &c. take a much humbler flight, and content themselves with instructing the mere workman, or sometimes give the master builder a few approved forms of roofs and other framings, with the rules for drawing them on paper; and from thence forming the working draughts which must guide the saw and the chisel of the workman. Hardly any of them offer any thing that can be called a principle, applicable to many particular cases, with the rules for this adaptation. We are indebted for the greatest part of our knowledge of this subject to the labours of literary men, chiefly foreigners, who have published in the memoirs of the learned academies dissertations on different parts of what may be termed the *Science of Carpentry*. It is singular, that the members of the Royal Society of London, and even of that established and supported by the patriotism of these days for the Encouragement of the Arts, have contributed so little to the public instruction in this respect. We observe of late some beginnings of this kind, such as the last part of Nicholson's *Carpenter's and Joiner's Assistant*, published by J. Taylor, Holborn, 1797. And it is with pleasure that we can say, that we were told by the editor, that this work was prompted in a great measure by what has been delivered in the *Encyclopædia Britannica* in the articles ROOF and STRENGTH OF MATERIALS. It abounds more in important and new observations than any book of the kind that we are acquainted with. We again call on such as have given a scientific attention to this subject, and pray that they would render a meritorious service to their country by imparting the result of their researches. The very limited nature of this work does not allow us to treat the subject in detail; and we must confine our observations to the fundamental and leading propositions.

pally ed to ners know- of this t.

Theory founded on what.

The theory (so to term it) of Carpentry is founded on two distinct portions of mechanical sciences, namely, a knowledge of the strains to which framings of timber are exposed, and a knowledge of their *relative* strength.

We shall therefore attempt to bring into one point of view the propositions of mechanical science that are more immediately applicable to the art of Carpentry, and are to be found in various articles of our work, particularly ROOF and STRENGTH OF MATERIALS. From these propositions we hope to deduce such principles as shall enable an attentive reader to comprehend distinctly what is to be aimed at in framing timber, and how to attain this object with certainty: and we shall illustrate and confirm our principles by examples of pieces of Carpentry which are acknowledged to be excellent in their kind.

Composition and Resolution of Forces.

The most important proposition of general mechanics to the carpenter is that which exhibits the composition and resolution of forces; and we beg our practical readers to endeavour to form very distinct conceptions of it, and to make it very familiar to their mind. When accommodated to their chief purposes, it may be thus expressed:

1. If a body, or any part of a body, be at once pressed in the two directions AB. AC (fig. 1. Plate XLVIII.), and if the intensity or force of those pressures be in the proportion of these two lines, the body is affected in the same manner as if it were pressed by a single force acting in the direction AD, which is the diagonal of the parallelogram ABDC formed by the two lines, and whose intensity has the same proportion to the intensity of each of the other two that AD has to AB or AC.

Such of our readers as have *studied* the laws of motion, know that this is fully demonstrated. Such as wish for a very accurate view of this proposition, will do well to read the demonstration given by D. Bernoulli, in the first volume of the *Comment. Petropol.*, and the improvement of this demonstration by D'Alembert in his *Opuscules* and in the *Comment. Taurinens.* The practitioner in Carpentry will get more useful confidence in the doctrine, if he will shut his book, and verify the theoretical demonstrations by actual experiments. They are remarkably easy and convincing. Therefore it is our request that the artist, who is not so habitually acquainted with the subject, do not proceed further till he has made it quite familiar to his thoughts. Nothing is so conducive to this

Illustrated by Experiment.

 as the actual experiment; and since this only requires the trifling expence of two small pulleys and a few yards of whipcord, we hope that none of our practical readers will omit it: They will thank us for this injunction.

2. Let the threads Ad, AFb, and AEc (fig. 2.), have the weights d, b, and c, appended to them, and let two of the threads be laid over the pulleys F and E. By this apparatus the knot A will be drawn in the directions AB, AC, and AK. If the sum of the weights b and c be greater than the single weight d, the assemblage will of itself settle in a certain determined form: if you pull the knot A out of its place, it will always return to it again, and will rest in no other position. For example, if the three weights are equal, the threads will always make equal angles, of 120 degrees each, round the knot. If one of the weights be three pounds, another four, and the third five, the angle opposite to the thread stretched by five pounds will always be square, &c. When the knot A is thus in equilibrio, we must infer, that the action of the weight d, in the direction Ad, is in direct opposition to the combined action of b in the direction AB, and of c, in the direction AC. Therefore, if we produce dA to any point D, and take AD to represent the magnitude of the force, or pressure exerted by the weight d, the pressures exerted on A by the weights b and c, in the directions AB, AC, are in fact equivalent to a pressure acting in the direction AD, whose intensity we have represented by AD. If we now measure off by a scale on AF and AE, the lines AB and AC, having the same proportions to AD that the weights b and c have to the weight d, and if we draw DB and DC, we shall find DC to be equal and parallel to AB, and DB equal and parallel to AC; so that AD is the diagonal of a parallelogram ABDC. We shall find this always to be the case, whatever are the weights made use of; only we must take care that the weight which we cause to act without the intervention of a pulley be less than the sum of the other two: if any one of the weights exceeds the sum of the other two, it will prevail, and drag them along with it.

Now since we know that the weight d would just balance an equal weight g, pulling directly upwards by the intervention of the pulley G; and since we see that it just balances the weights b and c, acting in the directions AB, AC, we must infer, that the knot A is affected in the same manner by those two weights or by the single weight g; and therefore that *two pressures, acting in the directions, and with the intensities,* AB, AC, *are equivalent to a single pressure having the direction and proportion of* AD. In like manner, the pressures AB, AK, are equivalent to AH, which is equal and opposite to AC. Also AK and AC are equivalent to AI, which is equal and opposite to AB.

We shall consider this combination of pressures a little more particularly.

Suppose an upright beam BA (fig. 3.) pushed in the direction of its length by a load B, and abutting on the ends of two beams AC, AD, which are firmly resisted at their extreme points C and D, which rest on two blocks, but are nowise joined to them: these two beams can resist no way but in the directions CA, DA; and therefore the pressures which they sustain from the beam BA are in the directions AC, AD. We wish to know how much each sustains? Produce BA to E, taking AE from a scale of equal parts, to represent the number of tons or pounds by which BA is pressed. Draw EF and EG parallel to AD and AC; then AF, measured on the same scale, will give us the number of pounds by which AC is strained or crushed, and AG will give the strain on AD.

It deserves particular remark here, that the length of AC or AD has no influence on the strain, arising from the thrust of BA, while the directions remain the same. The effects, however, of this strain are modified by the length of the piece on which it is exerted. This strain compresses the beam, and will therefore compress a beam of double length twice as much. This may change the form of the assemblage. If AC, for example, be very much shorter than AD, it will be much less compressed: the line CA will turn about the centre C, while DA will hardly change its position; and the angle CAD will grow more open, the point A sinking down. The artist will find it of great consequence to pay a very minute attention to this circumstance, and to be able to see clearly the change of shape which necessarily results from these mutual strains. He will see in this the cause of failure in many very great works.—By thus changing shape, strains are often produced in places where there were none before, and frequently of the very worst kind, tending to break the beams across.

The dotted lines of this figure show another position of the beam AD′. This makes a prodigious change, not only in the strain on AD′, but also in that on AC. Both of them are much increased; AG is almost doubled, and AF is four times greater than before. This addition was made to the figure, to show what enormous strains may be produced by a very moderate force AE, when it is exerted on a very obtuse angle.

The 4th and 5th figures will assist the most uninstructed reader in conceiving how the very same strains AF, AG, are laid on these beams, by a weight simply hanging from a billet resting on A, pressing hard on AD, and also leaning a little on AC; or by an upright piece AE, joggled on the two beams AC, AD, and performing the office of an ordinary king-post. The reader will thus learn to call off his attention from the means by which the strains are produced, and learn to consider them abstractedly merely as strains, in whatever situation he finds them, and from whatever cause they arise.

We presume that every reader will perceive; that the proportions of these strains will be precisely the same if every thing be inverted, and each beam be drawn or pulled in the opposite direction. In the same way that we have substituted a rope and weight in fig. 4. or a king-post in fig. 5. for the loaded beam BA of fig. 3. we might have substituted the framing of fig. 6. which is a very usual practice. In this framing, the batten DA is stretched by a force AG, and the piece AC is compressed by a force AF. It is evident, that we may employ a rope, or an iron rod hooked on at D, in place

Carpentry.

of the batten DA, and the strains will be the same as before.

This seemingly simple matter is still full of instruction; and we hope that the well-informed reader will pardon us, though we dwell a little longer on it for the sake of the young artist.

By changing the form of this framing, as in fig. 7. we produce the same strains as in the disposition represented by the dotted lines in fig. 3. The strains on both the battens AD, AC, are now greatly increased.

The same consequences result from an improper change of the position of AC. If it is placed as in fig. 8. the strains on both are vastly increased. In short, the rule is general; that the more open we make the angle against which the push is exerted, the greater are the strains which are brought on the struts or ties which form the sides of the angle.

The reader may not readily conceive the piece AC of fig. 8. as sustaining a compression; for the weight B appears to hang from AC as much as from AD. But his doubts will be removed by considering whether he could employ a rope in place of AC. He cannot: but AD may be exchanged for a rope. AC is therefore a strut, and not a tie.

In fig. 9. Plate XLIX. AD is again a strut, butting on the block D, and AC is a tie: and the batten AC may be replaced by a rope. While AD is compressed by the force AG, AC is stretched by the force AF.

If we give AC the position represented by the dotted lines, the compression of AD is now AG′, and the force stretching AC′ is now AF′; both much greater than they were before.* This disposition is analogous to fig. 8. and to the dotted lines in fig. 3. Nor will the young artist have any doubts of AC′ being on the stretch, if he consider whether AD can be replaced by a rope. It cannot, but AC′ may; and it is therefore not compressed, but stretched.

In fig. 10. all the three pieces, AC, AD, and AB, are ties, on the stretch. This is the complete inversion of fig. 3.; and the dotted position of AC induces the same changes in the forces AF, AG′, as in fig. 3.

Thus have we gone over all the varieties which can happen in the bearings of three pieces on one point. All calculations about the strength of carpentry are reduced to this case: for when more ties or braces meet in a point (a thing that rarely happens), we reduce them to three, by substituting for any two the force which results from their combination, and then combining this with another; and so on.

The young artist must be particularly careful not to mistake the kind of strain that is exerted on any piece of the framing, and suppose a piece to be a brace which is really a tie. It is very easy to avoid all mistakes in this matter by the following rule, which has no exception. (See Note AA.)

Rule for distinguishing the cases of compression and extension.

Take notice of the direction in which the piece acts from which the strain proceeds. Draw a line in that direction *from* the point on which the strain is exerted; and let its length (measured on some scale of equal parts) express the magnitude of this action in pounds, hundreds, or tons. From its *remote* extremity draw lines parallel to the pieces on which the strain is exerted. The line parallel to one piece will necessarily cut the other, or its direction produced: if it cut the piece itself, that piece is compressed by the strain, and it is performing the office of a strut or brace; if it cut its direction produced, the piece is stretched, and it is a tie. In short, the strains on the pieces AC, AD, are to be estimated in the direction of the points F and G *from* the strained point A. Thus, in fig. 3. the upright piece BA, loaded with the weight B, presses the point A in the direction AE; so does the rope AB in the other figures, or the batten AB in fig. 5.

In general, if the straining piece is within the angle formed by the pieces which are strained, the strains which they sustain are of the opposite kind to that which it exerts. If it be pushing, they are drawing; but if it be within the angle formed by their directions produced, the strains which they sustain are of the same kind. All the three are either drawing or pressing. If the straining piece lie within the angle formed by one piece and the produced direction of the other, its own strain, whether compression or extension, is of the same kind with that of the most remote of the other two, and opposite to that of the nearest. Thus, in fig. 9. where AB is drawing, the remote piece AC is also drawing, while AD is pushing or resisting compression.

In all that has been said on this subject, we have not spoken of any joints. In the calculations with which we are occupied at present, the resistance of joints has no share; and we must not suppose that they exert any force which tends to prevent the angles from changing. The joints are supposed perfectly flexible, or to be like compass joints; the pin of which only keeps the pieces together when one or more of the pieces draws or pulls. The carpenter must always suppose them all compass joints when he calculates the thrusts and draughts of the different pieces of his frames. The strains on joints, and their power to produce or balance them, are of a different kind, and require a very different examination.

General expression of the magnitude of the strain.

Seeing that the angles which the pieces make with each other are of such importance to the mag-

* The reader is requested to add accents to the lower C, the upper F, and the lower G, in this figure. In fig. 10. for *b*, read C′, and add accents to the upper F and the lower G. In fig. 12. the dotted line should be continued upwards, and marked L. In fig. 16. the letters should stand thus, C E *e* D *f* F B. The arrangements required, for delivering every plate with the text to which it belongs, have made it necessary to work off these engravings before the order of their occurrence, a circumstance with which the author of the remarks on this article was not acquainted, in time to have them corrected.

nitude and the proportion of the excited strains, it is proper to find out some way of readily and compendiously conceiving and expressing this analogy.

In general, the strain on any piece is proportional to the straining force. This is evident.

Secondly, the strain on any piece AC is proportional to the sine of the angle which the straining force makes with the other piece directly, and to the sine of the angle which the pieces make with each other inversely.

For it is plain, that the three pressures AE, AF, and AG, which are exerted at the point A, are in the proportion of the lines AE, AF, and FE (because FE is equal to AG). But because the sides of a triangle are proportional to the sines of the opposite angles, the strains are proportional to the sines of the angles AFE, AEF, and FAE. But the sine of AFE is the same with the sine of the angle CAD, which the two pieces AC and AD make with each other; and the sine of AEF is the same with the sine of EAD, which the straining piece BA makes with the piece AC. Therefore we have this analogy, Sin. CAD : Sin. EAD = AE : AF, and $AF = AE \times \frac{\text{Sin. EAD}}{\text{Sin. CAD}}$— Now the sines of angles are most conveniently conceived as decimal fractions of the radius, which is considered as unity. Thus, *Sin.* 30° is the same thing with 0.5, or $\frac{1}{2}$; and so of others. Therefore, to have the strain on AC, arising from any load AE acting in the direction AE, multiply AE by the sine of EAD, and divide the product by the sine of CAD.

This rule shows how great the strains must be when the angle CAD becomes very open, approaching to 180 degrees. But when the angle CAD becomes very small, its sine, (which is our divisor) is also very small; and we should expect a very great quotient in this case also. But we must observe, that in this case the sine of EAD is also very small; and this is our multiplier. In such a case, the quotient cannot exceed unity.

But it is unnecessary to consider the calculation by the tables of sines more particularly. The angles are seldom known any otherwise but by drawing the figure of the frame of carpentry. In this case, we can always obtain the measures of the strains from the same scale, with equal accuracy, by drawing the parallelogram AFCG.

Strains propagated to the points of support.

Hitherto we have considered the strains excited at A only as they affect the pieces on which they are exerted. But the pieces, in order to sustain, or be subject to, any strain, must be supported at their ends C and D; and we may consider them as mere intermediums, by which these strains are made to act on those points of support: Therefore AF and AG are also measures of the forces which press or pull at C and D. Thus we learn the supports which must be found for these points. These may be infinitely various. We shall attend only to such as somehow depend on the framing itself.

Action of a Straining Beam.

Such a structure as fig. 11. very frequently occurs, where a beam BA is strongly pressed to the end of another beam AD, which is prevented from yielding, both because it lies on another beam HD, and because its end B is hindered from sliding backwards. It is indifferent from what this pressure arises: we have represented it as owing to a weight hung on at B, while B is withheld from yielding by a rod or rope hooked to the wall. The beam AD may be supposed at full liberty to exert all its pressure on D, as if it were supported on rollers lodged in the beam HD; but the loaded beam BA presses both on the beam AD and on HD. We wish only to know what strain is borne by AD?

All bodies act on each other in the direction perpendicular to their touching surfaces; therefore the support given by HD is in a direction perpendicular to it. We may therefore supply its place at A by a beam AC, perpendicular to HD, and firmly supported at C. In this case, therefore, we may take AE, as before, to represent the pressure exerted by the loaded beam, and draw EG perpendicular to AD, and EF parallel to it, meeting the perpendicular AC in F. Then AG is the strain compressing AD, and AF is the pressure on the beam HD.

The form of the cutting joints of no great importance.

It may be thought, that since we assume as a principle that the mutual pressures of solid bodies are exerted perpendicular to their touching surfaces, this balance of pressures, in framings of timbers, depends on the directions of their butting joints: but it does not, as will readily appear by considering the present case. Let the joint or abutment of the two pieces BA, AD be mitred, in the usual manner, in the direction fAf'. Therefore, if Ae be drawn perpendicular to Af, it will be the direction of the actual pressure exerted by the loaded beam BA on the beam AD. But the reaction of AD, in the opposite direction At, will not balance the pressure of BA; because it is not in the direction precisely opposite. BA will therefore slide along the joint, and press on the beam HD. AE represents the load on the mitre joint A. Draw Ee perpendicular to Ae, and Ef parallel to it. The pressure AE will be balanced by the reactions eA and fA: or, the pressure AE produces the pressures Ae and Af; of which Af must be resisted by the beam HD, and Ae by the beam AD. The pressure Af not being perpendicular to HD, cannot be fully resisted by it; because (by our assumed principle) is reacts only in a direction perpendicular to its surface. Therefore draw fp, fi parallel to HD, and perpendicular to it. The pressure Aff will be resisted by HD with the force pA; but there is required another force iA, to prevent the beam BA from slipping outwards. This must be furnished by the reaction of the beam DA. (See Note BB.) In like manner, the other force Ae cannot be fully resisted by the beam AD, or rather by the prop D, acting by the intervention of the beam; for the action of that prop is exerted through the beam in the direction DA. The beam AD, therefore, is pressed to the beam HD by the force Ae, as well as by Af. To find what this pressure on HD is, draw eg perpendicular to HD, and eo parallel to it, cutting EG in r. The forces gA and oA will resist, and balance Ae.

Thus we see, that the two forces Ae and Af, which are equivalent to AE, are equivalent also to Ap, Ai,

Ao, and *Ag*. But because *Af* and *e*E are equal and parallel, and E*r* and *fi* are also parallel, as also *er* and *fp*, it is evident, that *if* is equal to *r*E, or to *o*F, and *i*A is equal to *re*, or to G*g*. Therefore the four forces A*g*, A*o*, A*p*, A*i*, are equal to AG and AF. Therefore AG is the compression of the beam AD, or the force pressing it on D, and AF is the force pressing it on the beam HD. The proportion of these pressures, therefore, is not affected by the form of the joint.

This remark is important; for many carpenters think the form and direction of the butting joint of great importance; and even the theorist, by not prosecuting the general principle through *all* its consequences, may be led into an error. The form of the joint is of no importance, in as far as it affects the strains in the direction of the beams; but it is often of great consequence, in respect to its own firmness, and the effect it may have in bruising the piece on which it acts, or being crippled by it.

[...]n of [...]rain [...]Tie.

The same compression of AB, and the same thrust on the point D by the intervention of AD, will obtain, in whatever way the original pressure on the end A is produced. Thus, supposing that a cord is made fast at A, and pulled in the direction AE, and with the same force, the beam AD will be equally compressed, and the prop D must react with the same force.

But it often happens that the obliquity of the pressure on AD, instead of compressing it, stretches it; and we desire to know what tension it sustains. Of this we have a familiar example in a common roof. Let the two rafters AC, AD (fig. 12.), press on the tie-beam DC. We may suppose the whole weight to press vertically on the ridge A, as if a weight B were hung on there. (See Note CC.) We may represent this weight by the portion A*b* of the vertical or plumb line, intercepted between the ridge and the beam. Then drawing *bf* and *bg* parallel to AD and AC, A*g* and A*f* will represent the pressures on AC and AD. Produce AC till CH be equal to A*f*. The point C is forced out in this direction, and with a force represented by this line. As this force is not perpendicularly across the beam, it evidently stretches it; and this extending force must be withstood by an equal force pulling it in the opposite direction. This must arise from a similar oblique thrust of the opposite rafter on the other end D. We concern ourselves only with this extension at present; but we see that the cohesion of the beam does nothing but supply the balance to the extending forces. It must still be supported externally, that it *may resist*, and by resisting obliquely, be stretched. The points C and D are supported on the walls, which they press in the directions CK and DO, parallel to A*b*. If we draw HK parallel to DC, and HI parallel to CK (that is to A*b*), meeting DC produced in I, it follows from the composition of forces, that the point C would be supported by the two forces KC and IC. In like manner, making DN = A*g*, and completing the parallelogram DMNO, the point D would be supported by the forces OD and MD. If we draw *go* and *fk* parallel to DC, it is plain that they are equal to NO and CI, while A*o* and A*k* are equal to DO and CK, and A*b* is equal to the sum of DO and CK (because it is equal to A*o* + A*k*). The weight of the roof is equal to its vertical pressure on the walls.

Thus we see, that while a pressure on A, in the direction A*b*, produces the strains A*f* and A*g*, on the pieces AC and AD, it also excites a strain CI or DM in the piece DC. And this completes the mechanism of a frame; for all derive their efficacy from the triangles of which they are composed, as will appear more clearly as we proceed.

External action of a Frame.

But there is more to be learned from this. The consideration of the strains on the two pieces AD and AC, by the action of a force at A, only showed them as the means of propagating the same strains in their own direction to the points of support. But, by adding the strains exerted in DC, we see that the frame becomes an intermedium, by which exertions may be made on other bodies, in certain directions and proportions; so that this frame may become part of a more complicated one, and, as it were, an element of its constitution. It is worth while to ascertain the proportion of the pressures CK and DO, which are thus exerted on the walls. The similarity of triangles gives the following analogies:

$$\text{DO} : \text{DM} = \text{A}b : b\text{D}$$
$$\text{CI, or DM} : \text{CK} = \text{C}b : \text{A}b$$
$$\text{Therefore DO} : \text{CK} = \text{C}b : b\text{D}.$$

Or, *the pressures on the points* C *and* D, *in the direction of the straining force* A*b*, *are reciprocally proportional to the portions of* DC *intercepted by* A*b*.

Also, since A*b* is = DO + CK, we have

$$\text{A}b : \text{CK} = \text{C}b + b\text{D (or CD)} : b\text{D, and}$$
$$\text{A}b : \text{DO} = \text{CD} : b\text{C}.$$

In general, any two of the three parallel forces A*b*, DO, CK, are to each other in the reciprocal proportion of the parts of CD, intercepted between their directions and the direction of the third.

And this explains a still more important office of the frame ADC. If one of the points, such as D, be supported, an external power acting at A, in the direction A*b*, and with an intensity which may be measured by A*b*, may be set in equilibrio, with another acting at C, in the direction CL, opposite to CK or A*b*, and with an intensity represented by CK: for since the pressure CH is partly withstood by the force IC, or the firmness of the beam DC supported at D, the force KC will complete the balance. When we do not attend to the support at D, we conceive the force A*b* to be balanced by KC, or KC to be balanced by A*b*. And, in like manner, we may neglect the support or force acting at A, and consider the force DO as balanced by CK.

It becomes a Lever.

Thus our frame becomes a lever, and we are able to trace the interior mechanical procedure which gives it its efficacy: it is by the intervention of the forces of cohesion, which connect the points to which the external forces are applied with the supported point or fulcrum, and with each other.

These strains or pressures A*b*, DO, and CK, not being in the directions of the beams, may be called *transverse*. We see that by their means a frame of

Carpentry.

carpentry may be considered as a solid body: but the example which brought this to our view is too limited for explaining the efficacy which may be given to such constructions. We shall therefore give a general proposition, which will more distinctly explain the procedure of nature, and enable us to trace the strains as they are propagated through all the parts of the most complicated framing, finally producing the exertion of its most distant points.

General Proposition.

We presume that the reader is now pretty well habituated to the conception of the strains as they are propagated along the lines joining the points of a frame, and we shall therefore employ a very simple figure.

Let the strong lines ACBD (fig. 13.) represent a frame of carpentry. Suppose that it is pulled at the point A by a force acting in the direction AE, but that it rests on a fixed point C, and that the other extreme point B is held back by a power which resists in the direction BF: It is required to determine the proportion of the strains excited in its different parts, the proportion of the external pressures at A and B, and the pressure which is produced on the obstacle or fulcrum C?

It is evident that each of the external forces at A and B tend one way, or to one side of the frame, and that each would cause it to turn round C if the other did not prevent it; and that if, notwithstanding their action, it is turned neither way, the forces in actual exertion are in equilibrio by the intervention of the frame. It is no less evident that these forces concur in pressing the frame on the prop C. Therefore, if the piece CD were away, and if the joints C and D be perfectly flexible, the pieces CA, CB would be turned round the prop C, and the pieces AD, DB would also turn with them, and the whole frame change its form. This shows, by the way, and we desire it to be carefully kept in mind, that the firmness or stiffness of framing depends entirely on the triangles bounded by beams which are contained in it. An open quadrilateral may always change its shape, the sides revolving round the angles. A quadrilateral may have an infinity of forms, without any change of its sides, by merely pushing two opposite angles towards each other, or drawing them asunder. But when the three sides of a triangle are determined, its shape is also invariably determined; and if two angles be held fast, the third cannot be moved. It is thus that, by inserting the bar CD, the figure becomes unchangeable; and any attempt to change it by applying a force to an angle A, immediately excites forces of attraction or repulsion between the particles of the stuff which form its sides. Thus it happens, in the present instance, that a change of shape is prevented by the bar CD. The power at A presses its end against the prop; and in doing this it puts the bar AD on the stretch, and also the bar DB. Their places might therefore be supplied by cords or metal wires. Hence it is evident that DC is compressed, as is also AC; and, for the same reason, CB is also in a state of compression; for either A or B may be considered as the point that is impelled or withheld. Therefore DA and DB are stretched, and are resisting with attractive forces. DC and CB are compressed, and are resisting with repulsive forces: and thus the support of the prop, combined with the firmness of DC, puts the frame ADBC into the condition of the two frames in fig. 8. and fig. 9. Therefore the external force at A is really in equilibrio with an attracting force acting in the direction AD, and a repulsive force acting in the direction AK. And since all the connecting forces are mutual and equal, the point D is pulled or drawn in the direction DA. The condition of the point B is similar to that of A, and D is also drawn in the direction DB. Thus the point D, being urged by the forces in the directions DA and DB, presses the beam DC on the prop, and the prop resists in the opposite direction. Therefore the line DC is the diagonal of the parallelogram, whose sides have the proportion of the forces which connect D with A and B. This is the principle on which the rest of our investigation proceeds. We may take DC as the representation and measure of their joint effect. Therefore draw CH, CG, parallel to DA, DB. Draw HL, GO, parallel to CA, CB, cutting AE, BF, in L and O, and cutting DA, DB in I and M. Complete the parallelograms ILKA, MONB. Then DG and AI are the equal and opposite forces which connect A and D; for GD = CH, = AI. In like manner DH and BM are the forces which connect D and B.

Carpentry.

The external force at A is in immediate equilibrio with the combined forces, connecting A with D and with C. AI is one of them: Therefore AK is the other; and AL is the compound force with which the external force at A is in immediate equilibrium. This external force is therefore equal and opposite to AL. In like manner, the external force at B is equal and opposite to BO; and AL is to BO as the external force at A to the external force at B. The prop C resists with forces equal to those which are propagated to it from the points D, A, and C. Therefore it resists with forces CH, CG, equal and opposite to DG, DH; and it resists the compressions KA, NB, with equal and opposite forces C*k*, C*n*. Draw *kl*, *no* parallel to AD, BD, and draw C*l*Q, C*o*P: It is plain that *k*CH*l* is a parallelogram equal to KAIL, and that C*l* is equal to AL. In like manner C*o* is equal to BO. Now the forces C*k*, CH, exerted by the prop, compose the force C*l*; and C*n*, CG compose the force C*o*. These two forces C*l*, C*o* are equal and parallel to AL and BO; and therefore they are equal and opposite to the external forces acting at A and B. But they are (primitively) equal and opposite to the pressures (or at least the compounds of the pressures) exerted on the prop, by the forces propagated to C from A, D, and B. Therefore the pressures exerted on the prop are the same as if the external forces were applied there in the same directions as they are applied to A and B. Now if we make C*v*, C*z* equal to C*l* and C*o*, and complete the parallelogram CVYZ; it is plain that the force YC is in equilibrio with *l*C and *o*C. Therefore the pressures at A, C, and B, are such as would balance if applied to one point.

Lastly, in order to determine their proportions, draw CS and CR perpendicular to DA and DB. Also draw A*d*, B*f* perpendicular to CQ and CP; and draw C*g*, C*i* perpendicular to AE, BF.

Carpentry.

The triangles CPR and BPf are similar, having a common angle P, and a right angle at R and f.

In like manner the triangles CQS and AQd are similar. Also the triangles CHR, CGS are similar, by reason of the equal angles at H and G, and the right angles at R and S. Hence we obtain the following analogies:

$$\begin{array}{lll} Co : CP = on : PB, = & CG : PB \\ CP : CR = & PB : fB \\ CR : CS = & CH : CG \\ CS : CQ = & Ad : AQ \\ CQ : Cl = AQ : kl, = & AQ : CH \end{array}$$

Therefore, by equality,

$$\begin{array}{ll} Co : Cl = & Ad : fB \\ \text{or } BO : AL = & Cg : Ci. \end{array}$$

That is, the external forces are reciprocally proportional to the perpendiculars drawn from the prop on the lines of their direction.*

Extensive consequences.

This proposition (sufficiently general for our purpose) is fertile in consequences, and furnishes many useful instructions to the artist. The strains LA, OB, CY, that are excited, occur in many, we may say in all, framings of carpentry, whether for edifices or engines, and are the sources of their efficacy. It is also evident, that the doctrine of the transverse strength of timber is contained in this proposition; for every piece of timber may be considered as an assemblage of parts, connected by forces which act in the direction of the lines which joined the strained points on the matter which lies between those points, and also act on the rest of the matter, exciting those lateral forces which produce the inflexibility of the whole. See STRENGTH OF MATERIALS, *Encyclopædia*.

Thus it appears that this proposition contains the principles which direct the artist to frame the most powerful levers; to secure uprights by shores or braces, or by tiers and ropes; to secure scaffoldings for the erection of spires, and many other more delicate problems of his art. He also learns from this proposition, how to ascertain the strains that are produced, without his intention, by pieces which he intended for other offices, and which, by their transverse action, put his work in hazard. In short, this proposition is the key to the science of this art.

We would now counsel the artist, after he has made the tracing of the strains and thrusts through the various parts of a frame familiar to his mind, and even amused himself with some complicated fancy framings, to read over with care the articles STRENGTH OF MATERIALS and ROOF in the *Encyclopædia*. He will now conceive its doctrines much more clearly than when he was considering them as abstract theories. The mutual action of the woody fibres will now be easily comprehended, and his confidence in the results will be greatly increased.

Decision of a Disputed and very Important Question.

There is a proposition (No. 19. article ROOF in the *Encyclopædia*), which has been called in question by several very intelligent persons; and they say that Belidor has demonstrated, in his *Science des Ingenieurs*, that a beam firmly fixed at both ends is not twice as strong as when simply lying on the props; and that its strength is increased only in the proportion of two to three; and they support this determination by a list of experiments recited by Belidor, which agree *precisely* with it. Belidor also says, that Pitot had the same result in his experiments. These are respectable authorities: but Belidor's reasoning is any thing but demonstration; and his experiments are described in such an imperfect manner, that we cannot build much on them. It is not said in what manner the battens were secured at the ends, any farther than that it was by *chevalets*. If by this word is meant a tressle, we cannot conceive how they were employed; but we see it sometimes used for a wedge or key. If the battens were wedged in the holes, their resistance to fracture may be made what we please; they may be made loose, and therefore resist little more than when simply laid on props. They may be (and probably were) wedged very fast, and bruised or crippled.

Our proposition mentioned distinctly the security given to the ends of the beams. They were mortised into remote posts. Our *precise* meaning was, that they were simply kept from rising by these mortises, but at full liberty to bend up at E and I, and between G and K. Our assertion was not made

---

* "The learned reader will perceive, that this analogy is precisely the same with that of forces which are in equilibrio by the intervention of a lever. In fact, this whole frame of carpentry is nothing else than a *built* or *framed lever* in equilibrio. It is acting in the same manner as a solid, which occupies the whole figure compressed in the frame, or as a body of any size and shape whatever that will admit the three points of application A, C, and B. It is always in equilibrio in the case first stated; because the pressure *produced* at B by a force applied to A is always such as balances it. The reader may also perceive, in this proposition, the analysis or tracing of those internal mechanical forces which are indispensably requisite for the functions of a lever. The mechanicians have been extremely puzzled to find a legitimate demonstration of the equilibrium of a lever ever since the days of Archimedes. Mr Vince has the honour of first demonstrating, most ingeniously, the principle assumed by Archimedes, but without sufficient ground, for *his* demonstration: but Mr Vince's demonstration is only a putting the mind into that perplexed state which makes it acknowledge the proposition, but without a clear perception of its truth. The difficulty has proceeded from the abstract notion of a lever, conceiving it as a mathematical line—inflexible, without reflecting how it is inflexible,—for the very source of this indispensable quality furnishes the mechanical connection between the remote pressures and the fulcrum; and this supplies the demonstration (without the least difficulty) of the desperate case of a straight lever urged by parallel forces. See ROTATION in the *Encyclopædia*."

from theory alone (although we think the reasoning incontrovertible), but was agreeable to numerous experiments made in those precise circumstances. Had we mortised the beams firmly into two very stout posts, which could not be drawn nearer to each other by bending, the beam would have borne a *much* greater weight, as we have verified by experiments. We hope that the following mode of conceiving this case will remove all doubts.

Let LM be a long beam (fig. 14.) divided into six equal parts, in the points D, B, A, C, E. Let it be firmly supported at L, B, C, M. Let it be cut through at A, and have compass joints at B and C. Let FB, GC be two equal uprights, resting on B and C, but without any connection. Let AH be a similar and equal piece, to be occasionally applied at the seam A. Now let a thread or wire AGE be extended over the piece GC, and made fast at A, G, and E. Let the same thing be done on the other side of A. If a weight be now laid on at A, the wires AFD, AGE will be strained and may be broken. In the instant of fracture we may suppose their strains to be represented by Af and Ag. Complete the parallelogram, and Aa is the magnitude of the weight. It is plain that nothing is concerned here but the cohesion of the wires; for the beam is sawed through at A, and its parts are perfectly moveable round B and C.

Instead of this process apply the piece AH below A, and keep it there by straining the same wire BHC over it. Now lay on a weight. It must press down the ends of BA and CA, and cause the piece AH to strain the wire BHC. In the instant of fracture of *the same* wire, its resistances Hb and Hc must be equal to Af and Ag, and the weight hH which breaks them must be equal to Aa.

Lastly, employ all the three pieces FB, AH, GC, with the same wire attached as before. There can be no doubt but that the weight which breaks all the four wires must be $= a\mathrm{A} + h\mathrm{H}$, or twice Aa.

The reader cannot but see that the wires perform the very same office with the fibres of an entire beam LM held fast in the four holes D, B, C, and E, of some upright posts.

In the experiments for verifying this, by breaking slender bars of fine deal, we get complete demonstration, by measuring the curvatures produced in the parts of the beam thus held down, and comparing them with the curvature of a beam simply laid on the props B and C: and there are many curious inferences to be made from these observations, but we have not room for them in this place.

The best manner of Framing Purlins.

We may observe by the way, that we learn from this case, that purlins are able to carry twice the load when notched into the rafters that they carry when mortised into them, which is the most usual manner of framing them. So would the bending joists of floors; but this would double the thickness of the flooring But this method should be followed in every possible case, such as breast summers, lintels over several pillars, &c. These should never be cut off and mortised into the sides of every upright: numberless cases will occur which show the importance of the maxim.

We must here remark, that the proportion of the spaces BC and CM, or BC and LB, has a very sensible effect on the strength of the beam BC; but we have not yet satisfied our minds as to the *rationale* of this effect. It is undoubtedly connected with the serpentine form of the curve of the beam before fracture. This should be attended to in the construction of the springs of carriages. These are frequently supported at a middle point (and it is an excellent practice), and there is a certain proportion which will give the easiest motion to the body of the carriage. We also think that it is connected with that deviation from the best theory observable in Buffon's experiments on various lengths of the same scantling. The force of the beams diminished much more than in the inverse proportion of their lengths.

In what cases Ties are better than Struts.

We have seen that it depends entirely on the position of the pieces in respect of their points of ultimate support, and of the direction of the external force which produces the strains, whether any particular piece is in a state of extension or of compression. The knowledge of this circumstance may greatly influence us in the choice of the construction. In many cases we may substitute slender iron rods for massive beams, when the piece is to act the part of a tie. But we must not invert this disposition; for when a piece of timber acts as a strut, and is in a state of compression, it is next to certain that it is not equally compressible in its opposite sides through the whole length of the piece, and that the compressing force on the abutting joint is not acting in the most equable manner all over the joint. A very trifling inequality in either of these circumstances (especially in the first) will compress the beam more on one side than on the other. This cannot be without the beam's bending, and becoming concave on that side on which it is most compressed. When this happens, the frame is in danger of being crushed, and soon going to ruin. It is, therefore, indispensably necessary to make use of beams in all cases where struts are required of considerable length, rather than of metal rods of slender dimensions, unless in situations where we can effectually prevent their bending, as in trussing a girder internally, where a cast iron strut may be firmly cased in it, so as not to bend in the smallest degree. In cases where the pressures are enormous, as in the very oblique struts of a centre or arch frame, we must be particularly cautious to do nothing which can facilitate the compression of either side. No mortises should be cut near to one side; no lateral pressures, even the slightest, should be allowed to touch it. We have seen a pillar of fir 12 inches long, and one inch in section, when loaded with three tons, snap in an instant when pressed on one side by 16 pounds, while another bore $4\frac{1}{2}$ tons without hurt, because it was inclosed (loosely) in a stout pipe of iron. (See Note DD.)

In such cases of enormous compression, it is of great importance that the compressing force bear equally on the whole abutting surface. The German carpenters are accustomed to put a plate of lead over the joint. This prevents, in some measure, the penetration of the end fibres. Mr Perronet, the celebrated French architect, formed his abutments into arches of circles, the centre of which was the re-

mote end of the strut. By this contrivance the unavoidable change of form of the triangle made no partial bearing of either angle of the abutment. This always has a tendency to splinter off the heel of the beam where it presses strongest. It is a very judicious practice. (See Note EE.)

When circumstances allow it, we must rather employ ties than struts for securing a beam against lateral strains. When an upright pillar, such as a flagstaff, a mast, or the uprights of a very tall scaffolding, are to be shoared up, the dependence is more certain on those braces that are stretched by the strain than on those which are compressed. The scaffolding of the iron bridge near Sunderland had some ties very judiciously disposed, and others with less judgment.

We should proceed to consider the transverse strains as they affect the various parts of a frame of carpentry; but we have very little to add to what has been said already in the article STRENGTH OF MATERIALS (*Encycl.*), and in the article ROOF. What we shall add in this article will find a place in our occasional remarks on different works. It may, however, be of use to recal to the reader's memory the following propositions.

General Theorems concerning the relative Strength of Beams.

1. When a beam AB (fig. 15.) is firmly fixed at the end A, and a straining force acts perpendicularly to its length at any point B, the strain occasioned at any section C between B and A is proportional to CB, and may therefore be represented by the product $W \times CB$; that is, by the product of the number of tons, pounds, &c. which measure the straining force, and the number of feet, inches, &c. contained in CB. As the loads on a beam are easily conceived, we shall substitute this for any other straining force.

2. If the strain or load is uniformly distributed along any part of the beam lying beyond C (that is, further from A), the strain at C is the same as if the load were all collected at the middle point of that part; for that point is the centre of gravity of the load.

3. The strain on any section D of a beam AB (fig. 16.) resting freely on two props A and B, is $w \times \frac{AD \times DB}{AB}$. (See ROOF, No. 19. and STRENGTH OF MATERIALS, No. 92., &c. *Encyclopædia.*) Therefore,

4. The strain on the middle point, by a force applied there, is one-fourth of the strain which the same force would produce, if applied to one end of a beam of the same length, having the other end fixed.

5. The strain on any section C of a beam, resting on two props A and B, occasioned by a force applied perpendicularly to another point D, is proportional to the rectangle of the exterior segments, or is equal to $w \times \frac{AC \times DB}{AB}$. Therefore,

The strain at C occasioned by the pressure on D, is the same with the strain at D occasioned by the same pressure on C.

6. The strain on any section D, occasioned by a load uniformly diffused over any part EF, is the same as if the two parts ED, DF of the load were collected at their middle points e and f. Therefore,

The strain on any part D, occasioned by a load uniformly distributed over the whole beam, is one half of the strain that is produced when the same load is laid on at D; and

The strain on the middle point C, occasioned by a load uniformly distributed over the whole beam, is the same which half that load would produce if laid on at C.

7. A beam supported at both ends on two props B and C (fig. 14.), will carry twice as much when the ends beyond the props are kept from rising, as it will carry when it rests loosely on the props.

8. Lastly, the transverse strain on any section, occasioned by a force applied obliquely, is diminished in the proportion of the sine of the angle which the direction of the force makes with the beam. Thus, if it be inclined to it in an angle of thirty degrees, the strain is one half of the strain occasioned by the same force acting perpendicularly.

On the other hand, the RELATIVE STRENGTH of a beam, or its power in any particular section to resist any transverse strain, is proportional to the absolute cohesion to the section directly, to the distance of its centre of effort from the axis of fracture directly, and to the distance from the strained point inversely.

Thus in a rectangular section of the beam, of which b is the breadth, d the depth (that is, the dimension in the direction of the straining force), measured in inches, and f the number of pounds which one square inch will just support without being torn asunder, we must have $f \times b \times d^2$, proportional to $w \times CB$ (fig. 15.) Or, $f \times b \times d^2$, multiplied by some number m, depending on the nature of the timber, must be equal to $w \times CB$. Or, in the case of the section C of fig. 16. that is strained by the force w applied at D, we must have $m \times fbd^2 = w \times \frac{AC \times DB}{AB}$. Thus if the beam is of sound oak, m is very nearly $= \frac{1}{9}$ (see STRENGTH OF MATERIALS, No. 116, *Encycl.*) Therefore we have $\frac{fbd^2}{9} = w \times \frac{AC \times CB}{AB}$. (See Note FF.)

Hence we can tell the precise force w which any section C can just resist when that force is applied in any way whatever. For the above-mentioned formula gives $w = \frac{fbd^2}{9CB}$, for the case represented by fig. 15. But the case represented in fig. 16. having the straining force applied at D, gives the strain at $C\ (= w) = f \times \frac{bd^2 \times AB}{9AC \times CB}$.

Example. Let an oak beam, four inches square, rest freely on the props A and B, seven feet apart, or 84 inches. What weight will it just support at

Carpentry.

its middle point C, on the supposition that a square inch rod will just carry 16,000 pounds, pulling it asunder?

The formula becomes $w = \frac{16000 \times 4 \times 16 \times 84}{9 \times 42 \times 42}$,

or $w = \frac{86016000}{15876}$, $= 5418$ pounds. This is very near what was employed in Buffon's experiment, which was 5312.

Had the straining force acted on a point D, half way between C and B, the force sufficient to break the beam at C would be $= \frac{16000 \times 4 \times 16 \times 84}{9 \times 42 \times 21} =$ 10836 lbs.

Had the beam been sound red fir, we must have taken $f = 10,000$ nearly, and m nearly 8; for although fir be less cohesive than oak in the proportion of 5 to 8 nearly, it is less compressible, and its axis of fracture is therefore nearer to the concave side.

Of Joints.

Having considered at sufficient length the strains of different kinds which arise from the form of the parts of a frame of carpentry, and the direction of the external forces which act on it, whether considered as impelling or as supporting its different parts, we must now proceed to consider the means by which this form is to be secured, and the connections by which those strains are excited and communicated.

The joinings practised in carpentry are almost infinitely various, and each has advantages which make it preferable in some circumstances. Many varieties are employed merely to please the eye. We do not concern ourselves with these: Nor shall we consider those which are only employed in connecting small works, and can never appear on a great scale; yet even in some of these, the skill of the carpenter may be discovered by his choice; for in all cases, it is wise to make every, even the smallest, part of his work as strong as the materials will admit. He will be particularly attentive to the changes which will necessarily happen by the shrinking of timber as it dries, and will consider what dimensions of his framings will be affected by this, and what will not; and will then dispose the pieces which are less essential to the strength of the whole, in such a manner that their tendency to shrink shall be in the same direction with the shrinking of the whole framing. If he do otherwise, the seams will widen, and parts will be split asunder. He will dispose his boardings in such a manner as to contribute to the stiffness of the whole, avoiding at the same time the giving them positions which will produce lateral strains on truss beams which bear great pressures; recollecting, that although a single board has little force, yet many united have a great deal, and may frequently perform the office of very powerful struts.

Our limits confine us to the joinings which are most essential for connecting the parts of a single piece of a frame when it cannot be formed of one beam, either for want of the necessary thickness or length; and the joints for connecting the different sides of a trussed frame.

Much ingenuity and contrivance has been bestowed on the manner of building up a great beam of many thicknesses, and many singular methods are practised as great nostrums by different artists: but when we consider the manner in which the cohesion of the fibres performs its office, we will clearly see that the simplest are equally effected with the most refined, and that they are less apt to lead us into false notions of the strength of the assemblage.

Of building up Beams.

Building a Girder or Lever.

Thus, were it required to build up a beam for a great lever or a girder, so that it may act nearly as a beam of the same size of one log—it may either be done by plain joggling, as in Plate L. fig. 17. A, or by scarfing, as in fig. 17. B or C. If it is to act as a lever, having the gudgeon on the lower side at C, we believe that most artists will prefer the form B and C; at least this has been the case with nine-tenths of those to whom we have proposed the question. The best informed only hesitated; but the ordinary artists were all confident in its superiority; and we found their views of the matter very coincident. They considered the upper piece as grasping the lower in its hooks; and several imagined that, by driving the one very tight on the other, the beam would be stronger than an entire log; but if we attend carefully to the internal procedure in the loaded lever, we shall find the upper one clearly the strongest. If they are formed of equal logs, the upper one is thicker than the other by the depth of the joggling or scarfing, which we suppose to be the same in both; consequently, if the cohesion of the fibres in the intervals is able to bring the uppermost filaments into full action, the form A is stronger than B, in the proportion of the greater distance of the upper filaments from the axis of the fracture: this may be greater than the difference of the thickness, if the wood is very compressible. If the gudgeon be in the middle, the effect, both of the joggles and the scarfings, is considerably diminished; and if it is on the upper side, the scarfings act in a very different way. In this situation, if the loads on the arms are also applied to the upper side, the joggled beam is still more superior to the scarfed one. This will be best understood by resolving it in imagination into a trussed frame. But when a gudgeon is thus put on that side of the lever which grows convex by the strain, it is usual to connect it with the rest by a powerful strap, which embraces the beam, and causes the opposite point to become the resisting point. This greatly changes the internal actions of the filaments, and, in some measure, brings it into the same state as the first, with the gudgeon below. Were it possible to have the gudgeon on the upper side, and to bring the whole into action without a strap, it would be the strongest of all; because, in general, the resistance to compression is greater than to extension. In every situation the joggled beam has the advantage; and it is the easiest executed. (See Note GG.)

Joggling preferable to Scarfing.

We may frequently gain a considerable accession of strength by this building up of a beam; especially if the part which is stretched by the strain be of oak, and the other part be fir. Fir being so much superior to oak as a pillar (if Muschenbroek's experiments may be confided in), and oak so much preferable as a tie, this construction seems to unite both

Carpentry. advantages. But we shall see much better methods of making powerful levers, girders, &c. by trussing.

Observe, that the efficacy of both methods depends entirely on the difficulty of causing the piece between the cross joints to slide along the timber to which it adheres. Therefore, if this be moderate, it is wrong to make the notches deep; for as soon as they are so deep that their ends have a force sufficient to push the slice along the line of junction, nothing is gained by making them deeper; and this requires a greater expenditure of timber.

Scarfings are frequently made oblique, as in fig. 18.; but we imagine that this is a bad practice. It begins to yield at a point, where the wood is crippled, and splintered off, or at least bruised out a little: as the pressure increases, this part, by squeezing broader, causes the solid parts to rise a little upwards, and gives them some tendency, not only to push their antagonists along the base, but even to tear them up a little. For similar reasons, we disapprove of the favourite practice of many artists, to make the angles of their scarfings acute, as in fig. 19. This often causes the two pieces to tear each other up. The abutments should always be perpendicular to the directions of the pressures. Lest it should be forgotten in its proper place, we may extend this injunction also to the abutments of different pieces of a frame, and recommend it to the artist even to attend to the shrinking of the timbers by drying. When two timbers abut obliquely, the joint should be most full at the obtuse angle of the end; because, by drying, that angle grows more obtuse, and the beam would then be in danger of splintering off at the acute angle.

e must t wedge hard.

It is evident, that the nicest work is indispensably necessary in building up a beam. The parts must abut on each other completely, and the smallest play or void takes away the whole efficacy. It is usual to give the butting joints a small taper to one side of the beam, so that they may require moderate blows of a maul to force them in, and the joints may be perfectly close when the external surfaces are even on each side of the beam. But we must not exceed in the least degree; for a very taper wedge has great force; and if we have driven the pieces together by very heavy blows, we leave the whole in a state of violent strain, and the abutments are perhaps ready to splinter off by a small addition of pressure. This is like too severe a proof for artillery: which, though not sufficient to burst the pieces, has weakened them to such a degree, that the strain of ordinary service is sufficient to complete the fracture. The *workman* is tempted to exceed in this, because it smooths off and conceals all uneven seams; but he must be watched. It is not unusual to leave some abutments open enough to admit a thin wedge reaching through the beam. Nor is this a bad practice, if the wedge is of materials which is not compressed by the driving or the strain of service. Iron would be preferable for this purpose, and for the joggles, were it not that by its too great hardness it cripples the fibres of timber to some distance. In consequence of this, it often happens that, in beams which are subjected to desultory and sudden strains (as in the levers of reciprocating engines), the joggles or wedges widen the holes, and work themselves loose: Therefore skilful engineers never admit them; and indeed as few bolts as possible, for the same reason: but when resisting a steady or dead pull, they are not so improper, and are frequently used.

Beams are built up, not only to increase their dimensions in the direction of the strain (which we have hitherto called their depth), but also to increase their breadth, or the dimensions perpendicular to the strain. We sometimes double the breadth of a girder which is thought too weak for its load, and where we must not increase the thickness of the flooring.

Building of Masts.

The mast of a great ship of war must be made bigger athwartship, as well as fore and aft. This is one of the nicest problems of the art; and professional men are by no means agreed in their opinions about it. We do not presume to decide; and shall content ourselves with exhibiting the different methods.

The most obvious and natural method is that shown in fig. 20. It is plain that (independent of the connection of cross bolts, which are used in them all when the beams are square) the piece C cannot bend in the direction of the plane of the figure without bending the piece D along with it. This method is much used in the French navy: but it is undoubtedly imperfect. Hardly any two great trees are of equal quality, and swell or shrink alike. If C shrinks more than D, the feather of C becomes loose in the groove wrought in D to receive it; and when the beam bends, the parts can slide on each other like the plates of a coach spring; and if the bending is in the direction *e f*, there is nothing to hinder this sliding but the bolts, which soon work themselves loose in the bolt-holes.

Method used in the French Navy.

Another Method.

Fig. 21. exhibits another method. The two halves of the beam are tabled into each other in the same manner as in fig. 17. It is plain that this will not be affected by the unequal swelling or shrinking, because this is insensible in the direction of the fibres; but when bent in the direction *a b*, the beam is weaker than fig. 20. bent in the direction *e f*. Each half of fig 20. has, in every part of its length, a thickness greater than half the thickness of the beam. It is the contrary in the alternate portions of the halves of fig. 21. When one of them is bent in the direction AB, it is plain that it drags the other with it by means of the cross butments of its tables, and there can be no longitudinal sliding. But unless the work is accurately executed, and each hollow completely filled up by the table of the other piece, there will be a lateral slide along the cross joints sufficient to compensate for the curvature; and this will hinder the one from compressing or stretching the other in conformity to this curvature.

Its imperfection.

The imperfection of this method is so obvious, that it has seldom been practised: but it has been combined with the other, as is represented in fig. 22. where the beams are divided along the middle, and the tables in each half are alternate, and alternate also with the tables of the other half. Thus 1, 3, 4, are prominent, and 5, 2, 6, are depressed. This construction evidently puts a stop to both slides, and obliges every part of both pieces to move together. *a b* and *c d* show

sections of the built-up beam corresponding to AB and CD.

No more is intended in this practice by any intelligent artist, than the causing the two pieces to act together in all their parts, although the strains may be unequally distributed on them. Thus, in a built-up girder, the binding joists are frequently mortised into very different parts of the two sides. But many seem to aim at making the beam stronger than if it were of one piece; and this inconsiderate project has given rise to many whimsical modes of tabling and scarfing, which we need not regard.

British method.

The practice in the British dock-yards is somewhat different from any of these methods. The pieces are tabled as in fig. 22. but the tables are not thin parallelopipeds, but thin prisms. The two outward joints or visible seams are straight lines, and the table No. 1. rises gradually to its greatest thickness in the axis. In like manner, the hollow 5 for receiving the opposite table, sinks gradually from the edge to its greatest depth in the axis. Fig. 23. No. 1. represents a section of a round piece of timber built up in this way, where the full line EFGH is the section corresponding to AB of fig. 22., and the dotted line EGFH is the section corresponding to CD.

This construction, by making the external seam straight, leaves no lodgment for water, and looks much fairer to the eye; but it appears to us that it does not give such firm hold when the mast is bent in the direction EH. The exterior parts are most stretched and most compressed by this bending; but there is hardly any abutment in the exterior parts of these tables. In the very axis, where the abutment is the firmest, there is little or no difference of extension and compression.

But this construction has an advantage, which we imagine much more than compensates for these imperfections, at least in the particular case of a round mast: it will draw together by hooping incomparably better than any of the others. If the cavity be made somewhat too shallow for the prominence of the tables, and if this be done uniformly along the whole length, it will make a somewhat open seam: and this opening can be regulated with the utmost exactness from end to end by the plane. The heart of those vast trunks is very sensibly softer than the exterior circles: Therefore, when the whole is hooped, and the hoops hard driven, and at considerable intervals between each spell—we are confident that all may be compressed till the seam disappears; and then the whole makes one piece, *much* stronger than if it were an original log of that size, because the middle has become, by compression, as solid as the crust, which was naturally firmer, and resisted farther compression. We verified this beyond a doubt, by hooping a built stick of a timber which has this inequality of firmness in a remarkable degree, and it was nearly twice as strong as another of the same size.

Our mastmakers are not without their fancies and whims; and the manner in which our masts and yards are generally built up, is not near so simple as fig. 23.: but it consists of the same essential parts, acting in the very same manner, and derives all its efficacy from the principles which are here employed.

Attended with peculiar advantages.

This construction is particularly suited to the situation and office of a ship's mast. It has no bolts; or, at least, none of any magnitude, or that make very important parts of its construction. The most violent strains perhaps that it is exposed to, is that of twisting, when the lower yards are close braced up by the force of many men acting by a long lever. This form resists a twist with peculiar energy: it is therefore an excellent method for building up a great shaft for a mill. The way in which they are usually built up is by reducing a central log to a polygonal prism, and then filling it up to the intended size by *planting* pieces of timber along its sides, either spiking them down, or cocking them into it by a feather, or joggling them by slips of hard wood sunk into the central log and into the slips. *N.B.* Joggles of elm are sometimes used in the middle of the large tables of masts; and when sunk into the firm wood near the surface, they must contribute much to the strength. But it is very necessary to employ wood not much harder than the pine; otherwise it will soon enlarge its bed, and became loose; for the timber of these large trunks is very soft.

The most general reason for piercing a beam is to increase its length. This is frequently necessary, in order to procure tie-beams for very wide roofs. Two pieces must be scarfed together.—Numberless are the modes of doing this; and almost every master carpenter has his favourite nostrum. Some of them are very ingenious: But here, as in other cases, the most simple are commonly the strongest. We do not imagine that any, the most ingenious, is equally strong with a tie consisting of two pieces of the same scantling laid over each other for a certain length, and firmly bolted together. We acknowledge that this will appear an artless and clumsy tie-beam; but we only say that it will be stronger than any that is more artificially made up of the same thickness of timber. This, we imagine, will appear sufficiently certain.

Various methods of scarfing.

The simplest and most obvious scarfing (after the one now mentioned) is that represented in fig. 24., No. 1. and 2. If considered merely as two pieces of wood joined, it is plain that, as a tie, it has but half the strength of an entire piece, supposing that the bolts (which are the only connections) are fast in their holes. No. 2. requires a bolt in the middle of the scarf to give it that strength; and, in every other part, is weaker on one side or the other. (See Note HH.)

But the bolts are very apt to bend by the violent strain, and require to be strengthened by uniting their ends by iron plates; in which case it is no longer a wooden tie. The form of No. 1. is better adapted to the office of a pillar than No. 2.; especially if its ends be formed in the manner shown in the elevation No. 3. By the sally given to the ends, the scarf resists an effort to bend it in that direction. Besides, the form of No. 2. is unsuitable for a post; because the pieces, by sliding on each other by the pressure, are apt to splinter off the tongue which confines their extremity.

Fig. 25. and 26. exhibit the most approved form of a scarf, whether for a tie or for a post. The key represented in the middle is not essentially necessary; the two pieces might simply meet square there. This form, without a key, needs no bolts (although they strengthen it greatly); but, if worked very true and close, and with square abutments, will hold together, and will resist bending in any direction. But the key is an ingenious and a very great improvement, and will force the parts together with perfect tightness. The same precaution must be observed that we mentioned on another occasion, not to produce a constant internal strain on the parts by overdriving the key. The form of fig. 25. is by far the best; because the triangle of 26 is much easier splintered off by the strain, or by the key, than the square wood of 25. It is far preferable for a post, for the reason given when speaking of fig. 24., No. 1. and No. 2. Both may be formed with a sally at the ends equal to the breadth of the key. In this shape fig. 25. is vastly well suited for joining the parts of the long corner posts of spires and other wooden towers. Fig. 25., No. 2., differs from No. 1. only by having three keys. The principal and the longitudinal strength are the same. The long scarf of No. 2., tightened by the three keys, enables it to resist a bending much better.

None of these scarfed tie-beams can have more than one-third of the strength of an entire piece, unless with the assistance of iron plates; for if the key be made thinner than one-third, it has less than one-third of the fibres to pull by.

We are confident, therefore, that when the heads of the bolts are connected by plates, the simple form of fig. 24. No. 1. is stronger than those more ingenious scarfings. It may be strengthened against lateral bending by a little tongue, or by a sally; but cannot have both.

The strongest of all methods of piecing a tie-beam would be to set the parts end to end, and grasp them between other pieces on each side, as in fig. 27. Plate LI. This is what the ship-carpenter calls *fishing* a beam; and is a frequent practice for occasional repairs. Mr Perronet used it for the tie-beams or stretchers, by which he connected the opposite feet of a centre, which was yielding to its load, and had pushed aside one of the piers above four inches. Six of these not only withstood a strain of 1800 tons, but, by wedging behind them, he brought the feet of the truss $2\frac{1}{2}$ inches nearer. The stretchers were 14 inches by 11 of sound oak, and could have withstood three times that strain. Mr Perronet, fearing that the great length of the bolts employed to connect the beams of these stretchers would expose them to the risk of bending, scarfed the two side pieces into the middle piece. The scarfing was of the triangular kind *(Trait de Jupiter)*, and only an inch deep, each face being two feet long, and the bolt passed through close to the angle.

In piecing the pump rods, and other wooden stretchers of great engines, no dependence is had on scarfing; and the engineer connects every thing by iron straps. We doubt the propriety of this, at least in cases where the bulk of the wooden connexion is not inconvenient. These observations must suffice for the methods employed for connecting the parts of a beam; and we now proceed to consider what are more usually called the joints of a piece of carpentry.

Square Joints.

Where the beams stand square with each other, and the strains are also square with the beams, and in the plane of the frame, the common mortise and tenon is the most perfect junction. A pin is generally put through both, in order to keep the pieces united, in opposition to any force which tends to part them. Every carpenter knows how to bore the hole for this pin, so that it shall draw the tenon tight into the mortise, and cause the shoulder to butt close, and make neat work; and he knows the risk of tearing out the bit of the tenon beyond the pin, if he draw it too much. We may just observe, that square holes and pins are much preferable to round ones for this purpose, bringing more of the wood into action, with less tendency to split it. The ship-carpenters have an ingenious method of making long wooden bolts, which do not pass completely through, take a very fast hold, though not nicely fitted to their holes, which they must not be, lest they should be crippled in driving. They call it *foxtail wedging*. They stick into the point of the bolt a very thin wedge of hard wood, so as to project a proper distance; when this reaches the bottom of the hole by driving the bolt, it splits the end of it, and squeezes it hard to the side. This may be practised with advantage in carpentry. If the ends of the mortise are widened inwards, and a thin wedge be put into the end of the tenon, it will have the same effect, and make the joint equal to a dovetail. But this risks the splitting the piece beyond the shoulder of the tenon, which would be unsightly. This may be avoided as follows: Let the tenon T, fig. 28. have two *very* thin wedges *a* and *c* struck in near its angles, projecting equally: at a very small distance within these, put in two shorter ones *b*, *d*, and more within these if necessary. In driving this tenon, the wedges *a* and *c* will take first, and split off a thin slice, which will easily bend without breaking. The wedges *b*, *d*, will act next, and have a similar effect, and the others in succession. The thickness of all the wedges taken together must be equal to the enlargement of the mortise toward the bottom.

Foxtail Wedging.

When the strain is transverse to the plane of the two beams, the principles laid down in No. 85, 86, of the article STRENGTH OF MATERIALS, will direct the artist in placing his mortise. Thus the mortise in a girder for receiving the tenon of a binding joist of a floor should be as near the upper side as possible, because the girder becomes concave on that side by the strain. But as this exposes the tenon of the binding-joist to the risk of being torn off, we are obliged to mortise farther down. The form (fig. 29.) generally given to this joint is extremely judicious. The sloping part *a b* gives a very firm support to the additional bearing *e d*, without much weakening of the girder. This form should be copied in every case where the strain has a similar direction.

Oblique Mortise and Tenon.

The joint that most of all demands the careful attention of the artist is, that which connects the ends of beams, one of which pushes the other very obliquely, putting it into a state of extension. The

most familiar instance of this is the foot of a rafter pressing on the tie-beam, and thereby *drawing* it away from the other wall. When the direction is very oblique (in which case the extending strain is the greatest), it is difficult to give the foot of the rafter such a hold of the tie-beam as to bring many of its fibres into the proper action. There would be little difficulty if we could allow the end of the tie-beam to project to a small distance beyond the foot of the rafter: but, indeed, the dimensions which are given to tie-beams, for other reasons, are always sufficient to give enough of abutment when judiciously employed. Unfortunately this joint is much exposed to failure by the effects of the weather. It is much exposed, and frequently perishes by rot, or becomes so soft and friable that a very small force is sufficient, either for pulling the filaments out of the tie-beam, or for crushing them together. We are therefore obliged to secure it with particular attention, and to avail ourselves of every circumstance of construction.

One is naturally disposed to give the rafter a deep hold by a long tenon; but it has been frequently observed in old roofs that such tenons break off. Frequently they are observed to tear up the wood that is above them, and push their way through the end of the tie-beam. This in all probability arises from the first sagging of the roof, by the compression of the rafters and of the head of the king-post. The head of the rafter descends, the angle with the tie-beam is diminished by the rafter revolving round its step in the tie-beam. By this motion the heel or inner angle of the rafter becomes a fulcrum to a very long and powerful lever much loaded. The tenon is the other arm, very short, and being still fresh, it is therefore very powerful. It therefore forces up the wood that is above it, tearing it out from between the cheeks of the mortise, and then pushes it along. Carpenters have therefore given up long tenons, and give to the toe of the tenon a shape which abuts firmly, in the direction of the thrust, on the solid bottom of the mortise, which is well supported on the under side by the wall plate. This form has the farther advantage of having no tendency to tear up the end of the mortise. This form is represented in fig. 30. The tenon has a small portion *ab* cut perpendicular to the surface of the tie-beam, and the rest *bc* is perpendicular to the rafter. (See Note CC.)

But if the tenon is not sufficiently strong (and it is not so strong as the rafter, which is thought not to be stronger than is necessary), it will be crushed, and then the rafter will shade out along the surface of the beam. It is therefore necessary to call in the assistance of the whole rafter. It is in this distribution of the strain among the various abutting parts that the varieties of joints and their merits chiefly consist. It would be endless to describe every nostrum, and we shall only mention a few that are most generally approved of.

Most approved Forms.

The aim in fig. 31. is to make the abutments exactly perpendicular to the thrusts. (See Note CC.) It does this very precisely; and the share which the tenon and the shoulder have of the whole may be what we please, by the portion of the beam that we notch down. If the wall plate lie duly before the heel of the rafter, there is no risk of straining the tie across or breaking it, because the thrust is made to direct to that point where the beam is supported. The action is the same as against the joggle on the head or foot of a king-post. We have no doubt but that this is a very effectual joint. It is not, however, much practised. It is said that the sloping seam at the shoulder lodges water; but the great reason seems to be a secret notion that it weakens the tie-beam. If we consider the direction in which it acts as a tie, we must acknowledge that this form takes the best method for bringing the whole of it into action.

Fig. 32. exhibits a form that is more general, but certainly worse. What part of the thrust that is not borne by the tenon acts obliquely on the joint of the shoulder, and gives the whole a tendency to rise up and slide outward.

The shoulder joint is sometimes formed like the dotted line *abcdefg* of fig. 32. This is much more agreeable to the true principle, and would be a very perfect method, were it not that the intervals *bd* and *df* are so short that the little wooden triangles *bcd*, *def*, will be easily pushed off their bases *bd*, *df*.

Fig. 33. No. 1. seems to have the most general approbation. It is the joint recommended by Price, and copied into all books of carpentry as the *true joint* for a rafter foot. The visible shoulder-joint is flush with the upper surface of the tie-beam. The angle of the tenon at the tie nearly bisects the obtuse angle formed by the rafter and the beam, and is therefore somewhat oblique to the thrust. The inner shoulder *ac* is nearly perpendicular to *bd*. The lower angle of the tenon is cut off horizontally as at *ed*. Fig. 34. is a section of the beam and rafter foot, showing the different shoulders.

We do not perceive the peculiar merit of this joint. The effect of the three oblique abutments, *ab*, *ac*, *ed*, is undoubtedly to make the whole bear on the outer end of the mortoise, and there is no other part of the tie-beam that makes immediate resistance. Its only advantage over a tenon extending in the direction of the thrust is, that it will not tear up the wood above it. Had the inner shoulder had the form *eci*, having its face *ic* perpendicular, it would certainly have acted more powerfully in stretching many filaments of the tie-beam, and would have had much less tendency to force out the end of the mortise. The little bit *ci* would have prevented the sliding upwards along *ec*. At any rate, the joint *ab* being flush with the beam, prevents any sensible abutment on the shoulder *ac*.

Fig. 33. No. 2. is a simpler, and in our opinion a preferable, joint. We observe it practised by the most eminent carpenters for all oblique thrusts; but it surely employs less of the cohesion of the tie-beam than might be used without weakening it, at least when it is supported on the other side by the wall plate.

Fig. 33. No. 3. is also much practised by the first carpenters.

Fig. 35. No. 1. is proposed by Mr Nicholson as preferable to fig. 33. No. 3., because the abutment of the inner part is better supported. This is certainly the case; but it supposes the whole

Carpentry. rafter to go to the bottom of the socket, and the beam to be thicker than the rafter. Some may think that this will weaken the beam too much, when it is no broader than the rafter is thick; in which case they think that it requires a deeper socket than Nicholson has given it. Perhaps the advantages of Nicholson's construction may be had by a joint like fig. 35. No. 2.

Circumstance to be attended to. Whatever is the form of these butting joints, great care should be taken that all parts bear alike, and the artist will attend to the magnitude of the different surfaces. In the general compression, the greater surfaces will be less compressed, and the smaller will therefore change most. When all has settled, every part should be *equally* close. Because great logs are moved with difficulty, it is very troublesome to try the joint frequently to see how the parts fit; therefore we must expect less accuracy in the interior parts. This should make us prefer those joints whose efficacy depends chiefly on the visible joint.

It appears from all that we have said on this subject, that a very small part of the cohesion of the tie-beam is sufficient for withstanding the horizontal thrust of a roof, even though very low pitched. If therefore no other use is made of the tie-beam, one much slenderer may be used, and blocks may be firmly fixed to the ends, on which the rafters might abut, as they do on the joggles on the head and foot of a king-post. Although a tie-beam has commonly floors or ceilings to carry, and sometimes the workshops and store-rooms of a theatre, and therefore requires a great scantling, yet there frequently occur in machines and engines very oblique stretchers, which have no other office, and are generally made of dimensions quite inadequate to their situation, often containing ten times the necessary quantity of timber. It is therefore of importance to ascertain the most perfect manner of executing such a joint. We have directed the attention to the principles that are really concerned in the effect. In all hazardous cases, the carpenter calls in the assistance of iron straps; and they are frequently necessary, even in roofs, notwithstanding this superabundant strength of the tie-beam. But this is generally owing to bad construction of the wooden joint, or to the failure of it by time. Straps will be considered in their place.

There needs but little to be said of the joints at a joggle worked out of solid timber; they are not near so difficult as the last. When the size of a log will allow the joggle to receive the whole breadth of the abutting brace, it ought certainly to be made with a square shoulder; or, which is still better, an arch of a circle, having the other end of the brace for its centre. (See Note EE.) Indeed this in general will not sensibly differ from a straight line perpendicular to the brace. By this circular form, the settling of the roof makes no change in the abutment; but when there is not sufficient stuff for this, we must avoid bevel joints at the shoulders, because these always tend to make the brace slide off. The brace in fig. 36. No. 1. must not be joined as at *b*, but as at *a*, or some equivalent manner. Observe the joints at the head of the main posts of Drury Lane Theatre, Fig. 41. Plate LIII.

Butting Joints. When the very oblique action of one side of a frame of carpentry does not extend but compress the piece on which it abuts (as in fig. 11.), there is no difficulty in the joint. Indeed a joining is unnecessary, and it is enough that the pieces abut on each other; and we have only to take care that the mutual pressure be equally borne by all the parts, and that it do not produce lateral pressures, which may cause one of the pieces to slide on the butting-joint. A very slight mortise and tenon is sufficient at the joggle of a king post with a rafter or straining beam. It is best, in general, to make the butting plain, bisecting the angle formed by the sides, or else perpendicular to one of the pieces. In fig. 36. No. 2. where the straining beam *ab* cannot slip away from the pressure, the joint *a* is preferable to *b*, or indeed to any uneven joint, which never fails to produce very unequal pressures on the different parts, by which some are crippled, others are splintered off, &c.

Directions for placing Iron Straps. When it is necessary to employ iron straps for strengthening a joint, a considerable attention is necessary, that we may place them properly. The first thing to be determined is the direction of the strain. This is learned by the observations in the beginning of this article. We must then resolve this strain into a strain parallel to each piece, and another perpendicular to it. Then the strap which is to be made fast to any of the pieces, must be so fixed, that it shall resist in the direction parallel to the piece. Frequently this cannot be done; but we must come as near to it as we can. In such cases we must suppose that the assemblage yields a little to the pressures which act on it. We must examine what change of shape a small yielding will produce. We must now see how this will affect the iron strap which we have already supposed attached to the joint in some manner that we thought suitable. This settling will perhaps draw the pieces away from it, leaving it loose and unserviceable (this frequently happens to the plates which are put to secure the obtuse angles of butting timbers, when their bolts are at some distance from the angles, especially when these plates are laid on the inside of the angles); or it may cause it to compress the pieces harder than before; in which case it is answering our intention. But it may be producing cross strains, which may break them, or it may be crippling them. We can hardly give any general rules; but the reader will do well to read what is written in No. 36, and 41, of the article Roof, (*Encycl.*) In No. 36, he will see the nature of the strap or stirrup, by which the king post carries the tie beam. The strap that we observe most generally ill-placed is that which connects the foot of the rafter with the beam. It only binds down the rafter, but does not act against its horizontal thrust. It should be placed farther back on the beam, with a bolt through it, which will allow it to turn round. It should embrace the rafter almost horizontally near the foot, and should be notched square with the back of the rafter. Such a construction is represented in fig. 37. By moving

Carpentry.

round the eye bolt, it follows the rafter, and cannot pinch and cripple it, which it always does in its ordinary form. We are of opinion that straps which have eye-bolts in the very angles, and allow all motion round them, are of all the most perfect. A branched strap, such as may at once bind the king post and the two braces which butt on its foot, will be more serviceable if it have a joint. When a roof warps, those branched straps frequently break the tenons, by affording a fulcrum in one of their bolts. An attentive and judicious artist will consider how the beams will act on such occasions, and will avoid giving rise to these great strains by levers.—A skilful carpenter never employs many straps, considering them as auxiliaries foreign to his art, and subject to imperfections in workmanship which he cannot discern nor amend. We must refer the reader to Nicholson's *Carpenter and Joiner's Assistant* for a more particular account of the various forms of stirrups, screwed rods, and other iron work for carrying tie-beams, &c.

As for those that are necessary for the turning joints of great engines constructed of timber, they make no part of the art of carpentry. (See Note II.)

Examples of different Pieces of Carpentry.

After having attempted to give a systematic view of the principles of framing carpentry, we shall conclude, by giving some examples which will illustrate and confirm the foregoing principles.

Roof of Greenwich Chapel.

Fig. 38. Plate LII. is the roof of the chapel of the Royal Hospital at Greenwich, constructed by Mr S. Wyatt.

	Inches Scantling.
AA, is the tie-beam, 57 feet long, spanning 51 feet clear, -	14 by 12
CC, Queen posts, - -	9 × 12
D, Braces, - - -	9 × 7
E, Straining beam, - -	10 × 7
F, Straining piece, - -	6 × 7
G, Principal rafters, - -	10 × 7
H, A cambered beam for the platform, -	9 7
B, An iron string, supporting the tie-beam,	2 × 2

The trusses are 7 feet apart, and the whole is covered with lead, the boarding being supported by horizontal ledgers *h*, *h*, of 6 by 4 inches.

This is a beautiful roof, and contains less timber than most of its dimensions. The parts are all disposed with great judgment. Perhaps the iron rod is unnecessary; but it adds great stiffness to the whole.

The iron straps at the rafter feet would have had more effect if not so oblique. Those at the head of the post are very effective.

We may observe, however, that the joints between the straining beam and its braces are not of the best kind, and tend to bruise both the straining beam and the truss beam above it.

St Paul's, Covent Garden.

Fig. 39. The roof of St Paul's, Covent Garden, designed by Mr Hardwick, and constructed by Mr Wapshot in 1796.

AA, Tie-beam spanning 50 feet 2 inches	16. 12
BB, Queen posts, - -	9 × 8
C, Straining beam, - -	10 × 8
D, King post (14 at the joggle), -	9 × 8
EE, Struts, - -	8 × 7½
FF, Auxiliary rafters (at bottom), -	10 × 8½
HH, Principal rafter (at bottom), -	10 × 8½
g g, Studs supporting the rafter, -	8 × 8

The trusses are about 10 feet 6 inches apart, and the dotted lines in the middle compartment show the manner in which the roof is framed under the cupola.

This roof far excels the original one put up by Inigo Jones. One of its trusses contains 198 feet of timber. One of the old roof had 273, but had many inactive timbers, and others ill disposed. The internal truss FCF is admirably contrived for supporting the exterior rafters, without any pressure on the far projecting ends of the tie-beam. The former roof had bent them greatly, so as to appear ungraceful. (See Note KK.)

We think that the camber (six inches) of the tie-beam is rather hurtful; because by settling, the beam lengthens; and this must be accompanied by a *considerable* sinking of the roof. This will appear by calculation. (See Note LL.)

Birmingham Theatre.

Fig. 40. Plate LIII. the roof of Birmingham theatre, constructed by Mr Geo. Saunders. The span is 80 feet clear, and the trusses are 10 feet apart.

A, Is an oak corbel, - -	9 × 5
B, Inner plate, - -	9 × 9
C, Wall Plate, - -	8 × 5½
D, Pole plate, - -	7 × 5

S, Ridge piece, - -	

This roof is a fine specimen of British carpentry, and is one of the boldest and lightest roofs in Europe. The straining sill Q, gives a firm abutment to the principal braces, and the space between the posts is 19½ feet wide, affording roomy workshops for the carpenters and other workmen connected with a theatre. The contrivance for taking double hold of the wall, which is very thin, is excellent. There is also added a beam (marked R), bolted down to the tie-beams. The intention of this was to prevent the total failure of so bold a trussing, if any of the tie-beams should fail at the end by rot.

Drury Theatre.

"Akin to this roof is fig. 41. Plate LIII. the roof of Drury-Lane theatre, 80 feet 3 inches in the clear, and the trusses 15 feet apart, constructed by Edward Grey Saunders.

A, Beams, - -	10 by 7

M, Principal braces to ditto,	14 and 12 × 12
N, Struts, - -	8 × 12
P, Straining beams, -	12 × 12

The main beams are trussed in the middle space with oak trusses 5 inches square. This was necessary for its width of 32 feet, occupied by the carpenters, painters, &c. The great space between the trusses afford good store rooms, dressing rooms, &c.

It is probable that this roof has not its equal in the world for lightness, stiffness, and strength. The main truss is so judiciously framed, that each of them will safely bear a load of 300 tons; so it is not likely that they will ever be quarter loaded. The division of the whole into three parts makes the exterior roofings very light. The strains are admirably kept from the walls, and the walls are even firmly bound together by the roof. They also take off the dead weight from the main truss one third.

Remarks. The intelligent reader will perceive that all these roofs are on one principle, depending on a truss of three pieces and a straight tie-beam. This is indeed the great principle of a truss, and is a step beyond the roof with two rafters and a king post. It admits of much greater variety of forms, and of greater extent. We may see, that even the middle part may be carried to any space, and yet be flat at top; for the truss-beam may be supported in the middle by an inverted king post (of timber, not iron), carried by iron or wooden ties from its extremities: and the same ties may carry the horizontal tie-beam K; for till K be torn asunder, or M, M, and P be crippled, nothing can fail.

The roof of St Martin's church in the Fields is constructed on good principles, and every piece properly disposed. But although its span does not exceed 40 feet from column to column, it contains more timber in a truss than there is in one of Drury-Lane theatre. The roof of the chapel at Greenwich, that of St Paul's, Covent-Garden, that of Birmingham, and that of Drury-Lane theatres, form a series gradually more perfect. Such specimens afford excellent lessons to the artists. We therefore account them a useful present to the public.

Project by Mr Nicholson. There is a very ingenious project offered to the public by Mr P. Nicholson. (*Carpenter's Assistant*, p. 68.) He proposes iron rods for king posts, queen posts, and all other situations where beams perform the office of ties. This is in prosecution of the notions which we published in the article Roof of the *Encyclopædia*. He receives the feet of the braces and struts in a socket very well connected with the foot of his iron king post; and he secures the feet of his queen posts from being pushed inwards by interposing a straining sill. He does not even mortise the foot of his principal rafter into the end of the tie-beam, but sets it in a socket like a shoe, at the end of an iron bar, which is bolted into the tie-beam a good way back.* All the parts are formed and disposed with the precision of a person thoroughly acquainted with the subject; and we have not the smallest doubt of the success of the project, and the complete security and durability of his roofs. We abound in iron, but we must send abroad for building timber. This is therefore a valuable project; at the same time, however, let us not over-rate its value. Iron is but about 12 times stronger than red fir, and is more than 12 times heavier; nor is it cheaper, weight for weight, or strength for strength.

Our illustrations and examples have been chiefly taken from roofs, because they are the most familiar instances of the difficult problems of the art. We could have wished for more room even on this subject. The construction of dome roofs has been (we think) mistaken, and the difficulty is much less than is imagined. We mean in respect of strength; for we grant that the obliquity of the joints, and a general intricacy, increases the trouble of workmanship exceedingly. Wooden bridges form another class equally difficult and important; but our limits are already overpassed, and will not admit them. The principle on which they should all be constructed, without exception, is that of a truss, avoiding all lateral bearings on any of the timbers. In the application of this principle, we must farther remark, that the angles of our truss should be as acute as possible; therefore we should make it of as few and of as long pieces as we can, taking care to prevent the bending of the truss beams by bridles, which embrace them, but without pressing them to either side. When the truss consists of many pieces, the angles are very obtuse; and the thrusts increase nearly in the duplicate proportion of the number of angles.

Wooden Bridges.

Framing of great levers. With respect to the frames of carpentry which occur in engines and great machines, the varieties are such that it would require a volume to treat of them properly. The principles are already laid down; and if the reader be really interested in the study, he will engage in it with seriousness, and cannot fail of being instructed. We recommend to his consideration, as a specimen of what may be done in this way, the working beam of Hornblower's steam engine. (See Steam-Engine, in the *Encyclopædia*.) When the beam must act by chains hung from the upper end of arch heads, the framing there given seems very scientifically constructed; at the same time, we think that a strap of wrought iron, reaching the whole length of the upper bar (see the figure), would be vastly preferable to those partial plates which the engineer has put there, for the bolts will soon work loose.

But when arches are not necessary, the form employed by Mr Watt is vastly preferable, both for simplicity and for strength. It consists of a simple beam AB (fig. 42, Plate LIII.), having the gudgeon C on the upper side. The two piston rods are attached to wrought iron joints A and B. Two strong struts

* See figures 40, 41, 42, Plate LII., and Mr Nicholson's work, p. 68, where these figures are particularly described.

DC, EC rest on the upper side of the gudgeon, and carry an iron string ADEB, consisting of three pieces; connected with the struts by proper joints of wrought iron. A more minute description is not needed for a clear conception of the principle. No part of this is exposed to a cross strain; even the beam AB might be sawed through at the middle. The iron string is the only part which is stretched; for AC, DC, EC, BC, are all in a state of compression. We have made the angles equal, that all may be as great as possible, and the pressure on the struts and strings a minimum. Mr Watt makes them much lower, as A*de*B, or Aδ*ε*B. But this is for economy, because the strength is almost insuperable. It might be made with wooden strings; but the workmanship of the joints would more than compensate the cheapness of the materials.

We offer this article to the public with deference, and we hope for an indulgent reception of our essay on a subject which is in a manner new, and would require much study. We have bestowed our chief attention on the strength of the construction, because it is here that persons of the profession have the most scanty information. We beg them not to consider our observations as too refined, and that they will study them with care. One principle runs through the whole; and when that is clearly conceived and familiar to the mind, we venture to say that the practitioner will find it of easy application, and that he will improve every performance by a continual reference to it."

IV. Notes.

AA. P. 629. This rule may be somewhat more accurately expressed in these words: From the point at which any three forces meet and balance each other, draw a line in the actual direction of any one of them, and from the extremity of this line draw two others, parallel to the directions of the other two forces respectively; then supposing the pieces affording these two forces to be produced indefinitely at their remoter ends, either of them which is cut by one of the two lines will be compressed, and act as a brace, and either of them which is not cut will be stretched, and act as a tie.

BB. P. 630. It is however difficult to imagine how the beam DA can furnish a force iA, to prevent the force Af from carrying the beam BA towards H, when DA only affords a repulsive abutment. The true resolution of the force AE is found by considering the intersection of GE with Ae, which are the directions of the separate forces composing it; these lines meeting in a point a little above r, we may call their intersection r^*; then in the triangle AEr^*, the side Ar^* will represent the pressure on the mitred joint, and r^*E the pressure on the beam HD; and the former being again resolved into AG and Gr^*, we have ultimately AG and G$r^* + r^*$E $=$ GE $=$ AF; for the horizontal and vertical forces, however they may be modified by intermediate combinations.

CC. P. 631. The reasoning contained in this and some of the subsequent articles may serve as an approximation to the truth in many cases of common occurrence; but the supposition, on which it is founded, is by no means generally admissible as affording a result mathematically accurate: for in reality, the distribution of the weight of a roof over the whole extent of the rafters, or the concentration of the whole weight in the point where they meet, is far from being an indifferent alternative, either with respect to the magnitude of the thrusts, or to the proper directions of the abutments or joints. In the case here discussed, where there is no king post, it is clear that the centre of gravity of the whole roof must be much nearer to the middle of the figure than the angular point, and that consequently the weights, supported by the two walls, will be very different from those which would be supported, if the whole load were placed at the summit: although, where there is a heavy king post, supporting also, as it ought to do, about half the weight of the tie beam, with its floors or cieling, the case will approach much nearer to the supposition here assumed.

For a common light roof, without a king post, the calculation or construction is very simple. When two rafters only meet at the summit, they must support each other by a horizontal thrust (see Artt. Bridge, Prop. Y): and this thrust, acting on each rafter as a lever, of which the lower end is the fulcrum, must be equivalent to the weight, acting at the horizontal distance of the centre of gravity from the fulcrum, which is a quarter of the whole span; consequently the thrust must be to the weight as a quarter of the span to the height, and the compound oblique thrust on the abutment will be represented by the hypotenuse of the triangle of which those lines are the sides: so that if we had a roof of the same height, and of half the breadth, the direction of its rafters would exactly represent the actual direction of the compound thrust on the end of the tie beam, and would consequently indicate the proper form for the abutment of the given structure.

But in the case of the unequal rafters represented in the figure, the determination becomes more complicated, and we must first find the direction of the mutual thrust of the rafters, which must evidently be such, that the perpendiculars falling on it from each end of the tie beam may be in the inverse proportion of the motive powers of the weights of the rafters, that is, of the products of those weights into the horizontal distances of the centres of gravity from the respective fulcrums, or into the segments of the tie beam made by a vertical line passing through the summit, which are proportional to these distances; and if we produce the base of the triangle, and find in it a point, of which the distance is to the length of the tie beam, as the smaller product to the difference of the products, a line drawn from the summit to this point will show the true direction of the thrust; and its magnitude may then be readily determined, by dividing either of the products by the respective perpendicular falling on this line.

Where, however, there is a king post supporting a heavy tie beam, it is necessary to determine the centre of gravity of the half roof, together with this addition; and the distance of the centre of gravity from the middle will then be to the half span, as the weight of one of the rafters with its load is to the weight of the whole roof, including the tie beam and

cieling; and if we erect a perpendicular passing through the centre of gravity thus found, and equal to the height, the oblique thrust on the abutment will be in the direction of the line joining the upper end of this perpendicular and the end of the tie beam.

DD. P. 634. In order to obtain a distinct idea of the operation of the forces concerned in this experiment, we must have recourse to Proposition C of this article, and substitute in the formula for the deflection $d = at\sqrt{\frac{M}{16f}}\text{TANG}\left(\sqrt{\frac{16f}{M}\cdot\frac{e}{a}}\right)$, $a=1$, $t = \frac{8}{6720} = \frac{1}{840}$, M = 1,900,000 pounds, the specific gravity of fir being .56, $f = 6720$, and $e = 6$, the middle of the pillar being considered as the fixed point: we then find $\sqrt{\frac{16f}{M}\cdot\frac{e}{a}} = 1.427$, which is the length of an arc of 81° 45°, and the tangent becomes 6.9, whence we have $d = \frac{1}{840} \times 4.2 \times 6.9 = .0345$, or somewhat more than the thirtieth of an inch: consequently the strength must have been reduced in the proportion of 1.207 to 1. (Art. BRIDGE, Prop. E.) But, considering how near the arc thus determined approaches to a quadrant, it is obvious that any slight variations of the quantities concerned in the calculation must have greatly affected the magnitude of the tangent: so that the loss of strength may easily have been considerably greater than this, as it appears to have been found in the expnriment. It would however scarcely have been expected that such a pillar, however supported, could withstand the pressure of 90 hundred weight, since Emerson informs us that the cohesive strength of a pillar of fir an inch in diameter is only about 35: but supposing the facts correct, the coincidence tends to show the near approach to equality of the forces of cohesion and lateral adhesion, as explained in the Introduction to this article.

EE. P. 635. A similar remark of the author has already been noticed in the article BRIDGE, at the end of the fifth section. In the form in which it is here expressed, it becomes still more objectionable: for with whatever part of a circular abutment a rafter equal to the radius may be brought into contact, it is very plain that its opposite end can never be either higher or lower than the original centre of curvature: and even if the curvature were made twice as great, so that the rafter might be equal to the diameter of the circle, it would be necessary that the lower end should slide upwards on the abutment as much as the upper end fell, in order to preserve the contact; and there would obviously be no force in the structure capable of producing such a change as this. Any general curvature of the joint must therefore be totally useless; but a judicious workman will make it somewhat looser below than above, when there is any probability that the rafters will sink, taking care however to avoid all bearing too near the surface, lest it should splinter; and for these reasons combined, making the end a little prominent somewhat above the middle of the surface which rests on the abutment.

With this precaution, the direction of the joint between a rafter and a tie beam ought to be made precisely perpendicular to the true thrust of the rafter, determined as already explained (Note CC): for in the first place, unless we trust either to the friction or to straps, the bearing cannot be more nearly horizontal than this, without danger of the rafters sliding outwards; and in the second place, if we made it more nearly vertical, we should lessen the vertical pressure on the end of the tie beam, immediately beyond the joint; a pressure which gives firmness to the wood, by pressing its fibres more closely together, and increasing their lateral adhesion or rather internal friction. If however the tie beam were not deep enough to receive the whole of the rafter so terminated, without too great a reduction of its depth, it would be proper to make the joint a little flatter, or more horizontal, and to restrain the end from sliding upwards by an iron strap fixed in a proper direction. We should preserve the end of the rafter as little diminished in breadth as possible, when the tie beam is wide enough to receive it; a moderate thickness, left on each side of the mortise in the tie beam, being sufficient to assist in securing the connexion of the ends of the beam with the intermediate parts.

FF. P. 635. The doctrine of the initial equality of the resistances to compression and extension, as stated in the article BRIDGE, enables us to demonstrate that the transverse strength can never exceed one sixth of that which would be derived from the resistance of all the fibres, cooperating at the distance of the whole depth from a fixed fulcrum, and acting with the weaker of the two powers appropriate to the body. It is true that the results of some direct experiments seem to favour the opinion that the cohesive power is the weaker; but where the flexure is already considerable, it is probable that this circumstance materially diminishes the primitive power of resisting compression, so that the principles, on which the calculation proceeds, are by no means strictly applicable to the case of a bar so broken.

GG P. 636. There seems to be a little confusion in the idea of the possibility of altering the nature of the action of the fibres of a beam by altering the place of the gudgeon in this manner: but the author has very properly abstained from making any practical application of the supposed modification thus introduced. With respect to the strength required for scarfing or joggling, it may be observed, that the whole of the compressed fibres of the concave side may be considered as abutting against the whole of the extended fibres on the convex side; and this abutment is equally divided throughout the length of the beam: so that if the scarfings or joggles in the whole length of the arm of a lever, taken together, are as strong as one half of the depth of the lever, exerting half its powers, from the inequality of tension, there will be no danger of the failing of these joints; and from this principle it will be easy

to determine the depth to which the joints ought to extend in any particular case. Hence also we may understand how a beam may become so short as to be incapable of transverse fracture in its whole extent: for the lateral adhesion between the different fibres of wood is generally far inferior to the longitudinal strength of the fibres; and if, for example, it were only one fourth as great, a beam less than twice as long as it is deep would separate, if urged in the middle by a transverse force, into two strata, from its incapacity of affording sufficient abutment, before its longitudinal fibres would give way.

HH. P. 638. If the bolts were sufficiently numerous, and sufficiently firm, so as to produce a great degree of adhesion or of friction between the parts, this joint might be made almost as strong as the entire beam, since there is nothing to prevent the co-operation of each side with the other throughout its extent: but much of the strength would be lost if the bolts became loose, even in an inconsiderable degree.

II. P. 642. The author has reasoned upon the direction of straps, as if it were universally necessary to economize their immediate strength only, without regard to the effect produced on the tightness of the joint: but it may happen that the principal purpose of the strap will be answered by its pressing the rafter firmly upon the beam, and this effect may be produced by a certain deviation from the horizontal position, with but little diminution of the strength of the strap: a deviation which has also the advantage of allowing the strap to embrace the whole of the beam, without weakening it by driving a bolt through it. We must not however endanger the crippling of the end of the beam, and the straps represented in fig. 38. may be allowed to be somewhat too erect.

KK. P. 642. It does not appear to be desirable that the ends of the rafters should be supported without any pressure on the ends of the beams, since these ends would bear a small weight without any danger of bending, and would thus lessen the pressure on the king post.

LL. P. 642. The half length being 25 feet, and the camber 6 inches, the excess of the oblique length will be $\sqrt{625.25} - 25$, or $\frac{1}{200}$ of a foot, that is, $\frac{1}{16}$ of an inch, which is all that the beam would appear to lengthen in sinking; nor would the settling of the roof be more "considerable" than about a quarter of an inch. But there seems to be no advantage in this deviation of the tie beam from the rectilinear direction; and the idea, which appears to be entertained by some workmen, that a bent beam partakes of the nature of an arch, is one of the many mischievous fallacies, which it is the business of the mathematical theory of Carpentry to dispel.

(O. R.)

CASIRI (Michael), a very learned Orientalist, of the sect of Syrian Christians called Maronites, was born at Tripoli in Syria in the year 1710. As the sect of Maronites were subject to the Pope, Casiri came to study at Rome, and entered into holy orders in 1734. In the following year he proceeded to Syria to assist at a Synod of the Maronites. He returned to Rome in 1738, and for ten years thereafter taught the brethren of his convent to read Arabic, Syriac, and Chaldaic, giving lectures also in Philosophy and Theology. In 1748 he passed into Spain, upon the invitation of Ravago, Confessor to Ferdinand VI., and was by his means employed in the Royal Library at Madrid. In 1749 he was named a member of the *Royal Academy of History;* in 1756, he was appointed *Interpreter of Eastern Languages* to the King; and soon thereafter joint Librarian of the Escurial, with a royal pension of 200 piastres, besides the ordinary emoluments of the office. In 1763 he became principal Librarian, a situation which he appears to have held till his death in 1791. *(Biographie Universelle.)*

The only work which entitles Casiri's name to be recorded among the benefactors of Literature is his celebrated *Catalogue of the Arabic Manuscripts* preserved in the Library of which he was Keeper. This rare and curious work, entitled *Bibliotheca Arabico-Hispana Escurialensis,* was published in two volumes, folio, at Madrid, the first volume in 1760, and the second ten years thereafter. Mr Gibbon expresses himself "happy in possessing a copy of this splendid and interesting work," which constitutes, indeed, one of the most valuable contributions that modern Europe has yet furnished towards the illustration of Eastern literature. By means of it, the literary treasures of the Escurial Library, the richest perhaps in Europe in the works of Arabic writers, are in a manner shared with the learned of other countries; thus affording an example, which it were to be wished, all other countries possessing similar treasures would imitate. The judicious manner in which it is compiled renders it a sort of digest of the attainments of the Saracens in science and literature during the most flourishing eras of their Empire. Its contents, as Mr Barington observes, "may indeed, under some of its heads, principally regard Spain; but they will, however, be found adequately to represent the general standard of learning, in its full extent and character, whether at Cordova or Fez, at Cairo or at Bagdad." (*Literary History of the Middle Ages*, p. 652.)

The manuscripts described amount to above eighteen hundred, and are classed in the following order: Grammar, Rhetoric, Poetry, Philology and Miscellanies, Lexicons, Philosophy, Politics, Medicine, Natural History, Jurisprudence, Theology, Geography, and History. The two last classes, with a copious Index, occupy the whole of the second volume. As a system of *Bibliography,* this arrangement of classes could not be allowed to be very perfect or scientific; but it was not the learned author's object to exhibit any such system; though some French Bibliographers seem to view his classification in that light, and express no small degree of wonder, that an Ecclesiastic, in the country of the Inquisition, should place so many classes before that

Casiri || Caste.

of *Theology*, which in their systems generally holds the first place. The title of each Manuscript is given in the original Arabic, with a Latin translation, and its age and author, when these are known, are pointed out; but this is not all; the title and description of the work is frequently followed with extracts, also in Arabic and Latin, by which some of the most curious or peculiar features of the piece are brought before the reader; thereby supplying the want of the original, as well to those who could read it if accessible, as to those who could not read it though at hand. The learned author has also collected various interesting and authentic particulars of Saracenic Biography, and corrects some prevalent errors regarding the lives of these writers. We have noticed an error of this kind, in our account, derived from Casiri, of the celebrated Arabian Philosopher ALHAZEN, given in the first volume of this Supplement.

In the preface, which is of considerable length, Casiri gives a general view of his labours, and commemorates the assistance which he received from the Government and from the Learned. Rich as the Escurial is in Arabic Manuscripts, its present stores are small, compared to what they once were; for Casiri mentions that, by a fire which happened in 1670, more than *three thousand* of these interesting pieces were consumed. They who have not access to this valuable work, which is indeed but rarely to be met with, will find a full view of its contents, with some critical comments, in the *First Appendix* to Harris's *Philological Inquiries*, and in the *Second Appendix* to Barington's *Literary History of the Middle Ages*. The latter writer closes his review by stating it as his opinion, that the Arabian literature, though it greatly outshone ours during the same period, has experienced upon the whole too much prodigality of praise. This may perhaps be true; but this writer has failed, as abler writers likewise have, to furnish a sound and thorough estimate of the attainments and services to which the Arabians are fairly entitled to lay claim in regard to the culture and advancement of learning. The erudition of Gibbon, vast and varied as it was, did not nearly embrace all that was necessary to a full appreciation of this portion of literary history. His general view may be just, his criticisms penetrating and comprehensive; but he was ignorant of the language, and of some branches of science, without a proficiency in which, such an estimate could not be drawn up with any pretensions either to critical or philosophical accuracy. He who attempts, with requisite endowments, to supply that great *desideratum*—a literary history of the Saracens during the flourishing periods of their literature, will find the work of Casiri an invaluable assistant in such an undertaking.

Definition.

CASTE. By this term is here distinguished the classification and distribution of the members of a community into certain classes or orders, for the performance of certain functions, with the enjoyment of certain privileges, or the endurance of certain burthens; and the establishment of hereditary permanence in these orders, the son being ordained to perform the functions, to enjoy the privileges, or sustain the burthens of the father, and to marry only in his own tribe, without mixture of the classes, in regular succession, through all ages.

Caste.

Origin of the Term.

The term *Caste* is borrowed from the Portuguese. It was the term applied by that people, who first of the European nations formed establishments in India, to the classes which they found established upon this principle among the inhabitants of that portion of the globe; and from them, as it was from their intercourse that the rest of the nations of modern Europe first derived their familiarity with the manners and institutions of the people of India, the term made its way, and was established in the other languages of Europe.

The institution itself appears in the early ages of society to have been very extensively introduced.

This Institution widely diffused.

In regard to the ancient Egyptians, the fact is universally and familiarly known. The President de Goguet, who, with singular industry, and no ordinary judgment and sagacity, explored the remains of ancient times, comprehends a great body of history in a few words. "We may farther observe," says he, "that, in the Assyrian empire, the people were distributed into a certain number of tribes, and that professions were hereditary; that is to say, children were not permitted to quit their father's occupation, and embrace another. We know not the time nor the author of this institution, which, from the highest antiquity, prevailed over almost all Asia, as well as in several other countries." It is not necessary here to surcharge the reader with the authorities which he quotes. The passage itself (P. i. B. i. Ch. i. Art. 3.) will be consulted by all who distrust the legitimacy of his inference, or desire to prosecute the inquiry.

It is stated in the common histories of Greece, that Cecrops distributed into four hereditary classes, or tribes, all the inhabitants of Attica. And we are informed by Plutarch, in his Life of Theseus, that by this prince, the class of priests, and that of nobles, in other words the magistrates or military leaders, were united into one: whence the society was composed of three classes; 1. The sacerdotal, legislating, and ruling class; 2. The class of husbandmen; and, 3. The class of tradesmen. "To the nobility," says the illustrious biographer, "he committed the choice of magistrates, the teaching and dispensing of the laws, and the interpretation of all holy and religious things; the whole city, as to all other matters, being as it were reduced to an exact equality; the nobles excelling the rest in honour, the husbandmen in profit, and the artificers in number. And Theseus was the first who, as Aristotle says, out of an inclination to popular government, parted with the regal power; which Homer also appears to attest, in his catalogue of the ships, where he gives the name of PEOPLE to the Athenians alone." There is a passage near the beginning of Plato's *Timæus*, which, though in a work of fancy, is not without some weight, as evidence either of conclusions which were drawn by men of research, or of traditions which were current among the people. In this passage, not only is it asserted, that, in the primeval state of the inhabitants of Attica, they resembled the Egyptians in the division into hereditary classes

and professions; but a very accurate description is given of those classes, five in number; viz. 1. The class of priests; 2. The class of handicrafts; 3. The class of shepherds and hunters; 4. The class of ploughmen; 5. The military class. *Πρωτον μεν το των ἱερεων γενος, απο των αλλων χωρις αφωρισμενον· μετα δε τουτο το των δημιουργων, ὁτι καθ' ἁυτο ἑκαστον, αλλῳ δε ουκ επιμεμιγμενον, δημιουργει· το τε των νομεων και των θηρευτων· το τε των γεωργων· και δη το μαχιμον γενος, απο παντων των γενων κεχωρισμενον, ὁις ουδεν αλλο πλην τα περι τον πολεμον ὑπο του νομου προσεταχθη μελειν.*

We are informed by Aristotle, that the people of Crete were divided into castes, after the manner of the Egyptians, by the laws of Minos. *Εοικε δε ου νυν ουδε νεωστι τουτ' ειναι γνωριμον τοις περι πολιτειας φιλοσοφουσιν, ὁτι δει διηρησθαι χωρις κατα γενη την πολιν, και το τε μαχιμον ἑτερον ειναι, και το γεωργουν· εν Αιγυπτῳ τε γαρ εχει τον τροπον τουτον ετι και νυν· τα τε περι την Κρητην. Τα μεν ουν περι Αιγυπτον, Σεσωστριος, ὡς φασι, ουτω νομοθετησαντος· Μινω δε τα περι Κρητην.* *Polit.* vii. 1.

It is worthy of observation, that certain vestiges at least of that ancient institution are *still* visible in Egypt. "La distinction par familles," says General Reynier (*De l'Egypte*, p. 56), "se retrouve encore dans les villes: l'exercise des arts et metiers est hereditaire: le fils imite les procedés de son pere, et ne les perfectionne pas."

We have a remarkable passage to prove, that, among the ancient Persians, the same division into castes existed which now has place among the Hindoos. In the *Zendavesta*, as translated by M. Anquetil Duperron, it is said: "Ormusd declared, There are three measures (literally weights, *i. e.* tests, rules) of conduct, four states, and five places of dignity. The states are, that of the priest; that of the soldier; that of the husbandman, the source of riches; and that of the artisan or labourer."—"We are told," says Sir John Malcolm (*Hist. of Persia*, i. 205), "that Jemsheed divided his subjects into four classes, and that he allotted to each a separate and fixed station in life; which seems to imply that the condition of the ancient Persians was like that of the modern Hindoos; and that the extraordinary institution of cast, which now exists in India, was once known in Persia." Sir John proceeds to state some reasons which induce him to doubt the reality of the fact; in not one of which, however, there is a particle of weight.

Sir John quotes, and translates for us a passage from Strabo, which asserts that a similar institution existed in Iberia. "Four kinds or classes of people inhabited that country. From what they consider the first class, they appoint their kings according to nearness of kindred and seniority; these administer justice, and head their armies: The second is of priests, who take charge of their political rights with respect to their neighbours: The third of soldiers and husbandmen: The fourth of the people in general, who are slaves of the king, and perform every menial office." This account of the distinctions of the castes is evidently incorrect, and by a man who was not well informed. The fact of the Iberians being distributed in a remarkable and uncommon manner, he knew; otherwise there would have been no occasion to single out the fact, in the description of this particular people. He knew also that they were divided into four principal classes. With regard to the matters of detail, however, his words bear internal evidence that either his information had been vague and inaccurate, or that his recollection had become so.

From a dissertation of Mr Joinville, on the religion and manners of the people of Ceylon, (*Asiat. Researches*, vii. 430.) we find that there is sufficient evidence to prove the existence of a similar institution, anciently, among the Buddhists of Ceylon; and by consequence to infer it, among the other Buddhists, spread over so large a portion of Asia.

After this evidence of the general diffusion of the institution of castes, in the rude ages of the world, especially in Asia, there is a temptation, from the following passage of Herodotus, (Lib. I. cap. 101.) to infer its existence among the Medes, at the commencement of the monarchy. *Εστι δε Μηδων τοσαδε γενεα, Βουσαι, Παρητακηνοι, Αστιζαντοι, Βουδιοι, Μαγοι.* There is nothing in the passage which serves to fix the meaning of the word *γενεα*; and the names, it is plain, are words of the ancient Median language. But we know that the *Μαγοι* were the priests; and hence there is reason to conclude, that the other words also are names of classes and professions; in other words, of hereditary castes.

The institution of castes may be traced in places with which we are more intimately connected. Mr Millar, to whom the world is indebted for almost the first lessons which it received, in tracing the facts of history up to the general laws of the human mind, has called our attention to the fact, that in the ancient condition of our Saxon ancestors, they were divided into four great classes: 1. The artificers and tradesmen; 2. the husbandmen; 3. those who exercised the honourable profession of arms; and, 4. the clergy. Mr Millar adds, (*Hist. View of the English Gov.* B. i. ch. ii.) "From the natural course of things, it should seem, that, in every country, where religion has had so much influence as to introduce a great body of ecclesiastics, the people, upon the first advances made in agriculture and in manufactures, are usually distributed into the same number of classes or orders. This distribution is accordingly to be found, not only in all the European nations, formed upon the ruins of the Roman Empire; but, in other ages, and in very distant parts of the globe. The ancient inhabitants of Egypt are said to have been divided into the clergy, the military people, the husbandmen, and the artificers. The establishment of the four great *castes*, in the country of Indostan, is precisely of the same nature."

Human nature is very uniform in the phenomena which it exhibits. The new world displays a striking resemblance to the old. The same stage of society presents nearly the same results. There is reason to conclude, that something which resembled the institution of castes existed among the ancient inhabitants of Peru and Mexico. The Count Carli, the celebrated author of the *Lettres Americaines*, when treating (Lett. xiii. and xiv.) of the laws of the Peruvians says: "Les citoyens furent distribués en classes ou tribus. * * * Il n'etoit pas permis, ni par marriage, ni par changement d'habitation, de con-

Caste.

fondre une classe avec l'autre: car la loi defendoit de se marier dans une autre famille que celle d'ou l'on sortoit. * * * N'oublions pas le soin qu'on avoit de l'education des enfans. C'etoit toujours le pere qui elevoit son fils. L'education consistoit à apprendre aux enfans rôturiers le metier que chaque pere de famille exerçoit," &c. We are informed by Clavigero (*Hist. of Mexico*, B. iv. § 5.), that "the sons in general learned the trades of their fathers, and embraced their professions; thus they perpetuated the arts in families, to the advantage of the state."

Such is the extent to which this institution has existed on the surface of the globe. We shall next endeavour to ascertain the state and condition of the human mind, to which it may be considered as owing its origin.

Origin, and Causes of the Wide Diffusion of this Institution.

The lowest and rudest state in which the human race are found to exist, may, in a certain general way, be described as the hunter state. That of the shepherd is the next stage in the progress toward the advantages of civilized life. The agricultural state succeeds; when men begin to cultivate the ground for the means of subsistence, and experience the benefit of fixed habitations.

So long as they continue in the condition of hunters or of shepherds, the division of labour is unknown, and all the multitude of blessings which it brings. Every family is itself the author of all the simple accommodations which it knows. The tent or hovel, the waggon or cart, is constructed by the men; the coarse garment is spun and even woven by the women.

In this situation of things, the accommodations with which it is possible for human beings to supply themselves are few and imperfect; and life is a scene of privation.

When population has so far multiplied as to render the produce of flocks and herds insufficient for the means of subsistence, and the cultivation of the land has become necessary, the inconveniences arising from the want of the division of labour becomes still more sensible and oppressive. The labours of the field are neglected while the family are engaged at the loom, or repelling the incursions of an enemy. The accommodations of lodging, of clothing, of taste, and fancy, are wretchedly supplied, when the business of extracting the means of subsistence from the soil, exacts the greater part of their time and attention.

The progress, however, of human improvement, though not necessarily, is commonly, in point of fact, at least in the more uncultivated ages, exceedingly slow. Men continue to suffer under the inconveniences which their present condition imposes upon them, complaining of their miseries, but unable to form a clear conception of the means of exemption, and doubtful of all the remedies which are pointed out to their attention. In the mean time, as the human mind is essentially progressive, and, unless in very extraordinary circumstances, never fails to make progression, the uneasiness which is felt under the inconveniences of a state to which the mind has become superior, and above which it is rising higher and higher every day, is continually increasing; and at last rises to such a height that some change is unavoidable; and the society are prepared to welcome the most plausible of the schemes which are proposed to them.

The grand steps which are made in improving the condition of mankind, though essentially the result of a progression in the minds of the society taken as a whole, are commonly the immediate suggestion of some one individual, or small number of individuals, whose conception of the necessity of a change, and of the means of relief, is more clear and determinate than that of the rest of the community.

In the earliest stages, when the human mind is weak and prone to superstition, the individuals who project the great improvements in the state of society, endeavour to accelerate the consent of the people, and overcome their reluctance to innovation, by giving to their projects the character of a divine revelation and command. The first legislators of almost every country, we find to have represented themselves as depositaries of the divine will, and entrusted with a revelation from heaven.

If we take the Hindoos as a model, the people divided into castes with whom our acquaintance is the most complete, we shall conclude, that some individual, wise enough to perceive the cause of the inconveniences under which men suffer while the division of labour is unknown, and placed in circumstances which enabled him to clothe himself with a divine authority, overcame in most places the reluctance of the people to so great a change of their manners and habits, and accelerated the date of their improvement, by persuading them that the divine power, or divine powers, now commanded them to be divided into classes for the performance of certain offices.

In the early stages of society, however, the wants of men are few; and the ideas of the legislator himself are incapable of extending to a great variety of cases. In such periods, the power of superstition is always exceedingly great. Unacquainted with the laws of nature, and exposed to the most dreadful vicissitudes, which they are altogether unable to foresee, human life appears to men in that situation to hang altogether upon invisible powers. The human mind is incessantly occupied with conjectures respecting what those unknown powers will produce, and with tormenting apprehensions that they will produce evil rather than good. The persons who, in this state of things, are skilful enough to create a persuasion that they are better acquainted than others with the will of these powers, more especially if accompanied with a persuasion that they have an influence over that will, and can turn it more or less whichever way they please, become an object of supreme regard. Nothing can be done without them. They are the most important class in the community. When society is first divided into classes, for the sake of the division of labour, the priests, therefore, are always a separate class, and always in the place of highest distinction.

After the evils to which men in the rude state of society conceive themselves liable from the unknown and invisible authors of physical events, the evils to which they are liable from the incursions of hostile men, appear the next in magnitude. While the in-

stitutions of society are imperfect, and the human mind is weak, these evils are very great, and present a terrific picture to an imagination perpetually haunted with fear. In the rude ages of society, therefore, the soldier is always a character of great importance. He is the barrier against those evils which rank next in order after the evils against which the priest affords relief. When classes are first formed, the military are, therefore, always a separate class, and next in rank and veneration to the class of the priests. It is remarkable, that the rank and consequence of both classes are founded upon fear. It is also remarkable, though a natural consequence, that, in all ages, they are most apt to be venerated by the most timid persons,—the most timid sex, for example; over whose imagination the priest and the soldier have a proverbial sway. It is farther observable, and a necessary consequence, that as the fears with respect to invisible powers, and with respect to the incursions of hostile men, gradually decline as society advances, and have less and less effect upon the imaginations even of those who are most apt to be governed by the passion of fear, so the respect for the castes of priest and soldier are destined to sink in relative importance, as the institutions of society are improved, and the human mind becomes strong.

After provision is made, in that early stage of society which we are endeavouring to describe, against the two classes of fears against which the priest and the soldier hold up their respective shields, the care of subsistence is the object of greatest importance. A class of husbandmen, therefore, is a necessary and never failing institution, and, in the scale of rank and consequence, this order follows immediately after the sacerdotal and the military castes.

Beside the means of subsistence, other accommodations are required. But, at first, very few are so much as known, and, by consequence, very few are demanded. One class of the community are, therefore, supposed to be sufficient for the supply of all other wants, and the performance of all other services.

It is obvious, that reflection upon the laws of human nature would lead us to draw a picture, nearly the same with this, if we were called upon to describe the state of society, at the time when the division of labour is first introduced, even if we had no specific facts to direct our inquiries. In a remarkable passage in Plato, in his second book *De Republica*, he ascribes the origin of political association and laws, to the benefits which were sought for by the division of labour. *Γιγνεται πολις, ὡς εγ' ῷμαι, επειδαν, τυγχανει ἡμων ἑκαςος, ουκ αυταρχης, αλλα πολλων ενδεης.* As men cannot be supplied with accommodations in any tolerable degree, but by the division of labour and employments, one man producing one thing, another another, and every man getting what he wants, by exchange with other men, an association of a certain number of men is necessary for well being; and hence society and laws. In exact coincidence with the deduction which we have presented above, he says, that the simplest form of a society would consist of four or five orders of men. *Αλλα μεν πρωτη γε και μεγιςη των χρειων ἡ της τροφης παρασκευη, δευτερα δε οικησεως, τριτη εσθητος και των τοιουτων.* . . . . . . *Ειη δ'αν ἡ γε αναγκαιοτατη πολις εκ τετλαρων η πεντε ανδρων.* The coincidence is very nearly complete between the speculation and the practice; between what is in this manner inferred, and what is recorded of ancient nations, and witnessed among the Hindus.

Under all the difficulties under which, especially in rude ages, human society, and the human mind, make progress, small are the steps which can be taken at once. When professions were separated, and the vast benefits derived from the separation began to be felt, the human mind was not sufficiently strong to perceive, that there was no danger whatsoever that they should ever again be combined and confounded. No; it was imagined to be another grand effort of the same wisdom which had made the separation, to take care of its permanence, and to make provision for securing the benefits of it through all ages. With this view it was thought necessary to ordain and sanction, by divine authority, that the son should follow the profession of the father, and be subject to the severest punishment if he engaged in any other occupation. To secure also, in each profession, the due succession of sons to fathers, it was necessary that marriage should be strictly regulated; and the method which obviously enough suggested itself for that purpose was, that the members of each class, male and female, should be compelled, under the severest penalties, to marry only among themselves, and never, by intermarriage, to ruin and confound the separate castes.

So far the *aim*, at any rate, was good. The benefit of the whole society was the object which all these regulations were accounted useful to promote, and no degradation of any of the classes was either intended by any of these enactments, or necessary for the ends which they were destined to serve.

The degradation of one set of the castes, in comparison with another, was the result of an afterthought, and in the pursuit of ends of a different description. When one of the castes, as that of the priests, or the soldiers, found itself possessed of an influence over the minds of the rest of the community, such, that it could establish certain points of belief in its own favour, it was never long before it availed itself of that advantage, and pushed it to the utmost. If it could inspire the belief that it was more noble, worthy of higher privileges, and greater honour, than the rest of the community, it never failed to get this point established as an incontrovertible right, not the result of the mere will of the community, but of an absolute law of nature, or even a revelation and command from God.

As every elevation of one class implies a correspondent degradation of another, and as there is no end to the elevation which one class will aim at, there is no end to the degradation which will be imposed upon another, if the state of the human mind is sufficiently weak to give to one class an unbounded influence over the belief of another. How naturally this extreme degradation is grafted upon the institution of castes, will immediately appear.

As we derive our most minute and practical acquaintance with the shape into which society is

Caste.

moulded by the establishment of castes, from our intercourse with the Hindus, the particulars which are at this day exhibited in Hindustan, and provided for by their laws, afford the most certain means of acquiring precise and specific ideas concerning this remarkable institution.

Of the Indian Castes in particular.

According to the sacred law book, entitled the "*Ordinances of Menu*," the Creator, "that the human race might be multiplied, caused the Brahmen, the Cshatriya, the Vaisya, and the Sudra (so named from the *Scripture*, *protection*, *wealth*, and *labour*), to proceed from his mouth, his arm, his thigh, and his foot." "For the sake of preserving this universe, the Being, supremely glorious, allotted separate duties to those who sprung respectively from his mouth, his arm, his thigh, and his foot. To Brahmens he assigned the duties of reading the Veda, of teaching it, of sacrificing, of assisting others to sacrifice, of giving alms, if they be rich, and, if indigent, of receiving gifts: To defend the people, to give alms, to sacrifice, to read the Veda, to shun the allurements of sensual gratification, are, in a few words, the duties of a Cshatriya: To keep herds of cattle, to bestow largesses, to sacrifice, to read the scripture, to carry on trade, to lend at interest, and to cultivate land, are prescribed or permitted to a Vaisya: One principal duty the Supreme Ruler assigns to a Sudra, namely, to serve the before-mentioned classes, without depreciating their worth."

Such is the employment of the castes; and such the authority whence it is derived. The next great peculiarity is, the degree of elevation which one set of the castes was enabled to usurp, and the correspondent degradation of the others.

Priests.

1. The Brahmens, or the priests. "Since the Brahmen sprung from the most excellent part," says the same divine code, immediately quoted, "since he was the first born, and since he possesses the Veda, he is, by right, the chief of this whole creation. Him the Being, who exists of himself, produced in the beginning from his own mouth, that, having performed holy rites, he might present clarified butter to the gods, and cakes of rice to the progenitors of mankind for the preservation of this world. What created being then can surpass Him, with whose mouth the gods of the firmament continually feast on clarified butter, and the manes of ancestors on hallowed cakes? Of created things, the most excellent are those which are animated; of the animated, those which subsist by intelligence; of the intelligent, mankind; and of men, the sacerdotal class. When a Brahmen springs to light, he is born above the world, the chief of all creatures. Whatever exists in the universe, is all, in effect, the wealth of the Brahmen; since the Brahmen is entitled to it all by his primogeniture and eminence of birth."

As the Brahman exclusively, or at least to a supreme degree, engrosses the regard and favour of the Deity, so he is entitled to the worship and adoration of mortals. Kings themselves, and the most exalted of men, are infinitely inferior to the meanest of the Brahmens. "Let the king," we again quote the ordinances of Menu, "having risen at early dawn, respectfully attend to Brahmens learned in the three Vedas, &c. . . . and by their decision, let him abide. Constantly must he show respect to Brahmens, who have grown old, who know the scriptures, who are pure." "The king must appoint seven or eight ministers, &c. . . . . To one learned Brahmen, distinguished among them all, let the king impart his momentous counsel. To him, with full confidence, let him entrust all his transactions; and with him, having taken his final resolution, let him begin all his measures." "Let him not, although in the greatest distress, provoke Brahmens to anger, by whom Brahma, the all-devouring fire, was created, the sea with waters not drinkable, and the moon with its wane and increase. What prince would gain wealth by oppressing those, who, if angry, could frame other worlds, and agents of worlds, could give being to new gods and mortals? What men, desirous of life, would injure those by the aid of whom, worlds and gods perpetually subsist; those who are rich in the knowledge of the Veda? A Brahmen, whether learned or ignorant, is a powerful divinity; even as fire, is a powerful divinity, whether consecrated or popular. Thus, though Brahmens employ themselves in all sorts of mean occupations, they must invariably be honoured; for they are something transcendently divine."

The least disrespect to one of the sacred order, is the most atrocious of crimes. "For contumelious language to a Brahmen," says the code of Menu, "a Sudra must have an iron style, ten fingers long, thrust red-hot into his mouth; and for offering to give instruction to priests, hot oil must be poured into his mouth and ears."

The laws give to the Brahmens the most remarkable advantages, over the other classes of the community. Neither the person, nor so much as the property of the Brahmen, can ever be touched, in awarding punishment for the most atrocious crimes. "Never shall the king," says one of the ordinances of Menu, "slay a Brahmen, though convicted of all possible crimes; let him banish the offender from his realm, but with all his property secure, and his body unhurt." This privileged order was entirely exempt from taxes. One of the most important of all duties is to bestow wealth upon the Brahmens, by incessant gifts and donations.

Military Caste.

2. The Cshatriyas, or the military caste. Though the Brahmens look down upon this class, they are looked up to by all the rest of the classes, with a prostrate veneration, inferior only to that with which the Brahmens are regarded. The difference of rank in India, is not a mere ceremonial distinction. The advantages which are conferred by it, or the injuries endured, are immense; and to the suffering party unspeakably degrading. Any infringement, even of the external marks of the abjectness of the degraded party, is punished as a heinous crime. "If a man of an inferior caste," says Halhed's *Gentoo Code*, "proudly affecting an equality with a person of superior cast, should speak at the same time with him, the magistrate in that case shall punish him to the extent of his abilities." It is unnecessary, under this head, to enter into details, which would occupy a disproportionate space.

Agricultural Caste.

3. The Vaisyas, the agricultural and commercial class. It is still less necessary to multiply particu-

Caste.

lars under this head. When the two extremes are sufficiently explained, what modifications of respect or disrespect belong to the intermediate stages, may be easily inferred.

Servile Caste.

4. As much as the Brahman is an object of intense veneration, so much is the Sudra an object of contempt, and even of abhorrence, to the other classes of his countrymen. The business of the Sudras is servile labour; and their degradation inhuman. The most abject and grovelling submission is imposed upon them as a religious duty, enforced by the most dreadful punishments. They are so completely deprived of an equal share in the advantages of the social union, that few of those advantages are reserved to them. The classes above them are restrained from injuring them, even in the case of the greatest crimes, by punishments far slighter, than those which are appointed for injuries done to the superior classes. The crimes which they commit, are punished with much heavier inflictions than equal crimes committed by individuals of the classes above them. Neither their persons nor their labour is free. "A man of the servile caste," says the sacred ordinance of Menu, "whether bought or unbought, a Brahmen may compel to perform servile duty; because such a man was created by the Self-existent for the purpose of serving Brahmens."

According to the principles of the same code, the Sudra was excluded from the benefits of property. "No collection of wealth must be made by a Sudra, even though he has power, since a servile man who has amassed riches gives pain even to Brahmens." "A Brahmen may seize without hesitation, the goods of his Sudra slave; for as that slave can have no property, his master may take his goods."

The degradation of the wretched Sudra extends not only to every thing in this life, but even to religion, and the prospect of future happiness. "Let not a Brahmen," says the above code, "give advice, nor what remains from his table, nor clarified butter, of which part has been offered, nor let him give spiritual counsel to such a man, nor inform him of the legal expiation for his sin; surely he who declares the law to a servile man, and he who instructs him in the mode of expiating sin, sinks with that very man into the hell named Asamvrita." Not only are the Sudras not allowed to read any of the sacred books; but, "If," says the *Gentoo Code*, "a man of the Sooder reads the Beids of the Shaster, or the Pooran, to a Brahman, a Chehteree, or a Bice" (Halhed's mode of spelling the names of the four castes), "then the magistrate shall heat some bitter oil, and pour it into the aforesaid Sooder's mouth; and if a Sooder listens to the Beids of the Shaster, then the oil, heated as before, shall be poured into his ears, and arzeez and wax shall be melted together, and the orifice of his ears shall be stopped up therewith. If a Sooder gets by heart the Beids of the Shaster, the magistrate shall put him to death. If a Sooder gives much and frequent molestation to a Brahman, the magistrate shall put him to death." From this specimen of particulars, a judgment may be formed with regard to the rest.

Though this is the primary and original formation of castes, the institution, unless where it happens to be early broken up, does not rest here. The distribution of the members of the community into four classes only, and the appropriation of their services to four species of employment, though a great step in improvement at the time they were instituted, must have become productive of many inconveniences, as the wants of society multiplied. The bare necessaries of life, with a few of its rudest accommodations, are all the means of gratification which it affords, or is capable of affording to mankind. As the desires of mankind, however, speedily extend beyond such narrow limits, a struggle must have early ensued between the first principles of human nature, and those of the political establishment.

Inconveniences which flow from this Institution as Society advances.

And this was not the only evil to which, under this primary institution, society was exposed. The different castes were strictly commanded to marry with those exclusively of their own class and profession; and the mixture of the classes by the union of the sexes, was guarded against by the most sanguinary laws. This, however, was a result which laws were not sufficiently powerful to prevent. Irregularities occurred, and children were born who belonged to no caste, and for whom there was no occupation. A more calamitous event could not fall upon human society. Unholy and infamous on account of that violation of the sacred law to which they owed their unwelcome birth, those wretched outcasts had no resource for subsistence, except two; either the bounty of the regular classes, to whom they were objects of contempt and abhorrence, not of sympathy, or the plunder of those classes by whom they were oppressed; a resource to which they would betake themselves with all the ingenuity of necessitous, and all the ferocity of injured men.

When a class of this description became numerous, they must have filled society with the greatest disorders. The nature of the case would have drawn the philosophical mind to this conclusion, had no testimony existed. It so happens, however, that this is one of the few facts in the ancient history of the Hindus, which can be ascertained from their records. In the preface to that compilation of the *Hindu Laws*, which was translated by Mr Halhed, it is stated that, after a succession of good kings who secured obedience to the laws, and under whom the people enjoyed felicity, came a monarch, evil and corrupt, under whom the laws were violated, the mixture of the classes was perpetrated, and a new and impious race were produced. The Brahmens put this wicked king to death; and, by an effect of miraculous power, created a successor, endowed with the most excellent qualities. Nevertheless the kingdom did not prosper, by reason of the Burren Sunker (so were the impure and irregular brood denominated); and it required all the wisdom of this sage and virtuous king to devise a remedy. He resolved to form a classification of the mixed race; and to assign them occupations. This accordingly was the commencement of arts and manufactures. The Burren Sunker became all manner of artisans and handicrafts. Of the classes into which they were distributed, one was appointed to the weaving of cloth, another to works in iron, and so in all other cases;

till the subdivisions of the race were exhausted, and the wants of the community were provided for. Among the Hindus, thirty-six castes of the impure race are enumerated, all inferior in rank and privileges even to the Sudra. To proceed farther in the detail, would be inconvenient and useless. By this supplement to the institution of the four primary castes, two great evils were remedied at once; the increasing wants of an improving society were supplied, and a class of men, who had been the pest of the community, were converted to its service.

The only remaining inquiry with respect to the institution of castes, which seems appropriate to this place, is that of its utility or inutility as a part of the social establishment.

A few words, we think, will suffice, to convey clear and determinate ideas upon this subject.

General View of the Effects of this Institution.

It is the distinction of man's nature, that he is a progressive being. It is by this grand characteristic that he is separated so widely from the inferior animals. When found in circumstances and situations in which the benefits of progression seem not to have been reaped, he is raised but a slight degree above the condition of some of the more perfect of the inferior animals. His peculiarity is, that he is susceptible of progression; and unless when he is placed in circumstances which impose extraordinary restraints upon the principles of his nature, does invariably and incessantly make progress. Even when he originates in a state little above that of the inferior animals, he rises, and gradually ascends from one stage to another, till his elevation above all the other inhabitants of this globe is immense; nor is there any limit which our knowledge permits us to set, to his final attainments and felicity. In whatever state the other animals originate, in that same state they remain through all ages; and seem altogether incapable of improvement.

In regard to man, therefore, considered as a class of beings, or an order of existence; every thing is to be considered as beneficently important, in proportion as it favours his progression; every thing is to be considered as mischievously important, in proportion as it obstructs and impedes that progression.

It is by this grand test of all that is good and evil in human institutions, that we shall endeavour to estimate the effects of the establishment of castes.

We shall not here adduce the elevation of one set of the classes, and the correspondent degradation of another, obviously the cause of infinite evil; because it may be with justice maintained, that this horrid elevation, and equally horrid depression, are not essential parts of the institution of caste, but arise from other causes, and may, in fact, be separated from that institution.

First of all, it is evident, that at the time when the number of castes and professions is established, unless it could be foreseen what are all the species of operations or arts, by which the desires of man, in all their possible varieties, are capable of being gratified; and what are all the possible divisions of labour from which any good can arise; the appointment of fixed, unalterable castes and professions, must oppose an irresistible barrier to human advancement in these two grand instruments of progression, the division of labour, and the practice of new arts, as invention may suggest them, or the multiplying desires of an improving society may create the demand. Since it is obviously impossible that all these things can be foreseen, it is abundantly certain, that the institution of any fixed number of arts and trades is exactly an institution for preventing the progression of mankind. This deduction appears to be conclusive; and, if there were no other argument, affords a complete answer to the question respecting the utility of castes.

Even in the trades and arts which are known and provided for at the time of the institution, it is by no means certain, that this fixed order of the persons who are to practise them is a contrivance well adapted for carrying these arts themselves, whether large in number or small, to their highest state of perfection. It by no means follows, that a man will do any thing better than any other man because his father did it before him. To establish a caste for any particular art or profession, is giving a sort of monopoly to that particular description of men. It is a wide monopoly, to be sure; but as far as the appropriation of the art to one class is calculated to have any effects, they must so far be such as it is of the nature of a monopoly to produce, and hence unfavourable to the progress of the art. The way which presents itself to the reasoning mind, as that which is best calculated for improving every branch of human industry or skill, is to open, as widely as possible, the doors to competition; not to exclude any man, of whatever origin, who may appear to have an extraordinary genius for any particular thing, but allow him, through competition, to reap the reward of his superiority, and hence to feel all the motives that can prompt him to excel. The acquirements of one generation are not transmitted to another more surely when they are transmitted from father to son, than when they are transmitted in the way of promiscuous instruction. Nor does it necessarily, or even commonly, happen, that the learner gets more careful instruction from his father, than he would from a man who is not his father; or, that he himself is more intent in his application, and careful to learn, because it is his father who instructs him.

In the sciences and the fine arts, the power of excelling in which depends upon rare combinations of circumstances, to limit the number of competitors, and shut up the field from all but the members of a particular tribe, is obviously a powerful expedient for diminishing the chance of progression. In regard to literature and knowledge the case is clear and decisive. To confine the prosecution of it to a particular tribe, is to insure a perpetuity of ignorance and misery to the human race. It will be decidedly the interest of the knowing class to maintain as much ignorance as possible among the rest of the community, that they may be able the more easily to turn and wind them conformable to their own purposes; and, for that end, to study, not real knowledge, not the means of making mankind wiser and happier, but the means of deluding and imposing upon them; the arts of imposture. With this clear and incontrovertible inference, how exactly does the historical fact cor-

respond? How truly and faithfully have the Brahmens acted up to that rule? They have made it a law revealed from heaven to keep the great bulk of the community in ignorance. And what branch of knowledge have they ever studied but the science of delusion? There is first their theology; a mass of absurd fictions to chain the imagination of ignorant and foolish men. And then there is astrology, which concludes the circle of all their studies, and may be justly styled the "Second Part of the Act of Imposture;" even their mathematics, in which they made some little progress, being studied in no other shape than as a part of the business of astrology.

Another circumstance appears to merit no slight regard. The institution of castes is calculated to multiply the evils, so dreadful in magnitude, which are apt to arise from the principles of population, and is opposed to the measures which are calculated to lessen or prevent them. The evils which are apt to be produced by an occasional superabundance of people in any one of the departments of industry and subsistence, are exceedingly diminished, when the greatest possible facility is given to the supernumerary individuals, of distributing themselves through all the other departments of industry and subsistence. And these evils, it is obvious, are all raised to the greatest height when the possibility of that distribution is taken away; and individuals, in whatsoever degree superabundant, are still confined to their own department. As this is a topic, the elucidation of which is easy to carry on, we shall content ourselves with the bare hint which has thus been given, and leave the developement to the reflections of the reader.

It may be added, as a supplement to what was said about the obstruction which, by the institution of castes, is given to progression, not only in the division of labour and the multiplication of arts, but even in perfecting the arts which are known and practised, that the strict confinement of one tribe of men to one tribe of operations must have a strong tendency to create a habit of routine, and hence an aversion to all innovation; a disposition to acquiesce in what has constantly been done, as if it were that which ought to be constantly done; and hence to deaden that activity of mind which is on the alert to catch at every chance of improvement,—that admirable temper, on which the greatest rapidity in the march of human amelioration essentially depends.

It was intended, after thus presenting the reasons on which we conclude that the institution of castes is an arrangement altogether opposite to the interests of human nature, to have stated and answered the reasons which have been advanced by Dr Robertson, in the *Appendix* to his *Historical Disquisition Concerning India*, and very recently by the Abbé Dubois, in his *Description of the Character, &c. of the People of India*, to prove that the institution of castes is really beneficial. But after looking over these reasonings, with a view to that answer, they have appeared to us to be so weak and insignificant, as to be altogether unworthy the trouble of transcription. A sufficient answer to every point which they adduce, will be found in the considerations which we have already urged upon the subject; and we doubt not, that we may safely intrust the decision to the judgment of the reader. (F. F.)

CASTI (Giambattista), an Italian Poet, was born of humble parents, in the year 1721, at Montefiascone, a small town in the States of the Church. It was there, too, that his studies commenced, in which he made such rapid progress, that he was appointed, in early youth, Professor of Greek and Latin, in an academy of his native town,—an employment which peculiarly directed his attention to Classical Poetry and Literature. He soon, however, quitted this obscure situation, and repaired to Rome, in search of more noble examples of emulation, and a higher recompence of public esteem than his birthplace afforded him. His learning, acuteness, and agreeable disposition, recommended him to the notice and friendship of the most eminent individuals of that capital. He was admitted a Member of the Academy *Degli Arcadi*, and it is believed he might easily have risen from a Canonship in the Cathedral of Montefiascone, which he had already obtained, to the enjoyment of much higher church benefices, had such been the chief objects of his ambition. But his love of freedom, and his restless inclination for travelling (which appears to have been characteristic of all the literary men of Italy), interfered with his ecclesiastical preferment. He gladly accepted the invitation of Prince Rosenberg (tutor to the Grand Duke Leopold), with whom he had become acquainted at Florence, to accompany him to Vienna, where he was presented to the Emperor Joseph. After this introduction, he visited almost all the capitals of Europe, from Petersburgh to Lisbon, and from Constantinople to Stockholm, directing his particular attention to the manners and civil institutions of the various countries through which he passed. On his return to Vienna, he was appointed *Poeta Cesario*, or Poet-Laureate, in the room of Metastasio, a situation which he held till some time after the death of the Emperor Leopold, when he resigned it, and retired to Florence in 1796. During two years residence in that city, he composed a great number of his works. At the end of that period, he went to live in Paris; and, though now far advanced in life, neither his habitual gaiety nor ardour of literary composition were in any degree abated. Scarce a day passed in which he did not add something to his principal poem, *Gli Animali Parlanti*, or write one of his poetical novels. At the same time, he delighted the society with which he lived by the unceasing liveliness of his conversation, which was rendered highly entertaining and interesting, by his knowledge of the world, and the extensive opportunities he had possessed of observing the manners and characters of mankind. Though, in 1803, he had passed the age of 82, the strength both of his mind and body still afforded the promise of a yet longer life; but he died during this year, in consequence of having caught a severe cold, in returning home at a late hour from a house where he had spent the evening. His funeral was attended by a great concourse of French and Italians, distin-

Casti.

guished by literary eminence, and an eloquent funeral oration was pronounced on this occasion by Corona, an Italian physician.

The chief work of Casti is *Gli Animali Parlanti, poema Epico Diviso, in XXVI. Canti.* In 1792 and 1793, the French revolution had attracted the attention and speculations of all Europe, and had introduced comparisons between new theories of government and ancient institutions. The rage of innovation, and dislike of established forms, having infected the minds of so large a proportion of the community, Casti resolved to exhibit, though under an allegorical veil, what he conceived to be the predominant feelings of the multitude, their avowed hopes, and secret designs. With this view, as he himself has expressed it in his preface, "he contrived a grand apologue, divided into parts, and forming a continued poem, in which animals being introduced as speakers and actors, a complete political story might be exhibited, exposing the defects of various political systems, and the absurdity of many institutions which had been from time to time adopted." Near the commencement of this apologue, the beasts assemble to choose a king, and after a good deal of intrigue, and various harangues, the lion is elected. On his death, the folly of the lioness regent, and perversity of the royal cub, excite murmurs, cabals, and at length a successful insurrection, which is headed by the dog. By thus assigning to animals human speech and passions, the author has very happily parodied the usual appearances and events of political revolutions in general; but often with some allusion to the political events of the day, to the characters of the reigning princes of Europe, and to that most portentous of all revolutions, the consequences of which at that time occupied so large a portion of the thoughts of mankind.

Accordingly, we find that in this work, Casti has pourtrayed and satirized the hypocrisy so often mixed in political pretensions—the secret ambition of leaders, who alternately supplant and succeed each other—the intolerance of cabals and parties, who proscribe all who have not ranged themselves under their banners, and who regard the maxims which happen to be then in vogue as fixed and immutable principles. He has represented, with peculiar felicity, the democratic declamations of the dog, once so loyal, the aristocratic surliness of the bear, the simple good-nature of Lion I. and the caprices of his cub Lion II. who is obviously intended for the late Czar of Muscovy. It must, however, be confessed, that the pleasantry of an apologue of twenty-six cantos, each of about 600 lines, is too much prolonged, and the too frequent negligence of the style, with the repetition of trivial and obvious morals, like those at the bottom of the page in the English *Æsop's Fables*, do not aid in sustaining the curiosity or interest.

This work of Casti, which raised him to a very high rank among the modern poets of his country, was begun at Vienna in 1794. His situation, however, as poet-laureate, was unfavourable to the freedom of political satire, and this obstacle to his favourite pursuit may have been one inducement to his resignation of that office. After his retirement, the poem was continued at Florence without interruption, and completed at Paris, where it was published in 1802, in 3 vols. 8vo, an impression which has been followed by various editions in Italy. It was translated into French, Spanish, and German, and we have also seen a free and abridged English version, executed with considerable vivacity and spirit. To most of the Italian editions, four apologues have been added, but which have no relation to the subject of the *Animali Parlanti*. One of them, entitled *Della Gatta e del Topo*, written, we believe, before the author was poet-laureate, and published certainly after he had resigned that situation, is supposed to pourtray those sinister events which clouded the prospects of aggrandizement anticipated by Joseph from his formidable league with Russia against the Turks.

Casti having completed his great work of the *Animali Parlanti*, anew directed his attention to the composition and publication of poetical novels. As far back as the year 1778, he had written eighteen of these *Novelle Galanti*, but his poetical avocations at the Imperial Court had interrupted his progress; and meanwhile those he had composed were surreptitiously printed, both in Italy and France, in a manner so inaccurate, and so much altered from the way in which they had been originally written, that they could scarcely be recognised by the author, as we learn from the *Protesta dell Autore*.

> "*Molti vi son che senza mio permesso*
> *Sparser le mie novelle, e v'han cangiato*
> *Ordine, senso, e versi, e strofe; e spesso*
> *Mi fan dir cio che non ho mai pensato,*
> *Che appena omai mi vi conosco io stesso.*"

Some too, as *La Bella Circassa*, and *La Figlia che non ha Giudizio*, which were not written by Casti, were added to these surreptitious publications:

> "*Saran belli e leggiadre poesie,*
> *Tutto quel che si vuol; ma non son mie.*"

In these circumstances, the injured poet assiduously prepared himself to enlarge the number of his novels, and to collect the whole in an edition which might be printed under his own immediate superintendence. He was prevented, however, by his sudden death; but his novels, which, at the period of his decease, amounted to forty-eight, were published by one of his Parisian friends, in 3 vols. 8vo, 1804, accompanied by a prefatory memoir of the author. The practice of tale-writing, which commenced with the author of the *Cento Novelle Antiche*, and was brought to such perfection by Boccaccio, had prevailed in Italy for nearly 500 years before the age of Casti. The Italian novelists invariably copied from each other, and from those inexhaustible stores of fiction, the *Fabliaux* of the Trouveurs. But the merit of Casti does not consist in the invention of his stories, all of which are borrowed, but in being the first among his countrymen who has clothed these tales in a poetical garb. His Novels are founded either on mythological stories, or on preceding Italian tales. To the first class belong *Aurora*, *L'Origine di Roma*, *Diana ed Endimione*, *Prometeo e Pandora*. Almost all the rest are poetical versions

Casti.

from Boccaccio, Massuccio di Salerno, and other Italian novelists. The longest, *La Papessa*, which is divided into three parts, is founded on the old story of Pope Joan. These tales are much admired by the Italians for purity of language, and harmony of versification, and they contain many ingenious and sarcastic reflections on the hypocrisy, errors, and vices of men in every age and condition of life. They are disfigured, however, by an unpardonable licentiousness, which is carried much farther than that of almost any of the prior novelists of Italy. Some of them also terminate rather flatly, and the octave stanza, in which they are all written, and which has a certain degree of heaviness, even in the hands of Ariosto and Berni, is ill adapted to the gaiety and levity of the lightest of all species of composition. One cannot mention the tales of Casti without being naturally led to compare them with those of Fontaine, which are founded on similar originals, and written in something of the same spirit. But, if there be more asperity and caustic raillery in Casti, he is infinitely inferior to the French poet in ease, *naiveté*, and grace. The language in which he was obliged to write, whatever may be its other excellencies, is less expressive of playfulness than the French, and the octave stanza, which he unfortunately chose, is not susceptible of the buoyancy and lightness of Fontaine's versification.

The *Animali Parlanti*, and the *Novelle* are the best known and most popular works of Casti; but he is also author of the *Poema Tartaro*, a satiric poem, in twelve cantos, on the Court of Catherine II. The scene of action, however, is laid in Asia, and all the names are fictitious. Russia is called Mogollia—St Petersburgh, Caracora—The Empress, Cattuna—the Grand Duke Paul, afterwards Czar, Cajucco—Orloff, Cuslucco—and Potemkin, Toto Toctabei. The first sketch of this mock-heroic poem was made by the author during his visit to St Petersburgh, in the train of Count Kaunitz, the Austrian Ambassador. On his return to Vienna, the Emperor Joseph having manifested a desire to hear it read, Casti new-modelled the composition, struck out whatever might be likely to prove offensive to crowned heads in general, and inserted a complimentary episode on the celebrated journey of his imperial patron into the Crimea. Notwithstanding the approbation which his poem met with from the Austrian court, Casti would not probably have published it during the life of the heroine; but numerous manuscripts of it having been circulated, some of them found their way to Italy, where it was repeatedly but very incorrectly printed, none of the impressions having been ever subjected to the revisal of the author.

In his capacity of poet-laureate, it was the duty of Casti to provide new dramatic entertainments at stated occasions and periods. The court and public of Vienna had probably grown weary, in the course of half a century, of the elegant moral monotony of Metastasio; and Casti, whose genius was diametrically opposite to that of his predecessor, could not have vied with him in the grand or serious opera. He therefore resolved to excite the mirth of the spectators by the revival of the *Opera Buffa*, in which he obtained great success. One of his productions in this line, entitled *La Grota di Trofonio*, is intended to ridicule the pretensions of false philosophers. The subject of another, *Il Re Teodoro in Venezia*, suggested by an episode in Voltaire's *Candide*, was assigned to him by the Emperor himself, who is said to have been much entertained with the lines

Casti ‖ Caubul.

> *Senza soldi e senza regno*
> *Brutta cosa è l'esser Re.*

A third burlesque opera, of which Cicero is the principal character, is founded on the plot of Catiline. Here the characters of the Roman senators and conspirators, with the orations against Catiline, are so parodied as to produce something of the same effect as our mock tragedies; or the ancient satiric drama of the Greeks.

On the whole, although neither the Novel nor the Apologue was by any means a new species of composition among the Italians, yet Casti may be regarded an original author, in so far as he has bestowed a new form on the first, and has given to the second an extent which it had not yet received, as well as directed it to an object to which it had not been previously applied. (M.)

CATOPTRICS. See the *Encyclopædia* under that head, and OPTICS in this *Supplement*.

CAUBUL. That extensive territory in the centre of Asia, which at present composes the kingdom of Caubul, is formed of various and disunited portions. The basis is a large tract of mountain table land, interposed between Persia and Indostan, and to which the Persians have given the generally received appellation of Afghaunistaun. To this original territory, conquest has added, on the east, Cashmeer, with the greater part of Moultaun and Lahore, called commonly the Punjaub; on the north, Bulkh, or Bactria; on the west, Heraut and a great part of Khorasan; and, on the south, a portion of Sinde and Beloochistaun. Several of these provinces are very slightly attached to the main body of the kingdom. Beloochistaun and Bulkh have been already described; and the provinces of Moultaun and the Punjaub are so connected with Indostan by natural boundaries and physical aspect, that we cannot forbear referring them to that country, notwithstanding the political events which, at present, sever them from it. Our details will refer chiefly to the remaining provinces, which may be considered as the integral portions of the kingdom of Caubul. Under the heads of AFGHANS, CAUBUL, and CANDAHAR, in the original work, will be found a summary of the very little that was known relative to this part of Asia. Mr Elphinstone's excellent account of his recent mission to Caubul, has thrown an entirely new light upon those regions; and will enable us to exhibit a much more full and satisfactory view, than was before possible, of their actual condition.

Names and Integral Parts of Caubul.

The modern Afghaunistaun was recognised by the ancients under the appellations of Aria, Drangiana, Arachosia, and Parapomisus; but these countries were scarcely known, unless by the marches of Alexander, who traversed them only partially; for, in advancing, he went chiefly to the north of this region, and to the south of it in returning. In modern times, Cau-

History.

Caubul. bul has shared all the revolutions which has changed the face of Southern Asia. In the eleventh century, under Mahmood of Ghuznee, it was the seat of an Empire, which extended from the Ganges to the Euphrates, and from the Jaxartes to the ocean. This sceptre was broken by the inroad of those innumerable hordes which, under Gengis and Timour, poured down from the interior of Tartary. Caubul was conquered, in 1506, by the Emperor Bauher, who made the city of that name his capital. This example was not followed by the Moguls his successors; but the plains of Afghaunistaun continued to be divided between Persia and India, while the mountainous tracts commonly maintained their independence. In the beginning of the last century, a tribe of Afghauns conquered Persia, and continued to reign over that Empire till its independence was re-asserted by Naudir Shauh. That daring Chief not only expelled the invaders, but rendered Caubul, in its turn, subject to Persia, and carried his arms into Indostan. After the death of Naudir, Ahmed Shauh, the head of one of the principal Afghaun tribes, founded the present kingdom of Caubul. He not only made it independent of every foreign power, but extended its boundaries on every side, twice entered Delhi, and annexed to his dominion several of the Indian provinces. In 1773, he was succeeded by his son Timour, a moderate Prince, who made it his chief aim to maintain tranquillity throughout his extensive dominions. In this object he with difficulty succeeded; but a train of policy, so adverse to the habits and inclination of his subjects, was not calculated to make his government respected, and he left, in 1793, a weakened sceptre to his posterity. In this kingdom, the Chiefs select from the sons of the deceased monarch the individual whom they judge best qualified to reign. The choice, in this instance, fell upon Zemaun Shauh. A half-brother, Mahmood, however, raised the standard of revolt, and, after various successes, obtained possession of the person of Zemaun, whom he deposed, and deprived of sight. Meantime another brother, Shujah, advanced a claim to the throne, which he made good, and was found reigning at Peshawer when Mr Elphinstone arrived there in 1808. Mahmood, however, had escaped from prison, had raised a new force, with which he had taken Candahar, and was advancing upon Peshawer. The mission afterwards learned that he had entered that city, driving Shujah before him. A civil war then ensued, in which the contending parties alternately obtained possession of the capital. Which of the two now holds the preeminence is not known, and is not of very much importance; but it is of importance to ascertain the general statistical and political state of a great kingdom, which borders so closely on our eastern possessions.

Boundaries. The kingdom of Caubul is bounded on the east by Indostan, on the north by Toorkistaun, or Independent Tartary, on the west and south by Persia. Its extent may be roughly stated at 600 miles from east to west, and 550 from north to south.

Mountains. Among the natural features of Caubul, the most remarkable is that portion of the great mountain chain of Asia, which passes along its northern frontier. The lofty peak of Hindoo Coosh or Koh, communicates its name to this range, which forms evidently a prolongation of the Hemalleh, or snowy chain, which divides India from the table land of Thibet. Hemalleh, however, extends from south-east to north-west, while Hindoo Coosh runs directly east and west. It is of stupendous height, and its most elevated summits clad in perpetual snow; yet they do not seem altogether to equal some of those which tower above the plains of Nepaul. The observations made by Lieutenant Macartney, apparently with considerable skill and attention, fixed the elevation of some peaks at 20,493 feet; though the operation, being performed at the distance of 100 miles, afforded too small an angle to secure rigorous accuracy. "The stupendous height of these mountains; the magnificence and variety of their lofty summits; the various nations by whom they are seen, and who seem to be brought together by this common object; and the awful and undisturbed solitude, which reigns amid their eternal snows, fill the mind with admiration and astonishment, that no language can express." This chain continues with undiminished magnitude for about 440 geographic miles west from Cashmeer, and then shoots into that elevated peak to which the name of Hindoo Coosh is peculiarly applied. West of this point, it becomes considerably lower; and travellers from Candahar to Bulkh cross it without meeting any perpetual snow. The Greek term of *Parapomisus* is here commonly applied to it. In approaching the frontier of Persia, the mountains become of still inferior elevation; though branches continue to stretch westward, which may be viewed as prolongations of the great central chain.

Next in magnitude to the Hindoo Coosh, ranks the ridge of Solimaun. It commences a little to the west of Peshawer, at a very high peak, covered with perpetual snow, called Suffaid Koh, and proceeds thence, with diminishing magnitude, almost directly south, till it sinks into the plains of Sinde and Beloochistan. Only a narrow valley, through which the Caubul river flows, is interposed between it and the central range, on the opposite side of which begins the Beloor Taugh, extending northward as far as Cashgar, and which may probably be considered as a continuation of the Solimaun. From these two principal ranges, a variety of others, in different directions, traverse the elevated plain of Afghaunistan. One of the most remarkable of these is the Salt range, which, beginning not far from Suffaid Koh, runs east-south-east, crosses the Indus at Karrabah, or Callabaugh, and is continued to the banks of the Jelum. It is composed in many places of solid salt, clear as crystal, and so hard that plates for the table are formed out of it. At Callabaugh, it is seen lying in large blocks, for the purpose of being conveyed to the countries situated up and down the river. In other respects, the mineralogical structure and composition of all these ranges is entirely unknown.

Rivers. Of the *rivers* of the kingdom of Caubul, the most considerable by far is the Indus. This stream has been proved, by recent discoveries, to have a much longer course than had hitherto been assigned to it

Caubul. by modern geography. It seems to have been traced to a mountainous track on the eastern border of Little Thibet, the same which, on its opposite side, gives rise to the Bramapoutra. Here two branches arise, near to each other, which, after widely diverging, unite a few journies to the north-east of Cashmeer. Soon after their combined streams turn to the south, and force their way across the barrier of Hindoo Coosh. Here the Indus is, for a long time, confined in a narrow channel between rocks, and after receiving the rapid river of Caubul, is broken into numerous whirlpools and eddies, which are heard to a great distance, producing a sound like that of a stormy sea. After passing the salt range at Callabaugh, the stream no longer meets with any obstruction, and pours its waters over the plain in various channels, which successively separate and reunite, till they are poured, by many mouths, into the Indian Ocean. Near Auch an important accession is received from the Punjnud, which bears the united waters of the five great rivers that traverse the Punjaub; yet all these combined are considerably inferior to the Indus before the junction. The whole course of this noble river is estimated at 1350 miles.

Among the rivers which fall into the Indus from the west, the principal is the Kama, which, rising on the opposite side of the same peak which gives rise to the Oxus, rolls through the mountainous country of Kaushkaur, then penetrates the barrier of Hindoo Coosh, and pours down with tempestuous rapidity into the valley beneath. It here joins the river of Caubul, and the united stream falls into the Indus a little above Attok. The western part of Afghaunistaun is watered by the Helmund, which rises near Caubul, and, after rolling for 200 miles through mountainous tracks, enters a fertile plain, which, however, is soon crossed, and its subsequent course directed through a desert, when it falls, beyond the Afghaun frontier, into the lake of Durra or Zereng. Its whole length is about 400 miles. It receives a considerable number of smaller streams from different parts of the chain of Parapomisus. Near Ghuznee several small streams concur in forming the only lake in this country, called Aubistandeh.

Climate and Seasons. The climate of Afghaunistaun exhibits the most striking varieties, in consequence of the abruptness with which the mountain ranges often rise from the deep plains beneath. A few hours journey carries the traveller from a place where snow never falls, to another where it never melts. In the plain of Jellalabad, immediately beneath Suffaid Koh, persons are often killed by the intensity of the hot wind, while regions of eternal ice are towering above. At Caubul, the winter, if not more severe, is more steady than in England. The inhabitants wear woollen cloths and great coats of tanned sheep skin; they often sleep round stones, and avoid, as much as possible, leaving the house till the vernal equinox brings milder weather. Ghuznee, from its high situation, suffers more from cold than any of the other cities; and snow there often lies deep after the vernal equinox. In Damaun, on the contrary, a province lying along the Indus, the heat is such that the inhabitants are obliged to wet their clothes before going to sleep, and to keep, during the whole night, a vessel with water standing by the bedside. The heat is still more intense in the plain of Seweestaun, on the south western frontier; whence the Afghauns are accustomed to make the odd exclamation, "O Lord, when thou hadst Sewee, why needest thou to have made Hell!"

The prevailing winds in Afghaunistaun are from the west and south-west. The latter begins in the middle of summer, and blows for about a hundred and twenty days without intermission. This wind, throughout all this country, is cool, while the east wind is hot. The chief rain is in winter. When this falls in the form of snow and melts at the return of heat, it is of great importance to agriculture; but in the form of rain, its effect is lost, and the main dependence of the husbandman is then upon another rain, much smaller in quantity, which falls in spring. The monsoon that produces the great rains of India, is scarcely felt in Afghaunistaun; and the latter may be considered in general as a dry country.

Soil. The soil is nearly as various as the climate. In well watered plains of moderate elevation, as Peshawer and Candahar, it is exceedingly fertile, and produces two full crops in the year. Wheat and barley, the grains of Europe, are cultivated in preference to rice and Indian corn. In the higher districts, only one crop can be raised in the year; and in some, the grain must be sown at the end of one autumn, that it may ripen before another. The loftier part of the mountain chains is of course condemned to perpetual ruggedness and sterility. On the other hand, in the level districts to the south, bordering upon Seestaun and Beloochistaun, extensive deserts are produced by the absence of water. The empire of desolation seems, on this side, to be continually spreading; the moving sand being blown by the south-west wind over the bordering fertile tracts, which it gradually covers, and converts into desert.

Animals. The account of the animals of Afghaunistaun is very imperfect. Lions are rare; tygers and leopards are more common; wolves, hyænas, foxes, and hares, everywhere abound. The agricultural labour is performed by oxen; but a species of broad-tailed sheep form the riches of the pastoral tribes. Horses occur in considerable numbers, but not of the same excellent quality as those bred in the extensive plains north of Hindoo Coosh.

Political Constitution. The political constitution of Caubul is by no means of that simple structure which is usual in Asiatic monarchies. The royal power has been compared to that which was exercised by the Scottish monarchs during the feudal ages. Over the great towns, the country in their immediate vicinity, and the foreign dependencies, their authority is direct, and almost supreme. The rest of the nation is divided into clans or communities, who act nearly independently of the sovereign, and from whom a contingent of troops and money is with difficulty levied. These communities are called Oolooss. They are governed by a Khaun, who is usually appointed by the King, but always out of the oldest family of the Oolooss. The Khaun, within his own community, is quite a limited monarch; he can undertake no-

thing of importance without the consent of the Jeerga, or representative assembly of the people. The judicial power, so far as exercised, is also vested in the Jeerga. The principle of private revenge, however, is deeply rooted in the mind of the nation, and an appeal to the Jeerga carries with it some degree of reproach; being supposed to indicate, in the individual who has recourse to such a remedy, a want either of power or courage to vindicate his own wrongs. Even the Jeerga recognises the right of retaliation, by making a formal offer to the offended party of delivering the criminal into his hands, that he may inflict his own punishment, though it is understood that he shall decline and leave the point to the determination of the Jeerga. Alliances are formed, and wars carried on by the Oolooss between themselves, without any concern or interference of the sovereign. This form of government keeps every part of the country in a state of tumult and ferment, and presents at first sight a very unfavourable contrast to that undisturbed tranquillity which, under an absolute government, reigns over the greater part of the plains of India. Mr Elphinstone, however, through this outward aspect of rudeness and turbulence, saw enough to convince him of the radical superiority even of this rude freedom. The powers of action, and, as it were, of vitality, lodged in each of these independent communities, enabled it to flourish, unaffected by the personal character of the sovereign, or even by the convulsions which subverted his throne. The succession of revolutions to which the kingdom has been exposed during the last half century, have produced effects visibly injurious on the great cities, and the districts situated along the high roads. But the more remote and independent parts of the country have proceeded in an uninterrupted career of improvement; cultivation has been extended, new aqueducts built, and various public establishments undertaken.

National Character and Manners.

Though the external appearance of the Afghauns be more uncouth than that of the Indian, they possess estimable qualities to which he is a stranger. A certain measure of reliance can be placed upon their statements of fact; not that they can compare with Europeans in veracity, or will scruple dissimulation, when any great interest is to be promoted; but they are far from that profound and habitual falsehood, which characterizes the natives of Persia and Indostan. They manifest also an active spirit of curiosity, to which the subjects of despotism are altogether strangers. Displays of European art and machinery, which by Indians were noticed evidently from mere politeness, without any real interest, excited in the Afghauns the highest gratification, and an anxious wish to examine the processes by which they were performed. There exists also more purity of manners than is observed in other Asiatic countries. Polygamy, indeed, and the purchase of wives, prevails here, as over all the East. They are well treated, however, and often acquire an ascendancy in the family, from which the severity of Mahometan institutions seems elsewhere to exclude them. In the country districts, where the system of seclusion cannot be carried to such a rigorous extent as in towns, the passion of love seems often to be felt in all its ardour. Many of their popular poems relate to amorous adventures, and detail incidents not dissimilar to those which form the subject of similar compositions in Europe. It is said to be not uncommon for a young man to set out for India, or some other foreign country, with a view of earning the purchase money of the female of whom he has become enamoured. This price being usually considerable, the procuring of an Afghaun wife is attended with difficulty, and men arrive often at the age of forty, before they are able to collect a sum sufficient. This has led to a very peculiar mode of penal infliction. The fine imposed, on conviction of any crime, is levied in young women, to be given as wives to the injured person or his friends. Murder is twelve young women; severe mutilation, six; and so on, diminishing for smaller offences.

Hospitality is a virtue for which the nation is eminently distinguished. Not only a stranger, but the bitterest enemy, beneath the roof of an Afghaun, is in perfect security. Usage has even established, that any individual, who enters his house, and places himself in the posture of a supplicant, shall receive the boon which he thus craves. Yet, with this even romantic courtesy and humanity, are combined almost universally the habits of plunder and robbery. The extent of these practices varies among different tribes; and in those placed under the immediate eye of the Sovereign they are much restrained; but scarcely any tribes are wholly exempted. Instances have occurred in which an Afghaun has received a stranger with all the rights of hospitality, and afterwards, meeting him in the open country, has robbed him. The same person, it is supposed, who would plunder a cloak from a traveller who had one, would give a cloak to one who had none. From these circumstances, it is conceived, that no European, carrying property along with him, could, with any degree of safety, travel through Afghaunistaun. Nothing except absolute poverty could afford him any chance of security.

The Afghaun nobles reside almost entirely at court. They maintain a considerable state; but do not move with that crowded and noisy attendance which forms the delight of the Indian great man. In their comparatively small retinue, order and silence are strictly observed; so that they are alighted, and often entered, before their approach is announced. Even those whose fortunes are most ample, do not display the magnificence usual among the Persian nobility. In an entertainment, to which the British mission were invited, the dishes, consisting of all kinds of roasted, boiled, and baked meats, were dyed of various colours, and profusely ornamented with gold and silver leaf. The English were surprised, however, to see the servants jointing the meat with a penknife, and laying it on the plates with their hands. The amusements consisted in dancing girls, and displays of fire works, neither of which being very excellent in its kind, the pleasure afforded was extremely moderate. The nobles employed in offices at court are the most corrupted part of the nation, and, with a few exceptions, are guilty of every species of meanness.

Among Afghauns of all descriptions, the favourite

amusement is hunting. They practise it against all descriptions of game, and in every possible variety of mode. Sometimes large parties assemble, and, forming a crescent, sweep the country, so as to inclose all the game to be found within the compass of a certain district. They do not excel much in shooting or hawking; but have a singular mode of chasing partridges. A number of horsemen, one after another, pursue the bird, and never allow it to rest a moment, till, being quite exhausted, it is easily beat down with a stick. Within doors, quail and cock-fighting afford favourite enjoyments; nor is any exercise which calls forth bodily strength and dexterity omitted. The Afghauns are also a social people; they give frequent dinner parties, and delight in serious as well as gay conversation. The inhabitants of the towns find great enjoyment in excursions to the gardens in the vicinity, which command usually magnificent prospects.

Literature.

Education, to a certain extent, is very general among the Afghauns. Moollahs, performing the office of schoolmasters, are established not only in towns, but even in every village. Unfortunately, the grand object is to enable their pupils to read the Koran in Arabic, often without understanding it; and not a fourth part of the lower orders can read their own language. The more advanced studies are the Persian classics, Arabic, grammar, logic, law, and theology. The two great seminaries of learning are Peshawer and Bukhara, the former of which has somewhat the preeminence. Although the superiority of the Persians in literature is acknowledged, yet their reputation of heresy deters all faithful *Soonnees* from repairing to their colleges. The Afghaun princes, in general, have been eminent encouragers of learning. Ahmed Shauh held weekly assemblies at his palace, often prolonged to a late hour, and in which various topics of theology, law, and literature, were discussed. He and most of his successors have practised poetical composition, though their fame does not rest upon that basis. The most celebrated of the Afghaun poets in Rehmaun; in whose pieces, however, so far as they were explained to Mr Elphinstone, he was not able to discover any merit; but he is willing to believe that this may have arisen from the defective nature of the few specimens which he obtained. More true poetical fire glows in the verses of Khooshhaul, a Khaun or Chieftain, whose valour maintained the independence of his tribe against the power of Aurungzebe. His odes seem well calculated to inspire his followers with the love of independence, and with a passion for war and glory. The poetical taste of the nation is also indicated by the reading of poetry being established as a regular profession, which is followed in the towns by a considerable number of individuals.

Agriculture.

The useful arts have made considerable progress. Agriculture is followed with assiduity. The grand process upon which its success depends, is that of irrigation, which is practised to a great extent, throughout all the kingdom. It is usually effected by small canals, into which the water is turned by dams, and sometimes by partial embankments. A much more laborious contrivance, called a *cauraiz*, is frequently employed. A chain of wells are sunk on a sloping field, and are connected by a subterraneous channel, so constructed, that the water of all the wells is poured into the lowest one, and thence into a water-course, from which it is conducted over the field. This laborious structure forms sometimes the mode in which a rich man employs his money; sometimes it is performed by an association formed among the poor. The ground is always watered before being ploughed. The ploughing is performed with two oxen, and is deeper than in India; the grain is sown always in broadcast, and a substitute for the harrow is formed by a plank, above which a man stands, to increase the pressure. The crop, in the course of its growth, is watered at least once, usually oftener. The sickle is the only instrument employed in reaping, and the grain is threshed by the treading of oxen. Two kinds of artificial grass are raised. Wheat forms the staple food of the inhabitants, and barley is chiefly used for horses. The cheapness of provisions, particularly of fruits and vegetables, is almost incredible. Grapes are considered dear when they exceed a farthing a pound, and the coarser species are sometimes given to cattle; the best apricots are less than a halfpenny a pound, and melons much cheaper. The smallest piece of copper money purchases ten pounds of spinage, twenty-five of cabbage, &c. The land is divided into very minute portions, and the proprietor and cultivator are usually the same person.

Manufactures.

Of the manufactures of Afghanistaun no mention is made; and they seem to be limited to objects of immediate consumption. Manufacturing industry is confined to the provinces annexed to the kingdom of Caubul by conquest from India. The most important branch is the manufacture of the shawls of Cashmeer. These beautiful fabrics are wrought in a shop or shed, consisting of a frame-work, at which from two to four people are employed. The plain shawls are woven with a shuttle, the variegated ones with wooden needles,—there being a needle for each species of coloured thread. A year or more is sometimes employed in the manufacture of a very fine shawl, but six or eight of the ordinary kind may be made in that period. The annual number produced in Cashmeer is estimated at about 80,000. The wool is imported chiefly from Great Thibet, by the way of Rodauk.

Commerce.

Afghaunistaun, from its situation, can only have an inland commerce. This is conducted by caravans, and the merchants usually employ camels for the conveyance of their goods; though when they have to cross any part of the chain of Hindu Coosh, horses and poneys must be used. Considerable obstacles are encountered from the roughness of the roads, the difficulty of finding water and provisions, and the attacks of the predatory tribes. In traversing the territories of the latter, strict order is observed, and the march is covered by parties of horse stationed at proper distances. During the night, a large proportion of the caravan remain on watch. In towns they lodge in the caravansaries, which consist of large squares, along each side of which the apartments are ranged, with a mosque in the centre. Each merchant usually hires, at a very easy rate, two rooms for himself and his goods. Afghaunistaun,

from its want of manufactures, yields few commodities which can bear the expence of so laborious a transport. The principal are, fruits of all kinds, furs, madder, and assafœtida. The produce of its subject provinces, the shawls of Cashmeer, the chintzes of Monltan, form more convenient articles of exchange. The trade of this country, however, is chiefly supported by its being the channel through which India maintains its communication with Persia and Toorkistaun. All the Indian manufactures are thus conveyed into those regions, while European goods are brought by the Russians, by way of Orenburg to Bukhara, and thence to Caubul. The English mission, after having, with great difficulty, conveyed some large mirrors across the desert, hoping thus to inspire the king with a high idea of British manufacture, were much astonished and mortified, in the first private house which they visited, to see two mirrors of greater dimensions, which they understood had been brought by the above channel. From Toorkistaun itself are imported vast numbers of horses, for the supply of all the great men and armies of India. These, in consequence of the immediate channel by which they arrive, are there erroneously called Caubul horses.

Principal Tribes.

Such are the general features of the kingdom of Caubul; but every district has its separate tribe, divided and subdivided into others, and every one having something peculiar to itself. Our limits will only allow us to notice some of the most prominent of these distinctions. The western Afghauns are divided chiefly into the Ghiljies and Dooraunees. The Ghiljies are the most warlike of all the Afghaun tribes. Ghuznee, situated in the heart of their territory, was the residence of the great Mahmood, and the Ghiljies formed the strength of those armies, with which he spread desolation over Asia. The conquest of Persia, at the beginning of the eighteenth century, was also effected by the Ghiljies, and they continued the ruling tribe till the invasion by Naudir Shauh. The restoration of the Afghaun monarchy being effected by Ahmed Shauh, the chief of the Dooraunees, the Ghiljies have never regained their former ascendancy. Their constitution is extremely democratic, the administration, in some districts, verging almost on total anarchy. This spirit, which was always prevalent, has gained much additional strength since the sovereign ceased to belong to their tribe, and to add to his constitutional prerogative the more revered character of hereditary chief of the Ghiljies. This distinction now belongs to the Dooraunees, who, since the elevation of Ahmed Shauh, have had the king of Caubul for the head of their tribe. The great Dooraunee Sirdars unite the influence derived from office and military command, to that which they enjoy in right of their birth. Accordingly, though the democratic principle is by no means crushed, the power both of the king and chiefs is greater here than in any other part of the kingdom. The character and deportment of the Dooraunees are the subject of much panegyric. They are brave, honourable, hospitable, ardently attached to their tribe, and, at the same time, more liberal and humane than the rest of their countrymen. This preeminence is admitted by the Ghiljies, even while they avow themselves their bitterest enemies. One of them being asked by Mr Elphinstone, what sort of people the Dooraunees were, answered, "Good people; they dress well, they are hospitable, they are not treacherous." Being then asked how his countrymen treated such as fell into their hands, he replied, "We never let one escape; and now, if I had an opportunity, I would not give one time to drink water. Are we not enemies?" He added, "Our hearts burn, because we have lost the kingdom, and we wish to see the Dooraunees as poor as ourselves."

The heights of Solimaun are occupied by the Khyberees, Vizerees, and Sheraunees, tribes still more barbarous than the names which they bear. They are all robbers, and some of them little better than savages, living in caves cut out from the rock. The Eusofzies inhabit the north-eastern extremity of Afghaunistaun, and occupy a fertile valley on the right bank of the Indus, watered by the river of Suant. They came into this region as conquerors, and have reduced all the original inhabitants to a state of slavery. The slaves being more numerous than the masters, perform all the laborious offices, and leave the latter in a state of almost total indolence. Although democracy be very prevalent throughout Afghaunistaun, it nowhere rises to such a height as among the Eusofzies, who indeed can scarcely be said to have any government whatever. The small number of the freemen, and a species of connection resembling that of a religious sect, which binds them to each other, are sufficient to prevent any violent disorder. Proud of this freedom, the Eusofzies regard themselves as the noblest of the Afghaun tribes, and look down with contempt even on the Dooraunees.

Cashmeer.

Cashmeer was wrested from the Mogul by Ahmed Shauh, and has ever since continued a subject province of Caubul. The soil is more fertile, and the inhabitants more industrious than in any other part of the Afghaun dominions. The capital of the same name is the largest city in the kingdom, containing from 150,000 to 200,000 inhabitants; and the revenue is estimated at 4,626,300 rupees, nearly half a million Sterling. The country is ruled by a governor, who exercises with severity all the functions of a sovereign. The Dooraunees, who compose the military force, indulge in unusual licence, and treat this fine country as a conquered province. These oppressions give rise to frequent insurrections; but as the Cashmerians are endowed with a very small portion of courage, their risings are quickly crushed by the arrival of an Afghaun army; and the yoke is rendered more severe by the abortive attempt at emancipation.

Principal Cities.

The principal cities of Afghaunistaun are Peshawer, Caubul, Candahar, and Heraut. Peshawer, at present the largest town in Caubul, is situated in a most beautiful and fertile plain, of about 35 miles in diameter. It is watered by several branches of the river of Caubul; and while it displays all the luxuriance of tropical fertility, is nearly environed by the snowy summits of the Hindoo Coosh, and the ridge of Solimaun. The city

itself is upwards of five miles in circumference, is built upon an irregular surface, and contains about 100,000 inhabitants. The houses are built of brick, generally unburnt, in wooden frames. They are usually three stories high, the lower story being occupied by shops. The streets are narrow, not being designed for wheel-carriages; and, though paved, they are slippery and inconvenient. The shops are commodious, and well supplied with a variety of articles; while greens, curds, and particularly water, are called through the streets. The inhabitants present a varied and picturesque appearance; "people of the town in white turbans, some in large, white, or dark blue frocks, and others in sheep-skin cloaks; Persians and Afghauns, in brown woollen tunics, or flowing mantles, and caps of black sheep-skin or coloured silk; Khyberees, with the straw sandals, and the wild dress and air of their mountains; Hindoos, uniting the peculiar features and manners of their own nation, to the long beard and the dress of the country; and Hazaurehs not more remarkable for their conical caps of skin with the wool appearing like a fringe round the edge, and for their broad faces and little eyes, than for that want of the beard, which is the ornament of every other face in the city. Among these might be discovered a few women, with long veils that reached their feet. Sometimes, when the king was going out, the streets were choked with horse and foot, and dromedaries bearing swivels, and large waving red and green flags; and, at all times, loaded dromedaries, or heavy Bactrian camels, made their way slowly through the streets."

The Balla Hissaur, or royal residence, is a castle of no strength. It contains some fine halls and magnificent gardens; but being only occasionally occupied by the king, is much neglected. This, and a fine caravansera, are the only public edifices that deserve notice. Few of the nobility have houses at Peshawer.

Caubul is a small city not supposed to contain more than 8000 inhabitants. It is, however, compact and handsome, and has for some time been the chief residence of the court. It is also a great emporium of trade, and the number and arrangement of its bazars have excited much admiration. Its climate and scenery have been a theme of panegyric to the writers of Persia and India. It is situated in a valley encompassed by mountains, and watered by numerous streams, which maintain perpetual verdure and fertility. A single district in the neighbourhood contains no less than 6000 orchards. In the province of Caubul are situated the remains of Ghuznee, once the proud capital of Western Asia. It is now reduced to 1500 houses, but proves its ancient greatness by some lofty minarets, situated without the walls, and by the tomb of the Sultan Mahmood, placed at the distance of three miles from the city.

Candahar is a large city, though, as Mr Elphinstone apprehends, not quite equal to Peshawer. It is built of an oblong form, and on a more regular plan than is usual in Asia. Its edifices, however, are not more elegant than those of the other cities of the kingdom. It is chiefly inhabited by Afghauns, who, however, are by no means allowed to enjoy the same rude freedom as on their mountains, but are subjected to a very rigorous system of law and police.

Heraut scarcely belongs to Caubul, being governed, almost independently, by a prince of the royal blood. It is a very ancient city, and somewhat surpasses the others in magnificence, being built, in a great measure, after the Persian model. It is supposed to contain about 100,000 inhabitants.

Population.

The following table of the population of the kingdom of Caubul, founded chiefly upon conjectural data, is supposed rather to fall short of, than to exceed the truth.

Afghauns, - - -	4,300,000
Beloches, - - -	1,000,000
Tartars of all descriptions, -	1,200,000
Persians, - - -	1,500,000
Indians (Cashmerees, Jauts, &c.), -	5,700,000
Miscellaneous tribes, - -	300,000
	14,000,000

See Elphinstone's *Account of Caubul and its Dependencies.* 4to. Lond. 1815. (B.)

CAUFIRISTAUN, a mountainous country of Asia, situated partly upon the Hindoo Coosh, and partly upon the Beloor Taugh. Its boundaries are Caubul, Budukshaun, and Bulkh. This territory consists of vast mountains covered with snow, inclosing a few narrow but fertile valleys. It is inhabited by a singular people, the Caufirs, who, in religion, manners, and institutions, have remained entirely distinct from all their neighbours. Their religion is entirely Pagan, and they cherish the deadliest antipathy against the Mahometan name. To have killed a Mussulman is the highest glory at which a Caufir can aspire. Their religious observances bear no resemblance to those established in any part of India. They acknowledge a supreme Deity, whom they call Imra; and, in their ceremonies, represent him by a stone called Imrtan, or the holy stone. But they observe, "This stands for him, but we know not his shape." They have besides numerous inferior deities, consisting chiefly of deceased Caufirs, who have distinguished themselves by any eminent qualities. The best mode of securing an apotheosis, is by giving numerous feasts to the village, hospitality and good cheer being held by this people in the highest veneration. The Caufirs are in almost continual war with their neighbours. They sometimes openly attack, but more commonly seek to surprise, their enemy. On succeeding, they set up a war-cry, sing a song of triumph, and massacre all without distinction. Numerous privileges are attached to the having killed a Mussulman. He who has performed this exploit, may wear a turban stuck with feathers, may flourish his axe over his head in the dance, and may set up a pole before his door, with a pin stuck in it for every slaughtered enemy. Their arms are bows, four and a half feet long, with light arrows, sometimes poisoned. When pursued, they unbend their bows, and use them as poles, by the aid of which they leap from rock to rock with astonishing agility. About thirty years ago, all their neighbours united in a general confederacy for the

Caufiristaun || Cavallo.

extirpation of the Caufirs. They penetrated the country in every direction, but found themselves unable to maintain their ground, and were soon obliged to retire with considerable loss.

The Caufirs are hospitable in the extreme. A stranger arriving at one of their villages is not only welcomed, but is expected to visit each of the principal men, where he is regaled with every dainty which the house can afford. Their wealth consists of cattle and slaves; the latter are always their own countrymen, as they never spare the life of a Mussulman. The government is chiefly conducted by consultations among the rich men. Their dress consists principally of goat-skins, with the hair turned outwards, two of which form a vest, and other two a kind of petticoat. They are less addicted to hunting than the Afghauns. The favourite amusement is dancing, of which they never tire. They cannot accommodate themselves to the Asiatic practice of seating themselves cross-legged on the ground, but sit in the European manner on benches and stools. They also use tables, and drink wine copiously, though not to intoxication, out of silver cups. These European habits have given rise to the hypothesis of their being a Greek colony, left during the expedition of Alexander; but all probability of this seems destroyed by the circumstance that their language contains no Greek admixture, and is closely allied to the Sanscrit. The two chief towns, or rather villages, of the Caufirs, are Caumdaish and Tsokooee. The former contains five hundred houses. See Mr Elphinstone's valuable *Account of Caubul*. (B.)

CAVALLO (TIBERIUS), an electrician and natural philosopher; born at Naples 30th March 1749; and son of a physician established in that city.

His father died when he was only eleven years old; but he received a liberal education through the kindness of his friends, and completed his studies at the University of Naples. He was originally destined for commerce, and came to England in 1771, in order to obtain more complete information respecting the various objects of mercantile pursuit. But he soon abandoned his intention of adopting that mode of life, and determined to devote his time almost exclusively to the cultivation of science, and to literary employments connected with it. The splendid improvements which had been lately made in electricity, easily directed his earliest attention to that amusing department of natural philosophy; but his studies were by no means confined to that subject; and the extent of his diversified researches may be understood from an enumeration of his principal publications.

1. *Extraordinary Electricity of the Atmosphere in October* 1775. *Phil. Trans.* 1776, p. 407. This observation was made at Islington, where the author then resided; and he seems to have been in some danger of becoming, like another Richmann, a martyr to his zeal in pursuit of his favourite science; for he says that he felt a number of severe shocks, while he was holding the wire of his kite.

2. *An account of some new Electrical Experiments. Phil. Trans.* 1777, p. 48. He here describes two atmospherical electrometers, and an exhausted tube containing some quicksilver, for illustrating the nature of electrical excitation. A paper of Mr Henly, in the same volume, contains also some communications from Mr Cavallo, and in particular a remark on the opposite electricities which he detected in the bow and strings of his violin.

3. *New Electrical Experiments. Phil. Trans.* 1777, p. 388. Relating to changes of the colours of pigments, with a description of a pocket electrometer.

4. *A complete Treatise on Electricity*, 8vo. London, 1777. German by Gehler, 8vo. Leipz. 1785. French by Silvestre, 8vo. Paris, 1785. Ed. 4, 3 vols. 8vo. London, 1795.

This Essay contains a clear and familiar account of the principal facts respecting electricity, which had been discovered at the time of its publication, as well as of the best apparatus and of the most interesting experiments. The first part relates to the general laws of the science; the second to the hypothetical theories, by which different authors have attempted to explain them, but without any mention of the calculations of Alpinus and Cavendish; the third part gives an account of the practical arrangement of electrical apparatus, and the fourth of some original experiments and instruments; the fifth part in the later editions, is a republication of the author's *Essay on Medical Electricity*. To the fourth edition a third volume is added, containing an account of the recent discoveries respecting animal electricity; of the author's multiplier, for detecting the presence of small quantities of electricity, by the repeated operation of two condensers connected together; and of some original and very important experiments, relating principally to the effect of the contact of different metals with each other, and exhibiting an imperfect outline of those properties, which have since furnished Volta and Davy with their ingenious explanations of the phenomena of the electrochemical battery.

Mr Cavallo has inadvertently attributed to Nollet the honour of having first entertained the opinion of the electrical nature of thunder and lightning: the German translator has thought it necessary to vindicate the scientific character of his own country, by laying claim to this conjecture on behalf of Winkler, but Mr Silvestre has remarked, with a laudable impartiality, that both Germany and France must on this occasion give way to England, since the first suggestion of the identity is found in a paper of Stephen Gray, published in the *Philosophical Transactions* about 1735.

5. *An account of some new Experiments in Electricity. Phil. Trans.* 1780, p. 15. Consisting of remarks on Professor Lichenberg's discovery of the peculiarity of the figures exhibited by strewing powders on the cake of the electrophorus; with an account of two improved electrometers.

6. *Thermometrical Experiments and Observations. Phil. Trans.* 1780, p. 585. This was a Bakerian lecture, delivered by appointment of the President and Council of the Royal Society; an appointment which entitles the lecturer to a small fee, left by the will of Mr Henry Baker, but which is commonly considered as rather complimentary than lucrative. These experiments relate to the effect produced by colouring the bulb of a thermometer exposed to the sun's rays, and to the intensity of heat at different

Cavallo. distances from its source. The most refrangible colours appeared to absorb the most heat; and it was observed that even the day-light, without sunshine, occasioned a perceptible difference in the indications of the different thermometers.

7. *An Essay on Medical Electricity*, 8vo, London, 1780. It is seldom that persons not medical have been sufficiently incredulous in their opinions respecting the operations of remedies; and the whole of the expectation held out in this work, has certainly not been fulfilled by later experience; but, as a candid and distinct relation of cases, it may still have its value.

8. *Account of a Luminous Appearance. Phil. Trans.* 1781, p. 329. One of the permanent arches since found to be connected with the aurora borealis. It was so bright that the stars could not be seen through it, and lasted about an hour.

9. *Thermometrical Experiments. Phil. Trans.* 1781, p. 509. A Bakerian lecture, relating to the evaporation of ether, to the expansion of mercury, and to a thermometrical barometer; that is, a very delicate thermometer, for ascertaining the temperature of boiling water at different heights above the level of the sea, according to the idea then suggested by Sir George Shuckburgh, and very lately resumed by other natural philosophers. Mr Cavallo observes that the instrument has the advantage of being very portable; but that unless the quantity of water be considerable, its boiling temperature will be somewhat unsteady.

10. *A Treatise on the Air and other Permanently Elastic Fluids.* 4to, Lond. 1781. This elaborate work commences with the principles of chemistry and of hydrostatics, and proceeds to relate all the known properties of the different kinds of elastic fluids, many of which had been very lately discovered; these are followed by an account of some original experiments, for example, on the gas produced by the deflagration of gunpowder, which is found to be chiefly nitrogen and carbonic acid, without any nitric oxyd; on the explosion of hydrogen mixed with atmospheric air, and on the evolution of gas from plants, respecting which the author finds some reason to differ from the opinions of Dr Ingenhurz. Considering that Mr Cavendish had not then discovered the composition of the nitric acid, it must be allowed that the experiments on gunpowder may justly be deemed an important step in the progress of chemical science.

11. *Description of an Improved Air Pump. Phil. Trans.* 1783, p. 435. The improvement was made by Haas and Hurter, and consisted in a mode of opening the valve of oiled silk mechanically, when the elasticity of the air became too weak to raise it. The rarefaction obtained went to about the thousandth of an atmosphere: in this state the air transmitted electricity, with a light equably diffused; and the balls of the electrometer exhibited no divergence. Some later improvements are said to have carried the rarefaction to $\frac{1}{3000}$.

12. *Description of a Meteor. Phil. Trans.* 1784, p. 108. This observation was made at Windsor, and is highly valuable, from the circumstance of a noise like thunder having been heard, about ten minutes after the explosion of the meteor was seen; Cavallo. hence the author concludes that its direct distance was 130 miles, and its height $56\frac{1}{2}$.

13. *The History and Practice of Ærostation*, 8vo, Lond. A work of temporary rather than of permanent interest; but which it was the more natural for Mr Cavallo to undertake, as he was one of the first who had made experiments on the means of employing hydrogen for raising bodies into the air by its levity.

14. *Mineralogical Tables.* f. Explanation. 8vo, Lond. 1785; containing a comparison of the different systems of mineralogical arrangement then most generally adopted, but at present almost wholly superseded by later methods.

15, 16. *Magnetical Experiments and Observations. Phil. Trans.* 1786, p. 62; 1787, p. 6. Two Bakerian lectures; the former relates chiefly to the magnetism of brass, and of some other metals, generally rendered discoverable by hammering them; in the latter, the same subject is continued; and it is shown that the same powers may be detected in the metals in question without hammering them, if they are placed on a very clean and wide surface of quicksilver. The limit, at which red hot iron begins to be attracted by a magnet, is found to be the heat at which it ceases to be visible in the day-light. A considerable change is observed in the magnetic powers of iron during its solution in acids: and the author endeavours to apply these experiments to the explanation of the variation of terrestrial magnetism, as derived from the effects of heat, and from internal changes in the constitution of the earth. Mr Bennet has endeavoured to explain the phenomena observed by Mr Cavallo, from the accidental operation of foreign causes, but he has not been perfectly successful in the attempt.

17. *A Treatise on Magnetism in Theory and Practice*, 8vo. Lond. 1787. Ed. 3. 1800. The arrangement resembles that of the Treatise on Electricity: under the head of Theory the name of Alpinus is mentioned with due respect. The original experiments are chiefly reprinted from the *Philosophical Transactions:* there is also a description of an improved mode of suspension for a magnetic needle, and there are several letters from Dr Lorimer on the terrestrial variation.

18. *Of the Methods of manifesting the presence of small quantities of Electricity. Phil. Trans.* 1788. p. 1. In this Bakerian lecture, Mr Cavallo proposes an improvement on Volta's condenser, and makes some remarks on Mr Bennet's doubler, which he thinks objectionable on account of the impossibility to deprive the plate of a small quantity of electricity adhering to it. His own instrument has the advantage of avoiding the friction to which the condensers and doublers in their original form were liable.

19. *Of the Temperament of musical intervals. Phil. Trans.* 1788. p. 238. The author's particular object is to calculate the exact scale for the division of a monochord, according to the system of a perfectly equal temperament: but he very candidly remarks, that "for playing solos," the usual temperament is the best, "giving the greatest effect to those concords which occur most frequently;" and he says,

Cavallo. that when a harpsichord was tuned according to the scale laid down on this monochord, the harmony was perfectly equal throughout, and the effect "the same as if one played in the key of E natural on a harpsichord tuned in the usual manner."

20. *Description of a new electrical Instrument, capable of collecting together a diffused quantity of Electricity. Phil. Trans.* 1788, p. 255. This collector consists of a fixed plate of tin, situated between two moveable ones; it is said to be more certain in its operation than the condenser, the results of which are liable to considerable irregularities from various accidents, and to be more free from the inconvenience of permanent electricity than the doubler.

21. *Description of a Micrometer. Phil. Trans.* 1791, p. 283. *Description and use of the Mother of Pearl Micrometer.* 8vo. Lond. 1793. A thin slip of mother of pearl with a fine scale engraved on it, placed in the focus of the eye-piece of a telescope: its principal use is for ascertaining the distance of an object, of known dimensions, by its apparent magnitude thus measured; for instance, for judging of the distance of a body of troops, in military operations: the mother of pearl is found to be more convenient than glass for receiving the divisions, and to be sufficiently transparent for transmitting the images of the respective objects.

22. *On the Multiplier of Electricity.* Nicholson's *Journal*, I. p. 394. 1797. In this letter Mr Cavallo attempts to show the advantage of his instrument over doublers of all kinds: Mr Nicholson, in a very respectful answer, expresses his doubts whether the objections to the doubler do not arise from its extreme sensibility only, as demonstrating the existence of an electricity too weak to affect the other instruments compared with it: Mr Cavallo had however remarked, that the inconvenience partly arose from the greater intensity of the charge communicated to the plate of the doubler during the operation, which required a longer time for the restoration of the natural equilibrium.

23. *An Essay on the medicinal properties of factitious Airs, with an Appendix on the nature of the Blood.* 8vo. London, 1798. The modern improvements in pneumatic chemistry have been still less productive of advantage to practical medicine, than the discovery of the powers of electricity, and this work can scarcely be considered as having conferred any material benefit on the public. The observations on the blood are chiefly the result of a minute and careful microscopical examination of its particles, but the author was not particularly happy in the light which he employed for viewing them.

24. *Elements of Natural or Experimental Philosophy*, 4 vols. 8vo. Lond. 1803. This work, the last and most valuable of the author's publications, will long serve as a useful manual of the most important parts of the mechanical and physical sciences. The first volume is devoted to mathematical and practical mechanics; beginning with matter and motion, and proceeding to simple machines. The second relates, first, to fluids; to the principles of hydrostatics, cohesion, hydraulics, pneumatics, sound, and music; and secondly, to the most important parts of chemistry. In the third volume we find the doctrine of heat, optics, electricity, and magnetism; and the fourth, besides astronomy and the use of the globes, contains a compendium of the history of aerostation; an account of meteors, including the recent discoveries respecting aeroliths; and a collection of useful tables. Cavallo.

25. Mr Cavallo was also an occasional contributor to several *Periodical Publications;* and his critical articles were not in every instance anonymous. He was made a Member of the Royal Academy of Naples in 1779, and a Fellow of the Royal Society of London in the month of December of the same year.

It is impossible to hesitate in attributing to Mr Cavallo the possession of very considerable powers of mind; but these powers seem to have been of a different nature from those which have distinguished some other individuals, remarkable for the faculty of acute reasoning, and brilliant invention, and apparently born to succeed in the highest flights of genius. Mr Cavallo's talents appear to have had more of the imitative character, and to have been rather calculated for the attainment of excellence in the fine arts than in science; but his memory was uncommonly retentive, and his industry seems to have been indefatigable. He used to relate, that when he was first compelled to study Euclid, he felt himself utterly incapable of comprehending the train of argumentation, and he was obliged to get the whole work by heart, both propositions and demonstrations, in order to impress the conclusions strongly on his mind; this expedient answered his purpose very well, as long as the impression lasted; but after some years he had forgotten his task, and he was obliged to go through the whole again, in the same manner, still finding it easier to commit the eight entire books, with all the unmeaning letters of reference, to the care of his ever faithful memory, than to acquire the spirit of the mode of reasoning, and to anticipate the steps of the demonstration; although, after having performed this second labour, he felt himself sufficiently master of the subject. It may be observed that he possessed considerable skill in music; and music was called by the ancients an imitative art; a description which may indeed be somewhat objectionable, with regard to the province of the original composer, who creates something altogether unlike what had ever before existed; but which may not improperly be applied to the occupation of a performer; and Mr Cavallo, even when his hearing was impaired, still retained a very correct taste in the execution of vocal music. He possessed also his country's aptitude for the painter's art; and he was particularly happy in cutting out striking likenesses of his acquaintances in paper. The principal object of his life was to collect and arrange the labours of others; and he was so much in the habit of collecting, that he had for many years made it his amusement to collect specimens of the hand writing of eminent persons, which he had extended to an immense number of individuals, of different ages and countries. But he was by no means incapable of copying from the great book of nature; and he made, in the course of his various researches, a number of original experiments, well calculated to

Cavallo || Cavan.

illustrate particular questions, relating to the sciences which he cultivated. In the latter part of his life, he had discontinued his attendance at the meetings of the Royal Society, as well as his contributions to the *Transactions;* but he was in the habit of frequenting some other literary conversations, at which he constantly met some of his oldest and kindest friends. A short time before his last illness, he was engaged in some experiments on Mr Deluc's perpetual pile of paper, and on the electricity of different specimens of crystals; but he does not appear to have obtained any new results from these investigations. He died at his residence in Wells Street, on the 26th of December 1809, and was buried in St Pancras Church Yard, near the tomb of General Paoli, with whom he had long been on terms of the greatest intimacy. *Literary Memoirs of Living Authors;* Dance's *Collection of Portraits; Gent. Mag.* 1809; *Suppl. Monthly Mag.* 1810. p. 86; Aikin's *General Biography,* Vol. X.; Chalmers's *Biographical Dictionary,* Vol. VII. (X. A.)

Extent and Divisions.

CAVAN, County, is situated midway between the Irish Sea and the Atlantic Ocean, from the shores of which its eastern and western extremities are each distant about 14 miles. Its boundaries towards the north are the mountains of Ballynageerah and Slieve Russel, and the waters of Lough Erne; the mountains of Leitrim mark its western extremity, while Bruce hill rises abruptly on the south. Its greatest length, from east to west, is about 51 English miles; and its greatest breadth, from north to south, 28 miles. Its area contains 758 square miles, or about 499,957 English acres. It is divided into seven baronies; Castleraghan, Clonmahon, Clonkee, Upper Loughtee, Lower Loughtee, Tullygarvy, Tullyhanco, and Tullyhan; and contains 30 parishes, of which 26, with 24 churches, are in the diocese of Kilmore, three in the diocese of Ardagh, and one in that of Meath. The principal places in it are Cavan, Kilmore, the see of a Bishop, Killyshandra, Belturbet, and Virginia; but they are all very small.

Face of the Country.

Cavan is almost entirely covered with hills; and in the north, the surface, soil, and climate, are equally bleak and uncomfortable. In some places, however, the appearance of the country is more favourable, especially in the vicinity of Farnham. Bogs and lakes are very numerous; so that, according to Mr Young, they, together with the hills, occupy at least half the county. The greatest part of the waters, which issue from the lakes of West Meath, flow through Cavan, till they discharge themselves into Lough Erne, and in their passage, in some places, they expand into small lakes, and in others, retain the appearance and character of rivers. The shores of many of these lakes are very beautiful. The form and outline of Lough Ramor, near Virginia, are good, but the banks are flat; towards the upper end of it, there is some little wood. It contains pike and trout. Near Bruce hill is the great lake of Gawnagh, out of which the Erne flows. Between Bailyborough and King's Court, on the summit of a mountain, is a famous pool, called Lough-an-Leighaghs, or the healing lake. To its waters many healing virtues are ascribed; but its natural peculiarities are more undoubted. It is never observed above a stated level; it has no visible outlet, nor any apparent source from which it derives its waters; and it never has been found to vary in temperature. Its extent is not above one square rood; on the surface the water is clear, but deeper it is muddy; and its medicinal qualities are said to reside in this mud. Perhaps the finest lakes in the county, with respect to picturesque beauties, are those near Farnham, which communicate with each other by a river.

The principal river is the Erne; the source of it has been already noticed; it flows through the barony of Tullyhanco, where it forms the extensive Lough Oughter, containing many islands, among which is Cloghter, where Bishop Bedel was confined by the rebels, in 1641. From this lough the Erne flows with an increased stream to Belturbet, and discharges itself into Lough Erne.

Soil.

There is not much variety of soil in this county; in the north it consists principally of a cold, wet clay. Near Farnham, it is a good loam, lying on slaty gravel, limestone, or blue whinstone; from Cavan to Belturbet, it is dry, rocky, and rough; from Kellyshandra to Knockwinn, dry gravel; and from Cavan to Virginia, heathy. In many parts, especially about Kilmore, there is plenty of limestone, but it is little used for agricultural purposes; near Killyshandra, there are beds of marl, which is laid on the heathy moors with success. There is said to be coal in Slieve Russel, but if there is, it is not worked, as the county is supplied with it from Newry. A great deal of turf is also burnt for fuel. According to the *Natural History of Ireland* (Dublin, 1726), iron ore was formerly dug "in this county, in a place called Doubally, in a dry mountain." At present, it is not known. There are several mineral waters in Cavan, particularly at Swadlingbar, Derrylester, Derrindaff, and Owen Brien, but they have not been accurately analysed.

Agriculture.

The largest estates in this county are two of 30,000 and 26,000 acres: besides these there are none of very great extent. Nearly the whole of the land, or about three fifths, according to Mr Young, is under tillage, but the agriculture in every respect is very bad. The size of the farms is from 50 to 100 acres, but these are generally divided into farms of from two to twenty acres, which are relet to the manufacturers or "cottars," who pay a high rent for them, by means of their other employments. Their principal object is to raise a sufficient quantity of oats and potatoes to feed their families, and of flax to give employment to the women and children. Most of the land is dug with the spade and trenched as in Armagh; where the plough is used, they put three or four horses to it; and when Mr Young visited the county, he found that all over it, the horses were yoked to the plough and harrows by the tail; that practice, however, is now disused. Almost the only grain sown is oats, which are reckoned to be in the proportion of seventy to one, to all other grain; there is scarcely any wheat. In 1809, there were 4300 acres of flax, from which 6500 bushels of seed were saved. Though the very tops of the hills are tilled, yet it does not appear that this county produces more grain than is necessary for its own consumption; nor has the bounty on the inland carriage of corn to Dublin increased the very trifling quantity brought to that market. From the coldness and mois-

Cavan. ture of the climate, all the corn of Cavan is obliged to be kiln-dried.

The stock-farms generally consist of about 100 or 150 acres; the farmers buy young cattle and sell them again without fattening; a few, however, fat bullocks or sheep, but the latter are very poor. There are very few dairy farms, though from these, as they are in the richest parts of the county, a good deal of butter is sent. Many pigs are kept by the cottars; and near all the cabins are to be seen goats tethered to the tops of the banks, or "ditches," as they are here called, which divide the fields.

Woods. Cavan was formerly celebrated for its extensive woods, and trees of an immense size; but, at present, it is in general bare of timber, except near Kilmore, Farnham, and a few other places. Mr Wakefield remarks, that the ash is confined to parts of this county, and to Tyrone and Fermanagh.

Manufactures. The linen manufacture is the staple; chiefly a thin linen seven-eighths wide. The weaving of it, however, is not so general as the spinning of the flax, which is the principal employment of the women and children in all parts of the county. Killyshandra and Coothill are the principal markets for linen; in the latter, great quantities of brown linen are sold. There are several bleaching-greens in the county. It is probable, however, that the cotton manufacture will root out that of linen, as, from the greater demand for cotton goods, it has already induced the manufacturers of Cavan to turn much of their attention to it. The food of the inhabitants is very plain and frugal, being little else besides oatmeal, potatoes, and milk; the two first are the only provisions for sale in any of the markets. The labourers are paid partly in money and partly in goods, and the weavers till enough for their own food.

County Cess. The county cess or tax is not collected *per* acre, but by a division called a "carver." A town land is divided into so many carvers, each of which, though of a totally different extent, pays the same sum.

Population. According to Dr Beaufort, in the year 1792, there were 16,314 houses; 81,570 inhabitants; 18.4 Irish acres to a house; 3471 inhabitants to a square Irish mile; 12,928 houses of one hearth; 571 of two; 122 of three; 65 of four; 34 of five; 36 of six; 15 of seven; 13 of eight; 7 of nine; 7 of ten; 19 more than ten, and under forty-four; none returned above forty-four: 559 new, and 2763 belonging to paupers. The total 18,139. A census, taken in 1797, states the number of houses at 18,056, which, reckoning as Dr Beaufort does, five persons to a house, would give a population of 90,280. According to Mr Wakefield, this county contains at least 6000 freeholders, one half of whom, he says, neglect to enrol their names. But there were registered up to February 1815, 134 fifty pound freeholders, 177 twenty pound, and 5720 forty shillings; in all, 6031. Of these, according to the same author, 1000 are under the Earl of Farnham, and his relation Colonel Barry. The proportion of Catholics to Protestants is as five to one; but there is only one Catholic who possesses landed property to a considerable extent. The Protestants are mostly dissenters.

See Coote's *Statistical Account of Cavan*.—Dr Beaufort's *Memoir of a Map of Ireland*.—Wakefield's *Account of Ireland*.—Young's *Tour in Ireland*. (C.)

Cavanilles. CAVANILLES (Antonio Joseph), a Spanish Ecclesiastic, who devoted himself with great assiduity to the study of Botany, and has published several important works, was born in 1745 at Valencia. He received his first education among the Jesuits in that university, and he ever retained the urbanity of character and manners characteristic of that celebrated order of men. These were, in him, accompanied with more estimable qualities of the heart than are usually attributed to that order, or than any other exclusively possesses. He early devoted himself to the studies of divinity and philosophy, and was distinguished for diligence and ability, not only in these pursuits, but in the mathematics, history, and belles lettres. He afterwards removed to Murcia, where he acquired so much credit, that he was chosen by the late Duke de l'Infantado to superintend the education of his sons. In the house of this nobleman he was perfectly domesticated, and when, after a course of years, the death of his patron broke up a circle of more than usual domestic virtue and felicity, at least in that elevated rank of life, the Abbé Cavanilles became only a more valuable and confidential friend of the survivors. He accompanied the sons of the Duke, in their father's lifetime, to Paris in 1777, where he resided twelve years, adding to his various information, and particularly cultivating the science of Botany, with all the aids which that celebrated capital was so well calculated to afford. Here he was more particularly associated with the famous Jussieu, and the pupils of his school. From the Linnæan botanists of Paris he was a good deal estranged. Yet he acquired a great inclination towards the Swedish school, and imbibed many of its good principles.

The first publication of the Abbé Cavanilles was in French, entitled *Observations sur l'article "Espagne" de la nouvelle Encyclopédie*. This pamphlet contained a defence of his country, against what appeared to him an unfair attack upon it; but we know not the particular subjects of the discussion. We have no difficulty in conceiving that they might be manifold, and that there were few opinions upon which a man of Cavanilles' correctness and orthodoxy of character, to say nothing of his patriotism, was likely to agree with the writers of the above mentioned celebrated work.

He soon after devoted himself to a study which promised him a less thorny path. In 1785 he published at Paris his first *Dissertation upon Monadelphous Plants*, a Latin 4to, containing the species of the genus *Sida*, with some plants nearly related thereto. The plates, uncoloured, were executed from his own drawings; as were those of the rest of his numerous publications. The specimens delineated in this first essay, were too small and imperfect. In that respect his following dissertations, making ten in all, have a considerable superiority. His subsequent figures were also better engraved. The descriptions are full and correct; the new species numerous; and the specific characters tolerably classical, though not quite uncontaminated by the feebleness and ambiguity of the French school. This work, in its beginning, not being received by the Linnæan botanists of Paris, and especially by L'Heritier, with

any respectful attention, the author, in an evil hour, was induced to complain, in the *Journal de Paris*, of neglect, and of injustice. L'Heritier had not noticed the book in his *Stirpes Novæ;* had published the same plants by different names, without citing Cavanilles; and had even antedated some of his own *Fasciculi*, to conceal, as it appeared, this literary incorrectness. His reply could not, in the opinion of unprejudiced witnesses, clear him of illiberal conduct; though, it is very certain, he neither did nor could borrow any thing from Cavanilles. It would have been better to have declared the truth; that his own plates were already engraved with different names, or that he had at least chosen such as seemed to him preferable. The authority of L'Heritier's works, by their transcendent merit, has prevailed, while Cavanilles has retained all the credit due to correctness of principle and intention. The 9th and 10th *fasciculi* of Cavanilles, on the *Monadelphous* Plants, were indeed published at Madrid, to which place the author returned in 1790. The number of plates, in the whole work, are 296, many of which, especially in the earlier part, contain several species. It cannot be denied that the merit of this work kept increasing as it advanced. The abilities of the writer gained strength by exercise, and his knowledge was enriched by experience. He is charged with admitting, as *monadelphous*, too many plants, the union of whose stamens is very slight or uncertain; but it were ungrateful to complain of any book for the riches of its materials. A more real fault is, that usual one, of too great, and artificial, a subdivision of genera. This is also the fault of the school in which he studied, though the great man at its head is perhaps as free from it as any leading writer.

Soon afterwards the Abbé Cavanilles began a larger and more comprehensive publication, in folio, entitled, *Icones et Descriptiones Plantarum quæ aut sponte in Hispania crescunt, aut in Hortis hospitantur.* The first volume appeared in 1791, containing 100 plates, with ample descriptions. It was followed by five more, of equal size and merit, the last of which came out in 1801. The whole work is enriched with critical remarks, and with much economical, as well as what may be called picturesque and sentimental, matter, respecting many native Spanish plants. The exotic part of these volumes is derived from the highly valuable and novel discoveries of the Spaniards in Mexico, Peru, and Chili, and the acquisitions of some voyagers to New Holland and the Philippine Islands. Hence numerous very fine plants, originally discovered by our own celebrated circumnavigators, but unfortunately not yet published by them, have first been made known in the pages of Cavanilles.

In the course of the botanical tours of our author, he collected materials for a general *History of the Kingdom of Valencia*, which appeared in 1795, in Spanish, making two volumes. This work, which we have never seen, is said to be rich, not only in what relates to the three kingdoms of nature, but likewise in statistic and antiquarian information.

Having, in June 1801, been entrusted with the Directorship of the Royal Garden at Madrid, he published in 1802, another work in his native tongue, containing the characters and descriptions of the plants demonstrated in his public botanical lectures. To these are prefixed an exposition of the elementary principles of the science, with explanations of botanic terms. Cavanilles was also a frequent and important contributor to the periodical work, entitled *Anales de Ciencias Naturales*, published at Madrid. Some observations of his, translated from thence, may be found in Dr Sim's and Mr König's *Annals of Botany*, Vol. I. 409. The first of these indeed, relative to certain seemingly lenticular bodies, supposed to have an important share in the impregnation of ferns and mosses, he has himself contradicted, as arising from an optical deception. His candid avowal of this, in a letter to Dr Swartz, is published in volume second of the said *Annals*, p. 587. We think him also mistaken in the true stigma of the *Iris*, his opinion being sufficiently refuted by those of Kolreuter and Sprengel, given in a note, in the very place just quoted; nor is his idea of the stamens of certain *Asclepiadeæ* correct. If he errs however, he errs with great authorities.

The subject of our present memoir undoubtedly excelled more in practical observation, than in physiological speculation. He is said to have prepared, and partly printed, the first volume of a *Hortus Matritensis*, being a sort of sequel to his *Icones;* for it was intended to contain, not merely the figures and descriptions of curious or new plants from the garden, but also of rare dried specimens from the museum at Madrid. This work, with any other project in favour of science which he might have formed, was cut short by his death, in May 1804, in the fifty-ninth year of his age. An engraved portrait of the Abbé Cavanilles, at the age of forty-four, is given in Schrader's *Neues Journal*, published at Erfurt, in 1805. Dr Swartz in the *Annals of Botany* above quoted, gives this testimony to his worth. "Cavanilles was, like many others, often rather hasty in his conclusions; but always eager to promote science. He was, indeed, a man of a very noble mind, and of the most generous communicative turn; so that I feel I have lost much by his untimely decease, which I shall ever regret." In these sentiments the writer of this article most sincerely concurs. (J. J.)

CAVENDISH (HENRY), a great and justly celebrated Chemist, Natural Philosopher, and Astronomer; son of Lord Charles Cavendish, and grandson of William, second Duke of Devonshire; born the 10th of October 1731, at Nice, where his mother, Lady Anne Grey, daughter of Henry, Duke of Kent, had gone, though ineffectually, for the recovery of her health.

Of a man, whose rank, among the benefactors of science and of mankind, is so elevated as that of Mr Cavendish, we are anxious to learn all the details both of intellectual cultivation and of moral character, that the labours of a biographer can discover and record. Little, however, is known respecting his earliest education: he was for some time at Newcombe's school, an establishment of considerable reputation at Hackney; and he afterwards went to Cambridge: but it is probable that he acquired his

Cavendish.

taste for experimental investigation in great measure from his father, who was in the habit of amusing himself with meteorological observations and apparatus, and to whom we are indebted for a very accurate determination of the depression of mercury in barometrical tubes, which has been made the basis of some of the most refined investigations of modern times. "It has been observed," says M. Cuvier, "that more persons of rank enter seriously into science and literature in Great Britain than in other countries: and this circumstance may naturally be explained from the constitution of the British Government, which renders it impossible for birth and fortune alone to attain to distinction in the state, without high cultivation of the mind; so that amidst the universal diffusion of solid learning, which is thus rendered indispensable, some individals are always found, who are more disposed to occupy themselves in the pursuit of the eternal truths of nature, and in the contemplation of the finished productions of talent and genius, than in the transitory interests of the politics of the day." Mr Cavendish was neither influenced by the ordinary ambition of becoming a distinguished statesman, nor by a taste for expensive luxuries or sensual gratifications; so that, enjoying a moderate competence during his father's life, and being elevated by his birth above all danger of being despised for want of greater affluence, he felt himself exempted from the necessity of applying to any professional studies, of courting the approbation of the public either by the parade of literature or by the habits of conviviality, or of ingratiating himself with mixed society by the display of superficial accomplishments. It is difficult to refrain from imagining that his mind had received some slight impression from the habitual recurrence to the motto of his family: the words *cavendo tutus* must have occurred perpetually to his eye; and all the operations of his intellectual powers exhibit a degree of *caution* almost unparalleled in the annals of science; for there is scarcely a single instance, in which he had occasion to retrace his steps, or to recal his opinions. In 1760, he became a Fellow of the Royal Society, and continued for almost fifty years to contribute to the *Philosophical Transactions* some of the most interesting and important papers, that have ever appeared in that Collection; expressed in language which affords a model of concise simplicity and unaffected modesty; and exhibiting a precision of experimental demonstration, commensurate to the judicious selection of the methods of research, and to the accuracy of the argumentative induction; and which have been considered, by some of the most enlightened historians, as having been no less instrumental in promoting the further progress of chemical discovery, by banishing the vague manner of observing and reasoning, that had too long prevailed, than by immediately extending the bounds of human knowledge with respect to the very important facts, which are first made public in these communications.

1. *Three Papers, containing Experiments on Factitious Air.* (*Phil. Trans.* 1766, p. 141.) It had been observed by Boyle, that some kinds of air were unfit for respiration; and Hook and Mayow had looked still further forwards into futurity with prophetic glances, which seem to have been soon lost and forgotten by the inattention or want of candour of their successors. Hales had made many experiments on gases, but without sufficiently distinguishing their different kinds, or even being fully aware that fixed air was essentially different from the common atmosphere. Sir James Lowther, in 1733, had sent to the Royal Society some bladders filled with coal damp, which remained inflammable for many weeks; little imagining the extent of the advantages which were one day to result to his posterity from the labours of that society, by the prevention of the fatal mischiefs which this substance so frequently occasioned. Dr Seip had soon after suggested, that the gas which stagnated in some caverns near Pyrmont was the cause of the briskness of the water; Dr Brownrigg of Whitehaven had confirmed this opinion by experiments in 1741; and Dr Black, in 1755, had explained the operation of this fluid in rendering the earths and alkalis mild. Such was the state of pneumatic chemistry when Mr Cavendish began these experimental researches: He first describes the apparatus now commonly used in processes of this kind, a part of which had been before employed by Hales and others, but which he had rendered far more perfect, by the occasional employment of mercury. He next relates the experiments, by which he found the specific gravity of inflammable air to be about $\frac{1}{11}$ of that of common air, whether it was produced from zinc or otherwise: first weighing a bladder filled with a known bulk of the gas, and then in a state of collapse; and also examining the loss of weight during the solution of zinc in an acid, having taken care to absorb all the superfluous moisture of the gas by means of dry potass. He also observed, that the gas obtained during the solution of copper in muriatic acid was rapidly absorbed by water, but he did not inquire further into its nature. The second paper relates to fixed air, which was found to undergo no alteration in its elasticity when kept a year over mercury; to be absorbed by an equal bulk of water or of olive oil, and by less than half its bulk of spirit of wine; to exceed the atmospheric air in specific gravity by more than one half, and to render this fluid unfit for supporting combustion, even when added to it in the proportion of 1 to 9 only. Mr Cavendish ascertained the quantity of this gas contained in marble and in the alkalies; but his numbers fell somewhat short of those which have been determined by later experiments: he also observed the solubility of the supercarbonate of magnesia. In the third part, the air produced by fermentation and putrefaction is examined: Macbride had shown that a part of it was fixed air; and our author finds that sugar and water, thrown into fermentation by yeast, emit this gas, without altering the quantity or quality of the common air previously contained in the vessel, which retains its power of exploding with hydrogen, exactly like common air: he also shows that the gas thus emitted is identical with the fixed air obtained from marble; and that the inflammable air, extricated during putrefaction, resembles that which is procured from zinc, although it appeared to be a little heavier.

2. *Experiments on Rathbone Place Water. Phil.*

Cavendish. *Trans.* 1767. P. 92. In this paper Mr Cavendish shows the solubility of the supercarbonate of lime, which is found in several waters about London, and is decomposed by the process of boiling, the simple carbonate being deposited in the form of a crust: the addition of pure lime water also causes a precipitation of a greater quantity of lime than it contains. These conclusions are confirmed by synthetical experiments, in which the supercarbonate is formed, and remains in solution.

3. *An Attempt to explain some of the principal Phenomena of Electricity by means of an Elastic Fluid. Phil. Trans.* 1771. P. 584. Our author's theory of electricity agrees with that which had been published a few years before by Æpinus, but he has entered more minutely into the details of calculation, showing the manner in which the supposed fluid must be distributed in a variety of cases, and explaining the phenomena of electrified and charged substances, as they are actually observed. There is some degree of unnecessary complication from the great generality of the determinations: the law of electric attraction and repulsion not having been at that time fully ascertained, although Mr Cavendish inclines to the true supposition, of forces varying inversely as the square of the distance: this deficiency he proposes to supply by future experiments, and leaves it to more skilful mathematicians to render some other parts of the theory still more complete. He probably found, that the necessity of the experiments, which he intended to pursue, was afterwards superseded by those of Lord Stanhope and M. Coulomb; but he had carried the mathematical investigation somewhat further at a latter period of his life, though he did not publish his papers: an omission, however, which is the less to be regretted, as M. Poisson, assisted by all the improvements of modern analysis, has lately treated the same subject in a very masterly manner. The acknowledged imperfections, in some parts of Mr Cavendish's demonstrative reasoning, have served to display the strength of a judgment and sagacity, still more admirable than the plodding labours of an automatical calculator. One of the corollaries seems at first sight to lead to a mode of distinguishing positive from negative electricity, which is not justified by experiment; but the fallacy appears to be referable to the very comprehensive character of the author's hypothesis, which requires some little modification to accommodate it to the actual circumstances of the electric fluid, as it must be supposed to exist in nature.

4. *A Report of the Committee appointed by the Royal Society, to consider of a Method for securing the Powder Magazine at Purfleet. Phil. Trans.* 1773. P. 42. *Additional Letter.* P. 66. Mr Cavendish, and most of his colleagues on the committee, recommended the adoption of pointed conductors: Mr Wilson protested, and preferred blunt conductors: but the committee persisted in their opinion. Later experiments, however, have shown, that the point in dispute between them was of little moment.

5. *An Account of some Attempts to imitate the Effects of the Torpedo by Electricity. Phil. Trans.* 1776. P. 196. The peculiarity of these effects is shown to depend in some measure on the proportional conducting powers of the substances concerned, and on the quantity of electricity, as distinguished from its intensity. Iron is found to conduct 400 million times as well as pure water, and sea water 720 times as well: and the path, chosen by the electric fluid, depending on the nature of all the substances within its reach, an animal, not immediately situated in the circuit, will often be affected, on account of the facility with which animal substances in general conduct the fluid. The shock of a torpedo, producing a strong sensation, but incapable of being conveyed by a chain, was imitated by the effect of a weak charge of a very large battery: and an artificial torpedo of wood being made a part of the circuit, the shock diffused itself very perceptibly through the water in which it was placed; but the experiment succeeded better, when the instrument was made of wet leather, which conducts rather better than wood, the battery being more highly charged, in proportion to the increase of conducting power.

6. *An Account of the Meteorological Instruments used at the Royal Society's House. Phil. Trans.* 1776. P. 375. Of the thermometers it is observed, that they are adjusted by surrounding the tubes with wet cloths or with steam, and barely immersing the bulbs in the water; since a variation of two or three degrees will often occur, if these precautions are neglected. For the correction of the heights of barometers, we have Lord Charles Cavendish's table of the depression arising from capillary action. The variation compass was found to exhibit a deviation from the meridian 15′ greater in the house of the Royal Society than in an open garden in Marlborough Street: there was also a mean error of about 7′ in the indications of the dipping needle; but it was difficult to ascertain the dip, without being liable to an irregularity, which often amounted to twice as much.

7. *Report of the Committee appointed to consider of the best Method of adjusting Thermometers. Phil. Trans.* 1777. P. 816. This paper is signed by Mr Cavendish and six other members, but it is principally a continuation of the preceding. It contains very accurate rules for the determination of the boiling point, and tables for the correction of unavoidable deviations from them: establishing 29.8 inches as the proper height of the barometer for making the experiment, if only steam be employed, and 29.5 if the ball be dipped in the water: but with all precautions, occasional variations of half a degree were found in the results.

8. *An Account of a New Eudiometer. Phil. Trans.* 1783. P. 106. Mr Cavendish was aware of the great difference in the results of eudiometrical experiments with nitrous gas, or nitric oxyd, according to the different modes of mixing the elastic fluids; and he justly attributes them to the different degrees of oxygenization of the acid that is formed. But he found that when the method employed was the same, the results were perfectly uniform; and he ascertained in this manner that there was no sensible difference in the constituent parts of the atmosphere under circumstances the most dissimilar: the air of London, with all its fires burning in the winter, ap-

pearing equally pure with the freshest breezes of the country. He also observed the utility of the sulfurets of potass and of iron for procuring phlogisticated air; but he does not seem to have employed them as tests of the quantity of this gas contained in a given mixture.

9. *Observations on Mr Hutchins's Experiments for determining the degree of Cold at which Quicksilver freezes. Phil. Trans.* 1783. P. 303. In experiments of this kind, many precautions are necessary, principally on account of the contraction of the metal at the time of its congelation, which was found to amount to about $\frac{1}{23}$ of its bulk; and the results which had been obtained, were also found to require some corrections for the errors of the scales, which reduced the degree of cold observed to 39° below the zero of Fahrenheit, or 71° below the freezing point, answering to —39.4° of the centesimal scale. In speaking of the evolution of heat during congelation, he calls it "generated" by the substances, and observes, in a note, that Dr Black's hypothesis of capacities depends "on the supposition that the heat of bodies is owing to their containing more or less of a substance called the matter of heat; and as" he thinks "Sir Isaac Newton's opinion, that heat consists in the internal motion of the particles of bodies, much the most probable," he chooses "to use the expression heat is generated," in order to avoid the appearance of adopting the more modern hypothesis; and this persuasion, of the nonexistence of elementary heat, he repeats in his next paper. It is remarkable that one of the first of Sir Humphry Davy's objects, at the very beginning of his singularly brilliant career of refined investigation and fortunate discovery, was the confirmation of this almost forgotten opinion of Mr Cavendish; and for this purpose he devised the very ingenious experiment of melting two pieces of ice by their mutual friction in a room below the freezing temperature, which is certainly incompatible with the common doctrine of caloric, unless we admit that caloric could have existed in the neighbouring bodies in the form of cold, or of something else that could be converted into caloric by the operation; and this transmutation would still be nearly synonymous with generation, in the sense here intended. However this may be, it is certain that, notwithstanding all the experiments of Count Rumford, Dr Haldalt, and others, Sir Humphry has been less successful in persuading his contemporaries of the truth of Mr Cavendish's doctrine of heat, than in establishing the probability of his opinions respecting the muriatic acid.

10. *Experiments on Air. Phil. Trans.* 1784. P. 119. This paper contains an account of two of the greatest discoveries in chemistry that have ever yet been made public: the composition of water, and that of the nitric acid. The author first establishes the radical difference of hydrogen from nitrogen or azote; he then proceeds to relate his experiments on the combustion of hydrogen with oxygen, which had partly been suggested by a cursory observation of Mr Warltire, a Lecturer on Natural Philosophy, and which prove that pure water is the result of the process, provided that no nitrogen be present. These experiments were first made in 1781, and were then mentioned to Dr Priestley; and when they were first communicated to Lavoisier, he found some difficulty in believing them to be accurate. The second series of experiments demonstrates, that when phlogisticated air, or nitrogen, is present, in the process, some nitric acid is produced; and that this acid may be obtained from atmospheric air, by the repeated operation of the electrical spark.

It has been supposed by one of Mr Cavendish's biographers, that if Mr Kirwan, instead of opposing, had adopted his chemical opinions, "he would never have been obliged to yield to his French antagonists, and the antiphlogistic theory would never have gained ground." But in this supposition there seems to be a little of national prejudice. Mr Cavendish by no means dissented from the whole of the antiphlogistic theory: and in this paper, he has quoted Lavoisier and Scheele in terms of approbation, as having suggested the opinion "that dephlogisticated and phlogisticated air are quite distinct substances, and not differing only in their degree of phlogistication, and that common air is a mixture of the two." He afterwards mentions several memoirs of Lavoisier in which phlogiston is entirely discarded; and says that "not only the foregoing experiments, but most other phenomena of nature, seem explicable as well, or nearly as well, upon this, as upon the commonly believed principle of phlogiston;" and after stating a slight conjectural objection, derived from the chemical constitution of vegetables, he proceeds finally to observe, that "Lavoisier endeavours to prove, that dephlogisticated air is the acidifying principle:" this is no more than saying, that acids lose their acidity by uniting to phlogiston, which, with regard to the nitrous, vitriolic, phosphoric, and arsenical acids, is certainly true; and probably with regard to the acid of sugar; "but as to the marine acid, and acid of tartar, it does not appear that they are capable of losing their acidity by any union with phlogiston;" and the acids of sugar and tartar become even less acid by a further dephlogistication. It is obvious that this argument amounts only to an exception, and not to a total denial of the truth of the theory: M. Cuvier has even asserted that the antiphlogistic theory derived its first origin from one great discovery of Mr Cavendish, that of the nature of hydrogen gas, and owed its complete establishment to another, that of the composition of water: but it would be unjust to deny to Lavoisier the merit of considerable originality in his doctrines respecting the combinations of oxygen; and however he may have been partly anticipated by Hooke and Mayow, it was certainly from him that the modern English chemists immediately derived the true knowledge of the constitution of the atmosphere, which they did not admit without some hesitation, but which they did ultimately admit, when they found the evidence irresistible. On the other hand, it has been sufficiently established, since Mr Cavendish's death, by the enlightened researches of the most original of all chemists, that Lavoisier had carried his generalization too far; and it must ever be remembered, to the honour of Mr Cavendish, and to the credit of this country, that we had not all been seduced, by the dazzling semblance of

Cavendish. universal laws, to admit facts as demonstrated, which were only made plausible by a slight and imperfect analogy.

11. *Answer to Mr Kirwan's Remarks upon the Experiments on Air. Phil. Trans.* 1784. P. 170. Mr Kirwan, relying on the results of some inaccurate experiments, had objected to those conclusions, which form the principal basis of the antiphlogistic theory. Mr Cavendish repeated such of these experiments as seemed to be the most ambiguous, and repelled the objections: showing, in particular, that when fixed air was derived from the combustion of iron, it was only to be referred to the plumbago, shown by Bergmann to exist in it, which was well known to be capable, in common with other carbonaceous substances, of affording fixed air.

12. *Experiments on Air. Phil. Trans.* 1785. P. 372. The discovery of the composition of the nitric acid is here further established; and it is shown that the whole, or very nearly the whole of the irrespirable part of the atmosphere is convertible into this acid, when mixed with oxygen, and subjected to the operation of the electric spark: the fixed air, sometimes obtained during the process, being wholly dependent on the presence of some organic substances.

13. *An account of Experiments made by Mr John Macnab, at Henley House, Hudson's Bay, relating to Freezing Mixtures. Phil. Trans.* 1786. P. 241. From these experiments Mr Cavendish infers the existence of two distinct species of congelation in mixed liquids, which he calls the Aqueous and Spirituous Congelations, and of several alternations of easy and difficult congelation when the strength is varied, both in the case of the mineral acids and of spirit of wine. The greatest degree of cold obtained was $-78\frac{1}{2}°$.

14. *An account of Experiments made by Mr John Macnab, at Albany Fort, Hudson's Bay. Phil. Trans.* 1788. P. 166. The points of easy congelation are still further investigated, and illustrated by comparison with Mr Keir's experiments on the sulfuric acid. It was found that the nitric acid was only liable to the aqueous congelation, unless it was strong enough to dissolve $\frac{1}{4}$th of its weight of marble; and that it had a point of easy congelation, when it was capable of dissolving $\frac{415}{1000}$, the frozen part exhibiting, in other cases, a tendency to approach to this standard. Mr Keir had found that sulfuric acid, of the specific gravity 1.78, froze at 46°; and that it had another maximum when it was very highly concentrated.

15. *On the Conversion of a Mixture of Dephlogisticated and Phlogisticated Air into Nitrous Acid, by the Electric Shock. Phil. Trans.* 1788. P. 261. Some difficulties having occurred to the Continental chemists in the repetition of this experiment, it was exhibited with perfect success, by Mr Gilpin, to a number of witnesses. This was an instance of condescension, which could scarcely have been expected from the complete conviction, which the author of the discovery must have felt, of his own accuracy, and of the necessity of the establishment of his discovery, when time should have been afforded for its examination.

16. *On the Height of the Luminous Arch, which was seen on Feb. 23. 1784. Phil. Trans.* 1790. P. 101. Mr Cavendish conjectures that the appearance of such arches depends on a diffused light, resembling the aurora borealis, spread into a flattened space, contained between two planes nearly vertical, and only visible in the direction of its breadth: so that they are never seen at places far remote from the direction of the surface; and hence it is difficult to procure observations sufficiently accurate for determining their height, upon so short a base: but in the present instance there is reason to believe that the height must have been between 52 and 71 miles. Cavendish.

17. *On the Civil Year of the Hindoos, and its Divisions, with an Account of three Almanacs belonging to Charles Wilkins, Esq. Phil. Trans.* 1792. P. 383. The subject of this paper is more intricate than generally interesting; but it may serve as a specimen of the diligence which the author employed in the investigation of every point more or less immediately connected with his favourite objects. The month of the Hindoos is lunar in its duration, but solar in its commencement; and its periods are extremely complicated, and often different for different geographical situations: the day is divided and subdivided sexagesimally. The date of the year, in the epoch of the Kalee Yug, expresses the ordinal number of years elapsed, as it is usual with our astronomers to reckon their days: so that the year 100 would be the beginning of the second century, and not the 100th year, or the end of the first century, as in the European calendar: in the same manner as, in astronomical language, 1817 December 31d. 18h. means six o'clock in the morning of the 1st of January 1818.

18. *Experiments to determine the Density of the Earth. Phil. Trans.* 1798. P. 469. The apparatus, with which this highly important investigation was conducted, had been invented and constructed many years before by the Reverend John Michell, who did not live to perform the experiments for which he intended it. Mr Cavendish, however, by the accuracy and perseverance with which he carried on a course of observations of so delicate a nature, as well as by the skill and judgment with which he obviated the many unforeseen difficulties that occurred in its progress, and determined the corrections of various kinds which it was necessary to apply to the results, has deserved no less gratitude from the cultivators of astronomy and geography, than if the idea had originally been his own. The method employed was to suspend, by a vertical wire, a horizontal bar, having a leaden ball at each end; to determine the magnitude of the force of torsion by the time occupied in the lateral vibrations of the bar; and to measure the extent of the change produced in its situation by the attraction of two large masses of lead, placed on opposite sides of the case containing the apparatus, so that this attraction might be compared with the weight of the balls, or, in other words, with the attraction of the earth. In this manner the mean density of the earth was found to be $5\frac{1}{2}$ times as great as that of water; and although this is considerably more than had been inferred from Dr Maskelyne's observations on the attrac-

tion of Shehallion, yet the experiments agree so well with each other, that we can scarcely suppose any material error to have affected them. Mr Michell's apparatus resembled that which M. Coulomb had employed in his experiments on magnetism, but he appears to have invented it before the publication of M. Coulomb's Memoirs.

19. *On an Improved Method of Dividing Astronomical Instruments. Phil. Trans.* 1809. P. 221. The merits of this improvement have not been very highly appreciated by those who are in the habit of executing the divisions of circular arcs. It consists in a mode of employing a microscope, with its cross wires, as a substitute for one of the points of a beam compass, while another point draws a faint line on the face of the instrument in the usual manner. The Duke de Chaulnes had before used microscopical sights for dividing circles; but his method more nearly resembled that which has been brought forwards in an improved form by Captain Hater; and Mr Cavendish, by using a single microscope only, seems to have sacrificed some advantages which the other methods appear to possess: but none of them has been very fairly tried; and our artists have hitherto continued to adhere to the modes which they had previously adopted, and which it would perhaps have been difficult for them to abandon, even if they had been convinced of the advantages to be gained by some partial improvements.

Such were the diversified labours of a philosopher, who possessed a clearness of comprehension, and an acuteness of reasoning, which had been the lot of very few of his predecessors since the days of Newton. Maclaurin and Waring, perhaps also Stirling and Landen, were incomparably greater mathematicians; but none of them attempted to employ their powers of investigation in the pursuit of physical discovery: Euler and Lagrange, on the Continent, had carried the improvements of analytical reasoning to an unparalleled extent, and they both, as well as Daniel Bernoulli and D'Alembert, applied these powers with marked success to the solution of a great variety of problems in mechanics and in astronomy: but they made no experimental discoveries of importance: and the splendid career of chemical investigation, which has since been pursued with a degree of success so unprecedented in history, may be said to have been first laid open to mankind by the labours of Mr Cavendish: although the further discoveries of Priestley, Scheele, and Lavoisier, soon furnished, in rapid succession, a superstructure commensurate to the extent of the foundations so happily laid. "Whatever the sciences revealed to Mr Cavendish," says Cuvier, "appeared always to exhibit something of the sublime and the marvellous: he weighed the earth; he rendered the air navigable: he deprived water of the quality of an element:" and he denied to fire the character of a substance. "The clearness of the evidence on which he established his discoveries, so new and so unexpected as they were, is still more astonishing than the facts themselves which he detected: and the works, in which he has made them public, are so many masterpieces of sagacity and of methodical reasoning: each perfect as a whole and in its parts; and leaving nothing for any other hand to correct; but rising in splendour with each successive year that passes over them; and promising to carry down his name to a posterity far more remote than his rank and connections could ever have enabled him to attain without them."

In his manners Mr Cavendish had the appearance of a quickness and sensibility almost morbid, united to a slight hesitation in his speech, which seems to have depended more on the constitution of his mind, than on any deficiency of his organic powers, and to an air of timidity and reserve, which sometimes afforded a contrast, almost ludicrous, to the sentiments of profound respect which were professed by those with whom he conversed. It is not impossible that he may have been indebted to his love of severe study, not only for the decided superiority of his faculties to those of the generality of mankind, but even for his exemption from absolute eccentricity of character. His person was tall, and rather thin: his dress was singularly uniform, although sometimes a little neglected. His pursuits were seldom interrupted by indisposition; but he suffered occasionally from calculous complaints. His retired habits of life, and his disregard of popular opinion, appear to have lessened the notoriety which might otherwise have attached to his multiplied successes in science; but his merits were more generally understood on the Continent than in this country; although it was not till he had passed the age of seventy that he was made one of the eight Foreign Associates of the Institute of France.

Mr Cavendish was no less remarkable in the latter part of his life, for the immense accumulation of his pecuniary property, than for his intellectual and scientific treasures. His father died in 1783; being at that time eighty years old, and the senior member of the Royal Society: but he is said to have succeeded at an earlier period to a considerable inheritance left him by one of his uncles. He principally resided at Clapham Common; but his library was latterly at his house in Bedford Square; and his books were at the command of all men of letters, either personally known to him, or recommended by his friends: indeed the whole arrangement was so impartially methodical, that he never took down a book for his own use, without entering it in the loan book; and after the death of a German gentleman, who had been his librarian, he appointed a day on which he attended in person every week for the accommodation of the few, who thought themselves justified in applying to him for such books as they wished to consult. He was constantly present at the meetings of the Royal Society, as well as at the conversations held at the house of the President; and he dined every Thursday with the club composed of its members. He had little intercourse with general society, or even with his own family, and saw only once a year the person whom he had made his principal heir. He is said to have assisted several young men, whose talents recommended them to his notice, in obtaining establishments in life; but in his later years, such instances were certainly very rare. His tastes and his pleasures do not seem to have been in unison with those, which are best adapted to the generality of mankind; and amidst the abundance of all the means of acquiring every earthly enjoyment, he must have wanted that sympathy, which alone is capable of redoubling our delights, by the consciousness

Cavendish.

that we share them in common with a multitude of our friends, and of enhancing the beauties of all the bright prospects that surround us, when they are still more highly embellished by reflection "from looks that we love." He could have had no limitation either of comfort or of luxury to stimulate him to exertion; even his riches must have deprived him of the gratification of believing, that each new triumph in science might promote the attainment of some great object in life that he earnestly desired; a gratification generally indeed illusory, but which does not cease to beguile us till we become callous as well to the pleasures as to the sorrows of existence. But in the midst of this "painful preeminence," he must still have been capable of extending his sensibility over a still wider field of time and space, and of looking forwards to the approbation of the wise and the good of all countries and of all ages: and he must have enjoyed the highest and purest of all intellectual pleasures, arising from the consciousness of his own excellence, and from the certainty that, sooner or later, all mankind must acknowledge his claim to their profoundest respect and highest veneration.

"It was probably either the reserve of his manners," says Cuvier, "or the modest tone of his writings, that procured him the uncommon distinction of never having his repose disturbed either by jealousy or by criticism. Like his great countryman Newton, whom he resembled in so many other respects, he died full of years and honours, beloved even by his rivals, respected by the age which he had enlightened, celebrated throughout the scientific world, and exhibiting to mankind a perfect model of what a man of science ought to be, and a splendid example of that success, which is so eagerly sought, but so seldom obtained." The last words that he uttered were characteristic of his unalterable love of method and subordination: he had ordered his servant to leave him, and not to return till a certain hour, intending to pass his latest moments in the tranquillity of perfect solitude: but the servant's impatience to watch his master diligently having induced him to infringe the order, he was severely reproved for his indiscretion, and took care not to repeat the offence, until the scene was finally closed. Mr Cavendish died on the 24th of February 1810; and was buried in the family vault at Derby. He left a property in the funds of about L.700,000, which he divided into six equal parts, giving two to Lord George Cavendish, the son of his first cousin, one to each of his sons, and one to the Earl of Bessborough, whose mother was also his first cousin. Some other personal property devolved to Lord George as residuary legatee; and a landed estate of L. 6000 a year descended to his only brother, Mr Frederic Cavendish of Market Street, Herts, a single man, and of habits of life so peculiarly retired, that any further increase of income would have been still more useless to him than it had been to the testator.

Much as Mr Cavendish effected for the promotion of physical science throughout his life; it has not been unusual, even for his warmest admirers, to express some regret that he did not attempt to do still more after his death, by the appropriation of a small share of his immense and neglected wealth, to the perpetual encouragement of those objects, which he had himself pursued with so much ardour. But however we might be disposed to lament such an omission, we have surely no reason to complain of his determination to follow more nearly the ordinary course of distribution of his property, among those whose relationship would have given them a legal claim to the succession, if he had not concerned himself in directing it. We may observe on many other occasions, that the most successful cultivators of science are not always the most strenuous promoters of it in others; as we often see the most ignorant persons, having been rendered sensible by experience of their own deficiencies, somewhat disposed to overrate the value of education, and to bestow more on the improvement of their children, than men of profounder learning, who may possibly have felt the insufficiency of their own accomplishments for insuring success in the world. But even if Mr Cavendish had been inclined to devote a large share of his property to the establishment of fellowships or professorships, for the incitement of men of talents to a more complete devotion of their lives to the pursuit of science, it is very doubtful whether he could have entertained a reasonable hope of benefiting his country by such an institution: for the highest motives that stimulate men to exertion are not those which are immediately connected with their pecuniary interests: the senators and the statesmen of Great Britain are only paid in glory; and where we seek to obtain the cooperation of the best educated and the most enlightened individuals in any pursuit or profession, we must hold out as incentives the possession of high celebrity and public respect; assured that they will be incomparably more effectual than any mercenary considerations, which are generally found to determine a crowd of commercial speculators to enter into competition for the proposed rewards, and to abandon all further concern with the objects intended to be pursued, as soon as their avarice is gratified. To raise the rank of science in civil life is therefore most essentially to promote its progress: and when we compare the state not only of the scientific associations, but also of the learned professions in this country and among our neighbours, we shall feel little reason to regret the total want of pecuniary patronage that is remarkable in Great Britain, with respect to every independent department of letters, while it is so amply compensated by the greater degree of credit and respectability attached to the possession of successful talent. It must not however be denied, that even in this point of view there might be some improvement in the public spirit of the country: Mr Cavendish was indeed neither fond of giving nor of receiving praise; and he was little disposed to enliven the intervals of his serious studies by the promotion of social or convivial cheerfulness: but it would at all times be very easy for an individual, possessed of high rank and ample fortune, of correct taste and elegant manners, to confer so much dignity on science and literature by showing personal testimonies of respect to acknowledged merit, as greatly to excite the laborious student to the unremitting exertions of patient application, and to rouse the man of brilliant talent to the noblest flights of genius.

Gentleman's Magazine, 1810, ii. P. 188.—Aikin's *General Biography*, Vol. X.—Chalmers's *Biographical Dictionary*, Vol. VII.—Thomson's *Annals*, Vol. I.—*Cuvier, Histoire de la Classe des Sciences Mathématiques*, 1811. P. cxxvi. (L. I.)

CELEBES, an extensive island in the Indian archipelago, situated between Java and Borneo, and extending from about 2° north, to 6° south latitude, and 119° to 125° east longitude. It is of the most irregular form, consisting of four long peninsulas, united together at a central point. It was first discovered by the Portuguese in 1525. In 1660, that people were driven out by the Dutch, who had to sustain a long series of contests with the natives, till, in 1699, they succeeded in forming a permanent settlement. Their principal establishment has always been Fort Rotterdam, at Macassar, on the western coast of the island, situated in 5° 9′ south latitude, and 119° 48′ east longitude. The fort is about 800 feet from the sea, well fortified with high and strong walls. The town lies on a plain to the north, and is tolerably built; the streets broad and crossing each other at right angles. The trade is not considerable, the country affording few articles of export except rice and a number of slaves for the supply of Java. The chief object of the Dutch in this settlement, was to secure their communication with the spice islands. They had repeated attacks to sustain from the Rajah of Macassar, whose power, in 1778, they finally subverted, and transferred the superiority to their ally, the Rajah of Bony. His territory is situated round the great bay on the southern coast, called the Bay of Bony, Sewa, or Ruggess. The inhabitants are termed Bonginese, or Bonnians, corrupted by the English into Buggesses. These are a very remarkable people, and possess many excellent qualities. In a manuscript account which we have seen, written by a gentleman long resident in this part of India, they are considered as by much the most meritorious of the inhabitants of the East India islands. They manufacture the cotton of their own country, and of Java, into a species of cloths, which, from their superior quality, are in universal demand throughout the archipelago. Their permanent residence he states to be around a great lake in the interior, which they leave at the commencement of the season favourable for navigation. They then sail down a river into the bay of Bony, whence they spread themselves over all the neighbouring seas. There is not a coast from the extremity of New Holland to the Malay peninsula, in which their prows are not habitually seen. Besides exchanging their own commodities for those of their neighbours, they act as carriers between the countries that lie remote from each other. Our informant describes their conduct as traders to be not less upright and honourable than it is active and enterprising. They defend themselves and their property against the attacks of the Malay pirates with the most heroic and desperate valour. Major Thorn, in his *Account of Java*, mentions an instance in which a Bonginese crew, being overcome and boarded, set fire to a barrel of powder which was on board, and thus blew up at once themselves and their assailants.

In 1814, the Rajah of Bony being considered inimical to the British Government, an expedition against him was sent from Java under General Nightingale. It arrived at Macassar on the 7th of June, and immediately landed. The British force, led by Col. Macleod, attacked the town and palace, and carried them in about an hour, though with some loss, the Rajah escaping into the interior of his dominions. A new government was then established; but the revolution in Europe has, we believe, restored this settlement to the Dutch, its former possessors.

The interior of Celebes, and the remainder of its coasts, are almost entirely unknown. The Great Bay of Gonong Tello, on the east coast, presents many natural advantages. Gold is exported from its coasts, and the amount is said to be capable of almost indefinite augmentation. Tortoise shell is likewise produced in considerable quantity. Bentham Bay, to the south-east of Macassar, has a fort with some trade: the country round produces excellent rice.

The exports are nearly similar to those of Borneo. Gold is found, as there, in alluvial soil, washed down by the rivers. Sometimes even springs, slightly impregnated with that metal, issue from the rocks. The total value of the gold exported is estimated by Mr Hamilton at L.120,000. (*East India Gazetteer.*) The cotton cloths manufactured in Celebes, called *cambays*, are universally worn through the Indian islands; but their use does not extend farther. The imports coincide precisely with those of Borneo. (B.)

CESAROTTI (Melchior), an Italian poet, was born at Padua, in the year 1730, of a family of considerable rank but small fortune. He was educated at the academy of Padua, where he early showed a strong inclination for literary pursuits, and made such progress in study, that he was raised to the Chair of Rhetoric in the Academy where he had been brought up, at a period of life when others were yet attending the lectures. Having been appointed to this charge, he devoted himself with the utmost zeal to the duties of his situation. He introduced several useful reforms in the system of education which was then practised, and endeavoured by incessant study to render his instructions as useful as possible to the youth committed to his care. The first fruits of his studies were Italian translations of the Prometheus of Æschylus, and three Tragedies of Voltaire, the merit of which, and the reputation he had acquired for learning and persevering application, successively procured him a distinguished employment at Venice, and the Professorship of Greek and Hebrew in the University of Padua. Cesarotti had held this situation for nearly thirty years at the date of the first French invasion of Italy. This poet did not, like Alfieri, scorn the pecuniary favours of the republican government, nor shun the acquaintance of its chiefs. He published several political tracts and essays by their order; and when the general of the invading army assumed the title of King of Italy, he was rewarded with two pensions of considerable amount, and distinguished

by various honours. He continued to reside partly at Padua, and partly at his country house of Selvaggiano, chiefly occupied with the composition of laudatory poems in return for the favours he had received, and with the superintendence of a complete edition of his works, when he was suddenly arrested by the hand of death on the 3d of November 1808.

Though held by Sismondi to be the first in point of celebrity of the modern Italian poets, Cesarotti is better known as a translator than an original author. The Italians have always been distinguished for the elegance and spirit of their translations from the classics; the Lucretius of Marchetti, the Æneid of Annibal Caro, and Anguillara's free version of the Metamorphoses of Ovid have deservedly exalted their reputation to the utmost height in this department of literature. Anguillara's translation of Homer, however, had been less popular and successful than his Metamorphoses, and there still remained room in Italy for a translation of the Prince of poets. The work, however, of Cesarotti, is far from being literal; he has modernized and accommodated the Iliad to the prevailing taste of the age; he has abridged it in some places, and added to it in others, according to his taste or fancy; and he has been often reproached with having given to the Greek bard the style and language of his favourite Ossian. In the late edition of the works of Cesarotti, the poetical version is followed by a literal prose one, accompanied with critical notes and dissertations, partly translated from Pope and Dacier.

Cesarotti acquired more fame by his version of Ossian than of Homer; and certainly no translation had ever more appearance of originality and inspiration. He has completely preserved the spirit of the supposed bard of Morven—his gigantic and gloomy grandeur; and, at the same time, has given us that harmony of versification, which we miss in the work of Macpherson. The Italian Ossian was first published at Padua in 1763, 2 vols. 8vo, at the expence of an English traveller, with whom Cesarotti had contracted a friendship. This edition was necessarily incomplete, as the translation of Macpherson at that time was so also; but the whole poems were printed at the same place about ten years afterwards in 4 vols. small 8vo. The *Poems* of Ossian also occupy four volumes in the recent complete edition of the works of Cesarotti, where they are accompanied by an examination of the question so much agitated in this country, with regard to the authenticity of these celebrated productions. Their appearance in this new form attracted much attention in Italy, and raised up many imitators of the Ossianic style, so different from the warm and glowing imagery of the earlier Italian poets.

His country was also indebted to Cesarotti for a number of valuable prose works. The *Course of Greek literature* was his chief undertaking; but the plan on which he had commenced was too vast to be completed. His Essays on the *Sources of the pleasure derived from Tragedy*, and on the *Origin and Progress of the Poetic Art*, are distinguished by elegant and ingenious criticism; while his treatises *Sulla Filosofia delle Lingue, et Sulla Filosofia de Gusto* (the last of which is principally intended as an apology for the peculiarities of his own style), show considerable acuteness and strength of understanding. In 1797, an Academy of *Sciences and Belles Lettres* had been established at Padua, of which Cesarotti was nominated perpetual Secretary. It was part of the duties of this situation to read at the stated meetings of the Academy the various essays which had been prepared by its members. Frequently, however, these were of such extent, that the Secretary found it expedient merely to give, in his own language, a general account of the object of the author, and the result of his investigations. These readings produced his Reports, entitled *Relazioni Academiche*, each of which reports is divided into three parts; the first containing the Essays on Experimental Philosophy, the second on Mathematics, and the third on Belles Lettres. The whole, however, may be regarded as a literary composition, since the departments of mathematics and philosophy exhibit only general views of the subjects of inquiry. Almost all the prose works of Cesarotti are distinguished by extensive erudition and a philosophical spirit, while his style is lively and forcible. But the Italian prose of the eighteenth century was very different from that written by Giovanni Della Casa, Machiavel, and their contemporaries in the sixteenth; and those critics, who have deplored the recent innovations on the ancient purity of the Tuscan tongue, chiefly attribute to Cesarotti the introduction of those Gallicisms and new modes of expression, which have corrupted the language of the golden age of Leo.

All the works of Cesarotti above mentioned, including several volumes of correspondence, have been published in a complete edition, which was commenced at Padua in the year 1800, under the author's own direction. It has been continued since his death by Joseph Barbieri, who was his successor in the chair of Greek and Hebrew at Padua, and who has also published *Memoirs* of the Life and Writings of his deceased friend, printed at Padua, 1810, 8vo.

It has been the fate of most literary men to be ranked either higher or lower by their own age than by posterity. Cesarotti will probably belong to the former class, who, perhaps after all, enjoy the pleasanter sort of reputation. But, though the praise of great and original genius may in future times be denied him, every age will admit his learning and talents, and the meritorious assiduity of his literary researches. (M.)

CEYLON. In the *Encyclopædia* the reader will find a description of this island and its more remarkable productions; with a short summary of its history, down to the year 1796, when the maritime provinces, then in possession of the Dutch, were conquered by the arms of Britain. We now propose to continue the historical sketch to the present time; and to add such details relative to the population, productions, trade, and commerce of the island, as recent information enables us to supply.

History.

The conquered provinces remained, for a short time, as an appendage to the presidency of Madras; but were afterwards rendered independent of the East India Company, and annexed to the Crown of

Great Britain. In the year 1798, the King of Candy died, and the Crown was transferred, by the intrigues of Pelemé Talavé, the Chief Adigar, or Prime-Minister, to a young Malabar, without birth, talents, or pretensions of any kind. The policy of the Adigar was decidedly hostile to the British Government; and his object was to amuse them with delusive negociations, while he awaited a favourable opportunity for expelling them from the island. After some time spent in secret preparations for war, hostilities were at length provoked by the aggressions of the Candians, in the spring of 1802; and two divisions of the British forces were in consequence moved into the interior, from Columbo and Trincomalee, under Major-General Macdowall and Colonel Barbut. They experienced very little resistance on their march, and the two divisions formed a junction at Candy. The city, however, was found entirely deserted by the Government and inhabitants, and had been set on fire in several places. The King had removed all his treasure, and the inhabitants had carried away or destroyed everything valuable. Mootto Sawmy, the brother of the late Queen, was now removed to Candy, and placed by the British troops upon the throne; but the people of authority in the neighbouring country showed no disposition to submit to his sway. The plan of the Chief Adigar appears to have been, to draw the British troops by detachments farther into the country, and then to cut off their retreat. This design he endeavoured to execute by means of the most profound and systematic dissimulation and treachery. Having lulled the British officers into a delusive security, by the conclusion of a treaty, which was intended only for deception, a great part of the troops were withdrawn from Candy, where they had begun to suffer from the sickliness of the rainy season, and a small garrison was left in the palace, under the command of Major Davie. The Candians, perceiving the success of their treachery, drew their lines nearer to the city, and entrenched themselves in strong positions in the immediate vicinity. In the mean time, the garrison daily decreased, in consequence of death and desertion; and Major Davie, at length, found himself under the necessity of submitting to a humiliating capitulation, the terms of which were only observed by the Candians, until they had got their enemies completely into their power, when the whole detachment were wantonly and perfidiously massacred.

Elated with this success, the King of Candy now began to entertain hopes of the total expulsion of the British from the island; and a war of ravage and spoliation was carried on for some time, which is remarkable only for the barbarity with which it was conducted on both sides. The repeated invasions of the Candians, however, were uniformly repulsed with great loss; and hostilities were, at length, suspended by a sort of tacit consent, originating, probably, from the weakness of the enemy, and the pacific disposition of the British administration. Meanwhile, the many acts of tyranny and arbitrary cruelty which had been exercised by the Candian monarch, justly rendered him odious to his own subjects; and a most barbarous outrage, committed upon some unoffending inhabitants of the English settlements, at last called forth the full and final vengeance of the British government. The war, which ensued in 1815, was short, and attended with the most decisive results. The capital was taken; the King made prisoner and deposed; and a grand convention having been held of the British authorities and the Candian chiefs, a treaty was proposed and ratified, by which the dominion of the whole Island of Ceylon was vested in the Sovereign of Great Britain.

Population.

From monuments still existing in Ceylon, this island evidently appears to have been much more populous, and much better cultivated, in former times, than at present. We have no accurate *data*, indeed, from which we can form an estimate of the precise amount of the actual population of Ceylon, but it probably does not exceed one million and an half. The inhabitants may be divided into four distinct tribes or nations, viz. the Ceylonese proper, who occupy the territories formerly belonging to the King of Candy, and the south and south-west coasts; the Malabars or Hindoos, who possess the north and east coasts, and the peninsula of Jaffnapatam; the Moors, who are dispersed over every part of the island, and who may be considered as the most industrious portion of the population; and the Vedas or Bedas, who appear to be the only indigenous tribe in the island, living in a savage state in the large forest which extends from the south to the east and north, upon the borders of our old limits, and into the Candian territory. Mr Percival and Mr Cordiner make a distinction between the Ceylonese and the Candians; but according to the latest and best authorities, referred to at the end of this article, they seem to be one and the same nation; having the same origin, language, religion, and habits. The population has been rapidly increasing for some years, owing principally to the introduction of vaccination, which has been generally practised, and with great success; insomuch, that the small-pox, which formerly committed great ravages in Ceylon, has now been wholly expelled from the island. This increasing population, however, is far from being in a prosperous condition, as, for some years past, it has pressed hard upon the means of subsistence. The distress was much aggravated in the years 1812, 1813, and 1814, by repeated droughts, which proved injurious to the cultivation of rice; while, in consequence of the superabundant population, the price of labour, during this great scarcity, continued at the same low rate as formerly. The territory within the old limits of the British government, does not produce a sufficient quantity of rice for the maintenance of its own inhabitants; much of that necessary article has been, at all times, imported from the coasts of Malabar and Coromandel, and from Bengal; and a very large supply was derived from the Candian country, which produced a considerable surplus. But as the population of these districts is also upon the increase, the supply derived from that source has necessarily suffered a proportional diminution.

Chief Towns.

The principal towns on the island are Candy, Co-

Ceylon.

lumbo, Point de Galle, and Trincomalee. Of these, Columbo and Trincomalee, which are situated within the old British territory, have been already described in the body of this work. The town of Candy was the native capital, previous to the entire conquest of the island. It is situated in the province of Tallanour, in the midst of lofty mountains covered with thick jungle; and the passes to it are narrow, and intersected with close hedges of thorn. The town itself is mean, and surrounded by a mud wall of no strength. Its length is about two miles; and it consists of one broad street, with numerous lanes branching from the principal thoroughfares. The houses are chiefly of mud, thatched with straw and leaves, with small apertures instead of windows. At one end of the great street stands the palaçe, an immense pile of building, constructed of stone and wood, and covered over with a species of white cement. It comprehends within its walls two temples dedicated to Boodh, or Buddhu,—one Hindoo pagoda,—the cemetery of the Kings of Candy,—and a great variety of arsenals and storehouses. The surrounding scenery is rich and beautiful. The land in the neighbourhood is highly cultivated, and interspersed with villages and rivulets. Some of the mountains are cleared to their summits, formed into ridges, and sown with grain; the valleys are fertilized by assiduous and skilful irrigation, and are clothed with areca, jack, cocoa-nut, and other trees, and with fields of paddy and other grain.

Candy.

Point de Galle.

Point de Galle, the only other town of which it seems necessary to give a description, is situated at the southern extremity of the island, on a low rocky promontory, backed by several ranges of hills, rising above one another, and covered with wood. The fort, in which most of the Europeans reside, is more than a mile in circumference, and contains a variety of large and commodious habitations. Europeans are here much less incommoded by the heat than in other parts of India; for although the town is situated within less than six degrees of the equator, the temperature is frequently as low as 72° of Fahrenheit, and never exceeds 86°. The disease, called Elephantiasis, is said to prevail a good deal among the poor residents at Point de Galle, and is ascribed to bad water and insufficient nourishment.

Character of the Ceylonese.

It seems difficult to give a faithful delineation of the character of the Ceylonese. In general, they are mild in their manners, and reserved in their address; not easily roused to resentment and bloodshed, yet proceeding with extraordinary determination in the prosecution of their object, when acting under the impulse of passion. Crimes of the deepest dye have occasionally been perpetrated among the lower castes; but the conduct of the better castes is generally correct and decorous. They are consummate masters of the art of insinuating themselves into the good opinion and favour of their superiors; and they possess a wonderful degree of address in working upon the feelings of others, while they can keep themselves free from every emotion.

Religion.

The religion of the Ceylonese consists in the worship of Boodh, which is also established in the Birman empire, and in the kingdom of Siam. This religion lays claim to great antiquity, and appears to have existed prior to the Braminical system; although the learned are not agreed concerning the age of Boodh, or Buddhu, or the country in which his religious doctrines were first promulgated. According to the mythology of the Ceylonese, this personage, whose footstep is still to be seen on the top of Adam's Peak, is said to have descended upon earth, and, after having performed a vast number of virtuous actions, and been transformed into a great variety of shapes, to have again ascended into heaven, where he acts as a mediator with the Supreme Being, and procures the pardon of his worshippers. Although the Ceylonese acknowledge the existence of one Supreme Being, yet they dedicate no temples to his worship; those of Buddhu being superior to all others. Buddhu is said to have always worn a yellow dress; and for this reason his priests still wear a dress of a similar colour; and his images, in the temples, are invariably yellow from the head to the feet. The religious kalendar of the Ceylonese comprehends seven other saints or subordinate deities, to each of whom they erect images, and ascribe peculiar powers and prerogatives; but their worship is inferior to that of Buddhu. Some of the Ceylonese temples, or pagodas, are magnificent structures, indicating a much higher degree of excellence in the arts, in some former period, than the natives at present possess. Some of these pagodas are endowed with great revenues, and possess high privileges. The priests are dividedi nto three ranks; of whom the highest order is set apart for the worship of Buddhu; the others minister to the worship of the inferior deities. The highest sacerdotal office is not compatible with any species of manual labour; and the priests, so long as they continue to exercise their functions, are doomed to the most rigorous celibacy. But, in the system of Buddhu, the priesthood does not constitute a peculiar caste; nor is the character indelible, as among the Brahmins; on the contrary, they are at liberty to renounce their sacred calling, and to resume their place among the laity.

Ceylon.

Christianity was first introduced into Ceylon by the celebrated Francis Xavier, in the year 1452; and the Portuguese, so long as they exercised their sway over the maritime parts of the island, continued to prosecute the work of conversion by means of their priests. When the Dutch became masters of the coast, they endeavoured to substitute the reformed faith for that of the Church of Rome. In the year 1801, the number of native inhabitants, who professed the Protestant faith, was calculated to exceed 342,000; while those of the Romish communion were reckoned to be still more numerous. In 1805, some missionaries were sent from England, for the purpose of instructing the Ceylonese in the principles of Christianity; and it is thought that the propagation of this doctrine would experience much fewer obstacles in this island than in Hindostan. In Ceylon, the rites of the ancient religion are said to be almost totally forgotten; and the inhabitants, more ignorant than bigotted, and more simple than prejudiced, would the more readily admit any religious impressions, which a devout teacher might make upon their minds.

A most excellent institution of the Dutch, and Schools.

Ceylon.

which redounds highly to their honour and liberality, consisted in the establishment of schools, for the instruction of the natives in the elements of useful knowledge, and in the principles of Christianity. These schools, of which one is erected in every parish, appear to have been placed under very judicious regulations. They continued to flourish under the Dutch; but when the English obtained possession of the island in 1796, the salaries of the masters had been left unpaid for about three years, and the schools, consequently, fell into decay. The Hon. Mr North, who became Governor of the island towards the end of the year 1798, spared no pains to re-establish them; and, under his auspices, they were increased in number, improved in management, and augmented in usefulness. But the liberal views and salutary arrangements of this enlightened gentleman were unfortunately counteracted, in a great measure, by the ill-judged parsimony of the British Government, who, in the year 1803, limited the annual allowance for the schools to the sum of L. 1500, although the whole saving was paltry, when weighed against the many and important advantages resulting from these beneficial establishments.

Agriculture and Manufactures.

The agriculture and manufactures of Ceylon are at present by no means in a flourishing state. This is chiefly owing to a want of capital; yet the obstacles which now exist might be removed, in a great measure, by proper encouragement, and a judicious direction of the industry of the inhabitants. The soil is rich and fertile, but great part of it is left waste; insomuch that the land does not at present produce the first necessaries of life in sufficient quantity to supply the wants of the population. Cotton has been ascertained to grow with the greatest facility, and to produce abundantly. The Nankin, Bourbon, and Brazil cottons have all been found to succeed; yet there has been hardly any cotton reared hitherto; and even the commonest cloths, for the use of the natives, are imported from the continent of India.

Productions. Cinnamon.

The principal productions of Ceylon are, 1. The cinnamon, for which it has long been famous, and which has attracted the particular attention of the different European governments that have successively taken possession of the island. The cinnamon tree is indigenous to Ceylon, where it grows wild to a considerable size. The bark of the tree consists of two coats, or layers, of which the interior constitutes the true cinnamon. This bark, after being peeled off, is laid in the sun to dry, when it curls up into rolls, as we commonly see it. The finest cinnamon is that which is obtained from the younger and smaller trees; a coarser sort is derived from the trees of larger dimensions and greater age. The cinnamon is collected by a particular caste, called Challias, who, on this account, enjoy peculiar privileges. When the bundles or sacks of cinnamon are stowed on board the ships, black pepper is strewed over each layer, so as to fill up the interstices; and both commodities are said to be improved by this method of stowing. Formerly, the crop of cinnamon was collected in the forests and jungles, the greater part of the trees being within the territories of the king of Candy; but during the latter period of the Dutch government, attempts were made, and ultimately with complete success, to cultivate cinnamon in plantations; and to their exertions we are indebted for the present flourishing state of this article of commerce. According to a calculation made by the Dutch, the annual consumption of cinnamon was estimated at 400,000 lbs.—say 5000 bales, of 80 lbs. each. When the island was transferred from the English East India Company to an immediate administration under the Crown (January 1802), the government entered into a contract with the Company, by which the latter acquired the exclusive privilege of exporting that article from the colony. It was agreed that the Ceylon government should deliver annually 400,000 lbs. of cinnamon, making 4,324½ bales, each bale consisting of, within a small fraction, 92½ lbs.; for which the Company granted a credit of L.60,000, making the price of the cinnamon 3s. *per* lb. The Company farther became bound to give credit to the colony for the amount of all clear profits which it should make on that commodity, beyond five *per cent*. No cinnamon, therefore, can be sold or exported from Ceylon but by the Company, with the exception of what is rejected by their agent there. In the year 1806, the Company proposed that 450,000 lbs. should be delivered annually, at 2s. 6d. *per* lb. instead of 400,000, at 3s.; which the government agreed to; and this agreement remained in force until 1810, when the parties reverted to the former contract. In 1814, the Company agreed to allow to the Ceylon government a sum of L.200,000 Sterling for surplus profits on their sales of cinnamon; and to give, in future, L.101,000 Sterling annually, instead of L.60,000, for a supply of 400,000 lbs. of that commodity. This contract is understood to have been entered into for seven years. But, in adjusting the accounts, it will appear that a large deduction must be incurred by the colony, in consequence of having very seldom delivered the stipulated quantity.

Cocoa-nut tree.

2. The cocoa-nut tree, which is perhaps the richest known in the world. Besides the nut, with its milk, this tree produces *mirra*,—a mild beverage, without acidity or powers of intoxication; *toddy*, from which the spirituous liquor called *arack* is distilled; cocoa-nut oil; the *jagery*, a kind of sugar, manufactured from the mirra; and the *coir*, from which ropes are made. The average quantity of arack exported annually from Ceylon may be stated at 5200 leagers, of 150 gallons each. The great markets for this article have hitherto been Madras and Bombay, with the Malabar and Coromandel coasts. Within the last three years, some hundreds of leagers have been brought to England, and sold from 5s. 6d. to 6s. 6d. *per* gallon.

Palmyra tree.

3. The palmyra tree, which, after the cocoa-nut tree, is the richest plant in the east. It requires ten years before it bears fruit, but, as is asserted, it will continue doing so for 300 years. This tree contributes in many ways to feed the lower class of natives in Ceylon. The fruit, when green, affords a pleasant beverage; and, when ripe, a nourishing and wholesome food. Sometimes the juice of it is expressed, which har-

dens and is preserved for a long time, and is eaten by the natives in different ways. The shell and the fibres, after the juice is pressed out, form excellent fattening food for cattle; and if the fruit be put under ground for two or three months, it strikes strong roots, which are also good for the food of man. The value of the tree, when cut down, is from four to five rix-dollars; and the annual revenue drawn by government from the duties on the exportation of palmyra timber amounts to about 25,000 rix-dollars. 4. The *arreca* nut is a very important article of Ceylon produce, being the best of the kind in India. The nuts are exported chiefly to the Coromandel and Malabar coasts; and the annual revenue derived by government from the duties on the exportation of this article may be stated at 125,000 rix-dollars. 5. Tobacco, which is cultivated in the district of Jafnapatam, of a peculiar quality, and prepared in a particular manner for chewing. 6. Ceylon produces various sorts of wood, of the finest and richest kinds, for cabinet-making. The scarcest and dearest is the *calamander*, of a hard and close grain, beautifully veined with different shades of black and brown. The *homander* greatly resembles it, but the veins are not so fine. The *ream* wood has also very beautiful veins of the same colours, but smaller and more regularly striped. The *jack-wood* very much resembles mahogany, and is used for the same purposes. The *ebony* and *satin* woods are well known. The *sappan* wood is a kind of log-wood, used for dyeing cotton cloth of a fine red, or rather very deep orange colour. 7. The pearl-fishery has been particularly described in the *Encyclopædia*. 8. Ceylon is rich in precious stones. Of these the most valuable are, the *oriental sapphire*, *topaz*, *ruby*, *amethyst*, and *blue sapphire*; the *cat's-eye*, which is the finest known of that kind; the *tourmaline*, of every shade; the *amethyst*, which is superior in brilliancy to that of Brazil; the *cinnamon* stone; the *garnet*, and the *moon-stone*, which is a species of opal. Ceylon also produces the finest jet and crystal of different tinges. Pepper, coffee, and cardamom, are likewise cultivated in Ceylon; but these productions, it is said, are not indigenous, having been introduced by the Dutch, who also made unsuccessful attempts to rear the silk-worm, and cultivate the mulberry-tree.

Arreca Nut. Tobacco. Timber. Precious Stones. Pepper, Coffee, and Cardamom.

Commerce.

As there are no manufactures of any consequence, the commerce of the island consists in the exportation of its natural productions, and the importation chiefly of rice and other grain, and cloth. The following table will show the respective value of the whole exports and imports, during a period of five years, with the amount of the duties annually collected by Government. The sums are expressed in rix-dollars.

	Exports.	Imports.	Duties.
1809,	2,660,795	2,635,235	440,327
1810,	2,777,997	3,112,748	480,433
1811,	2,781,633	3,574,313	461,495
1812,	2,442,895	4,215,399	410,185
1813,	2,443,940	6,378,739	408,819

From this table it will appear that there is a considerable commercial balance against Ceylon. This is occasioned by the great annual importations of rice and cloth; and it might be removed by giving greater encouragement to the cultivation of grain, and by the introduction of cotton, and the manufacture of that article into clothing for the natives. For these purposes our new acquisitions are eminently adapted. The Candian territory has always produced more rice than was wanted by its inhabitants; and cotton grows most luxuriantly in the interior of Ceylon. Nothing, in short, is wanted but industry and capital to render Ceylon perfectly independent for food and clothing.

Revenue, and Expenditure.

The relative amount of the revenue and expenditure of the Colonial Government, during the years 1811 and 1812, was as follows:

	Revenue.	Expenditure.
1811,	2,926,228 R.ds.	3,336,038 R.ds.
1812,	3,028,446	3,399,726

The balances constituted by the excess of the expenditure beyond the revenue have been covered by the issue of debentures; by the sums paid into the treasury by civil servants, for the civil fund, and borrowed by Government; by some balances that remained in favour of the Ceylon Government, in the hands of its agents at the presidencies of India; and by anticipating some of the public resources, which are understood to have been afterwards made good by the revenue of the pearl-fishery, in 1813. A considerable saving to the revenue might probably be effected by means of an improved method of collection, and by a diminution of the number of civil servants. But the greatest advantage would undoubtedly be derived from a well-directed attention to the improvement of the resources of this important colony, by stimulating the industry of its inhabitants, and encouraging the cultivation of its various articles of produce.—See Lord Valentia's *Travels*; *Asiatic Annual Register*; *The History of Ceylon*, by Philalethes, London, 1817; and particularly the following instructive work: *A View of the Agricultural, Commercial, and Financial Interests of Ceylon*, by Anthony Bertolacci, Esq. London, 1817. (H.)
